Activated carbon used for mercury control is often made from coal, typically a low-rank coal or lignite, and less often from coconut or walnut shell or other biomass feedstock such as wood. The feedstock, be it biomass or coal based, is subjected to thermal decomposition with strategic oxidation (often with steam) in order to produce an active sorbent for mercury adsorption with a high internal surface area. The carbon–steam reaction, shown here, is typically used to generate internal porosity and high-surface-area carbons.

$$C + H_2O \rightarrow CO + H_2 \tag{13.7}$$

If the temperature is too hot, the heating rate too slow, or if too much oxygen is present and not enough steam, then the resulting activated carbon will be less active than that produced under optimized conditions. Similarly, UBC in flyash has gone through a thermal decomposition process and been subject to reactions with steam, carbon dioxide, and oxygen. Although coal-fired boilers are clearly not optimized to produce UBC with a high activity for mercury adsorption, the activity of the carbon for mercury adsorption may differ significantly from one plant to another, depending on the coal type fired, the efficiency of the boiler, the furnace exit oxygen of the furnace, and moisture content of the coal and humidity of the secondary air.

The impact of the coal type on the resulting carbon activity can be determined from the coalification curve. Peat, although not coal, is the first material that plant matter was converted into as it began the coalification process. Peat consists of high moisture content, high volatile content, and will produce a highly active carbon type when thermally decomposed. Graphite, although not coal, sits on the other end of the coalification curve and is the end product of material passing through the coalification curve. Graphite has little moisture and no volatiles, and consists of an unreactive carbon type before and after heat treatment. In between these two endpoints are the different types of coal we burn in power plants at present, with the more reactive carbon types produced from the younger coals (i.e., lignites and sub-bituminous coals) and the less reactive carbon types being produced from the older coals (low-volatile bituminous and anthracite coals).

The order of coals from youngest to oldest from the coalification curve is maintained in the heating value and proximate analysis charts produced by Hendrickson in 1975 [9], reproduced in Perry's Chemical Engineers' Handbook [10]. As shown in those charts, the younger the coal, the more moisture content, the more

volatiles, the less fixed carbon, and the lower the heating value. It is also true that the char produced from the initial stages of combustion known as *devolatilization* (which takes place in <25 ms in pulverized coal (PC) boilers) is more reactive for younger coals and less reactive for older coals. The char produced from younger coals is more reactive for essentially two reasons. First, the solid organic network comprising the char structures contain more aliphatic material (i.e., attachments to organic rings, such as methane and toluene and components that can easily be released as light gases), and the aromatic structures are less ordered and graphitic in nature (i.e., the rings contain fewer inclusions and the ring structures tend to be more planar with respect to each other) [11, 12]. Second, in large part due to the first reason (i.e., the nature of the solid carbon structure), the char produced from the younger coals tends to have a higher porosity and internal surface area than char produced from the older coals.

The higher moisture content of the younger coals also tends to yield higher medium-sized pores or mesopores, through which increase the reaction rate of chars with oxygen would, if the chars survived, yield more active carbon structures for mercury capture.

Firing a coal that yields char with a high reactivity results in two trends that tend to cancel each other out in terms of yielding highly active UBC, outlined as follows: The higher reactivity does indeed relate to a higher activity for mercury capture. However, the higher reactivity also means that more of the carbon will be burned out in the furnace by oxygen and will not survive to serve as an actor for mercury adsorption or oxidation. A good example of this is PRB coal. PRB coal yields a highly reactive char type that is very effective for oxidizing and adsorbing mercury. However, most power plants that burn PRB coal have very low UBC in their flyash, because most of the carbon burns out in the boiler, before reaching the backpass.

It has been shown that high oxygen contents tend to decrease the reactivity of coal chars by consuming the outer surface of the char (eating the char particles from the outside in), while high-steam concentrations tend to increase the char reactivity by increasing the char mesoporosity and Brunauer–Emmett–Teller (BET) surface area [13]. The water molecules, with orders of magnitude lower reaction rate than oxygen with carbon, are able to penetrate the micropores of the coal char and react with their inner walls, thus widening the micropores and creating mesopores, without reducing the particle diameter. Hence, higher moisture contents in the furnace may increase the carbon activity for mercury if the active carbon produced is not all consumed by oxygen in the furnace.

13.2.4 Concentration of UBC Needed to Oxidize or Remove Mercury from Flue Gas

The mechanism of carbon enhancement of mercury oxidation is consistent with bench-, pilot-, and full-scale Hg-adsorption and speciation data, which have shown a direct relationship between mercury adsorption and carbon concentration [1, 5, 14]. At low carbon concentrations, the rate of Hg adsorption

is of the same magnitude as the rate of mercury desorption. As the carbon concentration increases, assuming at least some chlorine in the flue gas, mercury adsorption begins to dominate over mercury desorption, until most of the mercury is observed to be removed from the flue gas. The mechanism is observed even more clearly for mercury speciation. At very low concentrations of carbon in the flue gas (i.e., PRB-fired power plants with high carbon burnout), the mercury will neither be oxidized nor adsorbed. For slightly higher concentrations of UBC (i.e., up to about 4.0% in the ash) in the absence of much calcium, extensive mercury oxidation will be observed, and for still higher concentrations of UBC, mercury removal will dominate even without much calcium present (as observed at power plants with high levels of UBC in the ash, that is, 20–50% UBC).

If firing conditions can be changed to increase the UBC in the flyash from PRB coal by just 0.2%, a significant increase in mercury oxidation will likely be observed, while an increase in UBC to several percent may result in high removals of mercury in the flyash (calcium content of the ash will also have an impact on removal for PRB coals). On the other hand, UBC concentrations as much as 10% in the flyash from bituminous coal may not produce high mercury removals or complete mercury oxidation.

In the same pilot-scale system [7] from which the data shown in Figure 13.1 were obtained, the concentration of UBC in the flyash needed to oxidize mercury across a baghouse was also measured (see Figure 13.2 published previously [6]). Combustion modifications were used to increase the concentration of UBC from the PRB coal, which is a highly reactive carbon type. As shown in Figure 13.2, the resulting increase in UBC was highly effective at oxidizing mercury. The coal blends were primarily of PRB and bituminous coals, where the average UBC type produced was also effective for oxidizing mercury.

13.3
Synergistic Relationship between UBC and Calcium in Flyash

13.3.1
Calcium Enhances the Retention of Mercury on Carbon

A fundamental investigation by Gale *et al.* [6] on the impact of calcium on mercury removal in power plants found that the presence of calcium, in the form of PRB flyash, injected hydrated lime, calcium carbonate, or calcium, enhanced mercury removal from the flue gas under certain conditions. Among other things, it was demonstrated that adding different forms of calcium to the baghouse collecting bituminous coal flyash changed the measured form of mercury at the baghouse outlet from about 90% oxidized with about 25% removed across the baghouse, to over 80% of the mercury removed across the baghouse. It was further shown [6] that calcium powders would only increase mercury removal across the baghouse if they were mixed with the UBC in the flyash. Without UBC from flyash, the

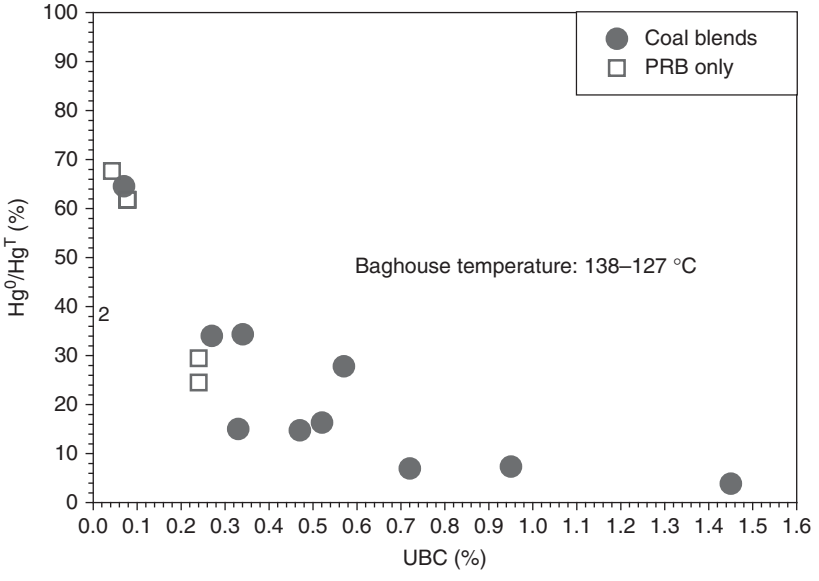

Figure 13.2 Mercury oxidation versus UBC [6]. (Reproduced with permission from Ref [6]. Copyright © 2009, Elsevier Limited.)

calcium powders had no effect, even for flue gas containing a high percentage of oxidized mercury.

The synergistic relationship of calcium and UBC for the removal of mercury also extends to mercury removal across an electrostatic precipitator (ESP) [6]. Contour lines showing the concentration of calcium and UBC necessary to achieve different mercury removal percentages derived in this work are reproduced here in Figures 13.3–13.5. All of this work was performed on low-sulfur coals, with SO_3 concentrations <2 ppmv, so the impact of calcium on protecting the carbon from deactivation by SO_3 was not significant.

As shown in Figures 13.3–13.5, different combinations of calcium and carbon concentrations can be used to obtain the same mercury removal percentages at the inlet and outlet of an ESP. The contour lines shown in these figures were created from data interpolation. No extrapolations were made. Therefore, all of the points on each of the contour lines are achievable.

13.3.2 Calcium/Carbon Synergism is Limited to a Range of Conditions

Synergism between calcium and UBC in flyash or injected activated carbon was found to be effective only for UBC concentrations in the flyash that would otherwise yield significant mercury oxidation with moderate mercury capture. If a large concentration of UBC was present, such that mercury removal was already high, the impact of adding calcium would be far less effective or not effective at all.

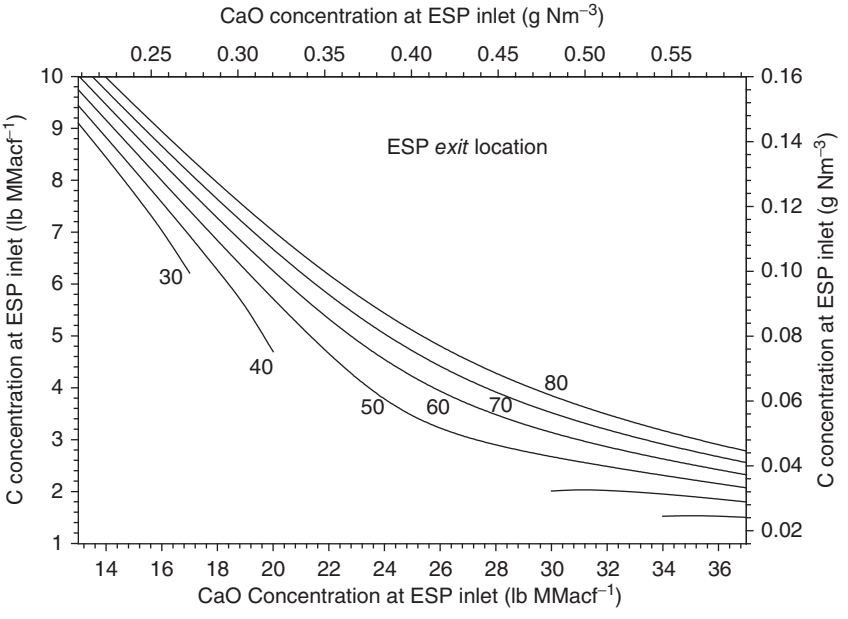

Figure 13.3 Predicted Hg removal contours for PRB/eastern bituminous blend tests (ESP exit) [6]. (Reproduced with permission from Ref [6]. Copyright © 2009, Elsevier Limited.)

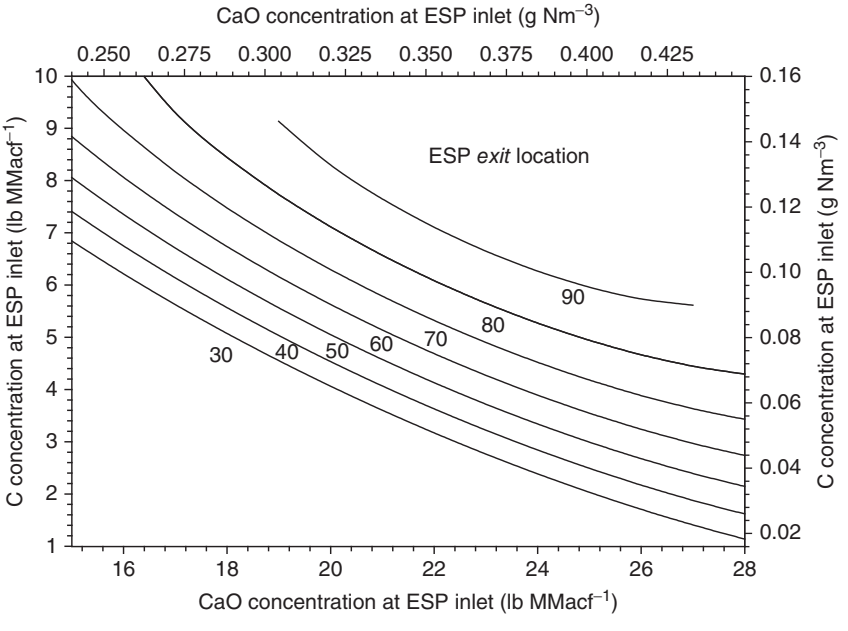

Figure 13.4 Predicted Hg removal contours for PRB/West Elk blend tests (ESP exit) [6]. (Reproduced with permission from Ref [6]. Copyright © 2009, Elsevier Limited.)

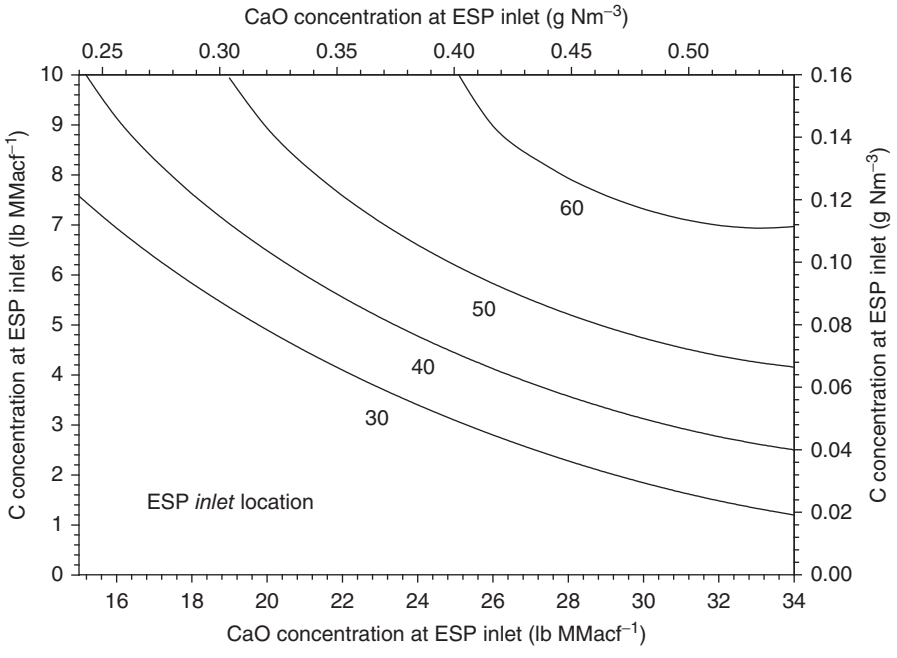

Figure 13.5 Predicted Hg removal contours for PRB/West Elk blend tests (ESP inlet) [6]. (Reproduced with permission from Ref [6]. Copyright © 2009, Elsevier Limited.)

Furthermore, the calcium/carbon synergism work by Gale *et al.* [1, 5, 6], was confined to relatively low-chlorine coals, that is, with flue-gas concentrations below 50 ppmv.

13.4 Potential Combustion Modification Strategies to Mitigate Mercury Emissions

Coal blending, although technically not a combustion modification, is a way to change the nature of the combustion by burning a different fuel type with a more or less active carbon type, more or less moisture, and more or less calcium than normally fired, all of which have the potential to impact the overall mercury removal strategy. The specific application of this method will vary significantly from plant to plant, depending on the plant configuration, coal type currently being burned, efficiency of the boiler, and availability and cost of different coal types.

Several specific examples are provided for clarification.

In a power plant that currently fired PRB coal, did not have an SCR or wet scrubber, and had a fairly high furnace efficiency, such that the UBC in the flyash was 0.1% or less, co-firing with a higher rank coal, well up on the coalification curve would likely increase the mercury capture to perhaps 80% or 90% across the ESP or even more across a baghouse.

A similar but much less efficient power plant that burned bituminous coal, resulting in >10% UBC in the flyash, may be able to significantly reduce mercury emissions by blending with or switching completely to PRB coal. If so, the power plant would have the added benefit of a much lower UBC concentration in their flyash.

Although these examples are realistic, it is not likely that the anticipated regulatory standards can be met through coal blending alone, as most standards are anticipated to require >95% removal of the mercury from the flue gas, which is unlikely to be achievable by coal blending for most power plants.

Reduced combustion efficiency is another way to increase the UBC concentration in the flyash and thereby increase the mercury removal in the particulate collection device (PCD). This would be most effective while burning PRB coal or lignite and would provide the least problem with high UBC concentrations in the ash. However, increasing the UBC in the flyash while firing PRB or lignite is quite difficult, because of the highly active carbon type.

It should be understood that if this approach is taken to increase the UBC in the flyash, it must be done in a way so as to only increase the UBC from the char. If radical measures are taken to produce a highly unstable flame or channeling of gases that are not completely burned, there is a possibility that some of the UBC produced will be from unburned volatile matter. Carbon produced in the ash from unburned volatile matter, or soot, will not produce the desired results. Soot once formed through incomplete combustion of volatiles is unreactive and will not provide an active carbon concentration in the flyash for the promotion of either mercury oxidation or capture.

Reburning is a technology where fuel is fired in the furnace downstream of the main burners to reduce NO_x that were formed in the primary combustion zone, by creating a reducing zone at the location of the reburning. As the objective of reburning is to create a reducing zone, there will be less oxygen needed to burn all of the solid fuels and so provides a great opportunity to combine this technology with production of activated carbon types for mercury adsorption in the flyash. Reburning can be done with natural gas, but it can be done with a variety of different solid fuels, including the same coal that is fired through the main burners. If the reburning system is designed for both the reduction of NO_x and for limited burnout and activation by steam, the cost should be reasonable to solve both the NO_x and Hg emissions problems. This may be a possible approach for smaller plants that are trying to extend their life and cannot afford to add an SCR unit for deNO_x.

Furnace intrusion modifications is the final area of combustion modification possibilities for existing coal-fired power plants. This broad area of modification requires intrusion into the furnace itself to either add equipment or redirect part of flame flow downstream of the furnace. An example of such a modification would be a highly isolated jet of inert gas that was directed through part of a flame or the whole furnace, sweeping unburned char out of the flame zone, and transporting it downstream unreacted and quenched so that it would not continue to burn. Another example would be a mechanical device or high-temperature vanes in a

boiler that would extract some of the char from the flame zone downstream before it was completely burned out.

The Thief Process is an example of a commercial Furnace Intrusion Modification [15]. The Thief Process extracts coal out of the flame zone through a pipe outside the furnace and then reinjects the UBC downstream where it can be used as a sorbent to capture mercury.

13.5
Effects of Combustion Modifications on Mercury Oxidation across SCR Catalysts

13.5.1
Inhibition of Mercury Oxidation can Occur in Low-Chlorine Flue Gas

Although it is unlikely that combustion modifications would be used as a mercury mitigation strategy at a power plant where an SCR was installed for deNO_x, combustion modifications, or tuning for other reasons can have a significant effect on mercury oxidation across the SCR catalyst. Walsh *et al.* [16] showed that as little as 10 ppmv of CO can significantly inhibit the oxidation of mercury across an SCR catalyst in flue gas with an HCl concentration of 2.0 ppmv, which is typical of the HCl concentration at some plants firing PRB coal. Hence, care should be taken when considering combustion modification that might increase the CO concentration when firing a low-chlorine coal and using an SCR to oxidize mercury.

At chlorine concentrations as high as 50 ppmv, there was no effect of the CO concentration on mercury oxidation.

Although ammonia slip can inhibit mercury oxidation across SCR catalysts in low-chlorine flue gas, the concentration of NO treated has little impact [17]. Nevertheless, efforts to change UBC or lower NO through combustion modifications could have negative impacts on mercury oxidation across an SCR by increasing the concentration of carbon monoxide.

Fuel and Flue-Gas Additives

John Meier, Bruce Keiser, and Brian S. Higgins

14.1
Background

The primary mercury oxidation pathway during coal combustion occurs as a function of coal halogen content and subsequent release during the combustion process. Native oxidation occurs [1] through the reaction of mercury with HCl (or Cl^- or Cl_2 produced by the Deacon reaction [2]), utilizing the inherent chlorine in the coal.

The easiest and most readily available method to increase mercury oxidation is through the introduction of halogen-containing material to the fuel before combustion. Typical methods include treating the coal with a liquid solution containing halogen salts, such as $CaBr_2$ or $CaCl_2$. These salt compounds vaporize and dissociate, or react during combustion, to form molecular halogen compounds or precursors in the flue gas, primarily forming HBr, Br_2, HCl, and Cl_2. These halogen species then oxidize elemental mercury to its oxidized form, which is readily capturable across downstream air quality control devices.

Additives to promote enhanced mercury capture were first implemented to augment mercury capture by activated carbon. Initial generic-powdered activated carbon injection (ACI) studies noted that with low chlorine fuels (e.g., $<200\,\mu g\,g^{-1}$) there was poor mercury removal relative to units burning higher chlorine coal (e.g., $>500\,\mu g\,g^{-1}$) [3]. Because of this result, manufacturers began impregnating the activated carbon with various halogen additives (i.e., iodine, chlorine, or bromine). While all of these halogens are effective in oxidizing mercury and facilitating activated carbon mercury capture [4], bromine-based additives have often exhibited the best cost performance.

An additional factor affecting mercury capture by activated carbon is the flue-gas temperature. At elevated flue-gas temperatures, approaching 200 °C, activated carbon efficiency is reduced, specifically for elemental mercury [5]. By increasing the portion of oxidized mercury in the gas stream, high-temperature mercury capture is improved with activated carbon.

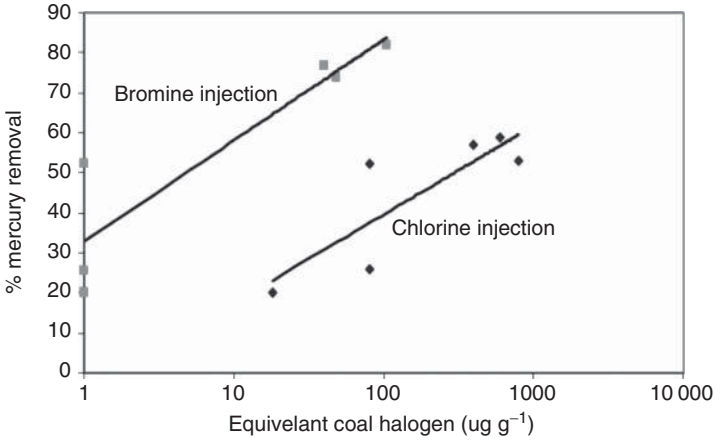

Figure 14.1 Mercury oxidation in coal-fired boilers with bromine and chlorine addition .

The effect of the concentration of several halogen-based oxidants have been considered by Senior *et al.* [6] Figure 14.1 illustrates the difference in native capture as a function of halogen concentration in the coal, where the halogen concentration is artificially augmented. Increased mercury removal is directly attributed to higher halogen concentration before coal combustion. In this study, bromine addition reaches 80% mercury removal (Br ~ 100 μg g^{-1}), while the peak mercury removal with chlorine (Cl ~ 1000 μg g^{-1}) does not exceed 60%, even with a concentration 10-fold larger.

14.1.1
Bromine-Salt Mercury Oxidation

The case studies presented here show results from injecting a bromine salt solution into a boiler to produce a molecular halogen or molecular halogen precursor, which promotes mercury oxidation. The proprietary bromine salt solution injected by Nalco is branded as MerControl® 7895 technology. In the results that follow, the data is presented as micrograms per gram, representing the number of micrograms of *MerControl 7895 solution* per gram of coal. This is equivalently referred to as milligrams per kilogram or parts per million weight.

14.1.2
Fuel Additive Injection Equipment

The application of halogen salt solutions is typically to the coal before injection into the furnace. The point of application is usually at the coal feeders just before the pulverizers. Permanent injection systems include a bulk storage tank, metering pumps, and injection assemblies. The pumps are controlled relative to plant operational data; for example, coal flow, gross mega watts, and/or

outlet mercury speciation (when a plant continuous mercury monitor (CMM) is available). The injection point is a simple lance comprising an open-ended stainless steel tube, without a nozzle, or a constriction, which may plug. An even distribution of the product across the coal flow is not required at the application point as the additive will be well mixed with coal during the pulverization process.

Different precombustion application locations have been investigated, at various points from the coal yard to the burners. The application equipment is less expensive the further upstream the chemistry is added. Alternatively, the control response to a downstream feedback control parameter (e.g., a stack mercury measurement) is faster the further downstream the chemistry is added. However, these differences are slight and neither approach appears to have a strong advantage over the other.

Alternative injection strategies include injecting the oxidizer additives directly into the boiler or in the back-pass through a grid injection system.

Injection into the boiler can be performed by using compressed or fan-boosted air to facilitate mixing. Often, this is performed by combining the oxidizer injection with other air or chemical injection systems such as over-fired air or a selective noncatalytic reduction (SNCR) system. The key point is to confirm that there is good mixing with all of the flue gas. One reason to pursue this approach is to remove the bromine from the coal handling and milling systems; however, an operational performance advantage to doing this has not been established.

Halogen-containing solutions can also be injected into the flue gas downstream of the economizer using a grid injection system. The decreased flue-gas temperature at this injection point may require the use of a larger quantity and/or a more hazardous reagent, such as hydrobromic acid. Either may raise the costs and safety concerns with handling and storage. Again, good mixing needs to be confirmed. It has not been demonstrated that injection downstream of the economizer is more effective or more economical than precombustion addition of halogen salts.

14.1.3 Case Study Results

The following two sections present results from different case studies. The first section summarizes conditions where an halogen based fuel additive will likely lead to advantageous performance and the second summarizes conditions where there is likely not an advantageous performance.

Note that every boiler application must be individually analyzed, as results are heavily dependent on flue-gas temperatures, coal constituents, post combustion temperatures, mixing, residence time, metal surface characteristics, and, most importantly, the operation of downstream air pollution control devices. Nalco commonly demonstrate the effectiveness of fuel additives, with and without activated carbon, through field trials to help our clients fully understand the cost–benefit of various operational scenarios.

14.1.3.1 Case Studies where Halogen-containing Fuel Additives are Advantageous

Nalco has performed a number of demonstrations with fuel additives with the specific goal of reducing mercury compliance costs. In this section, the results from three case studies are reviewed:

Case Study One: Optimized carbon and halogen-containing additive for preservation of fly ash quality in concrete reuse
Case Study Two: Bituminous coal with performance shortfalls and SCR (selective catalytic reduction)/wFGD (wet flue-gas desulfurization)
Case Study Three: Subbituminous coal with high fly ash unburned carbon.

Case Study One: Optimized Carbon and Halogen Oxidizer for Concrete Applications

The demonstration site for this case study was a 615-MW boiler, burning low-sulfur subbituminous coal. The boiler was equipped with low-NO*x* burners and a cold-side electrostatic precipitator (CS-ESP) for particulate control. No desulfurization equipment was installed [7]. The coal chlorine content averaged 100 $\mu g\, g^{-1}$ during the demonstration, resulting in only 30–35% native mercury oxidation during baseline measurements.

The goal of this demonstration was to achieve 90% mercury capture, with <2 $lb\, MMacf^{-1}$ activated carbon addition rates. Through previous testing, the client had determined that at <2 $lb\, MMacf^{-1}$ activated carbon addition, the fly ash integrity was sufficient to permit economic reuse as a concrete feedstock.

A temporary MerControl 7895 technology injection system was installed, with injection occurring at the coal feeders before the pulverizer. ACI was injected both before and after the air heater. However, the injection before the air heater produced much better results and therefore only these data are presented.

Case Study One: Results Two temporary CMMs were installed at the exit of the economizer and at the stack. The inclusion of the inlet CMM was to provide information regarding changing coal conditions and was considered representative of the coal mercury concentration.

In Figure 14.2, injection of over 2.5 $lb\, MMacf^{-1}$ of a standard halogenated activated carbon, introduced before the air heater, resulted in about 91% mercury capture. Also, in Figure 14.2, two nonhalogenated activated carbons were injected with the application of a fuel additive, MerControl 7895 technology. ACI-I is a higher reactivity carbon designed to be used in conjunction with fuel additives. ACI-II is a standard nonhalogenated activated carbon. The significant difference in performance between the two activated carbons emphasizes that all activated carbons are not equal in terms of performance when used in conjunction with fuel additives.

ACI-I required 50% less carbon than ACI-II to reach 91% mercury capture, using the same fuel additive injection rate (168 $\mu g\, g^{-1}$). ACI-I, with a fuel additive concentration of 168 $\mu g\, g^{-1}$ in coal, required 80% less carbon to reach 91% mercury capture, when compared to results obtained with a standard halogenated activated carbon alone.

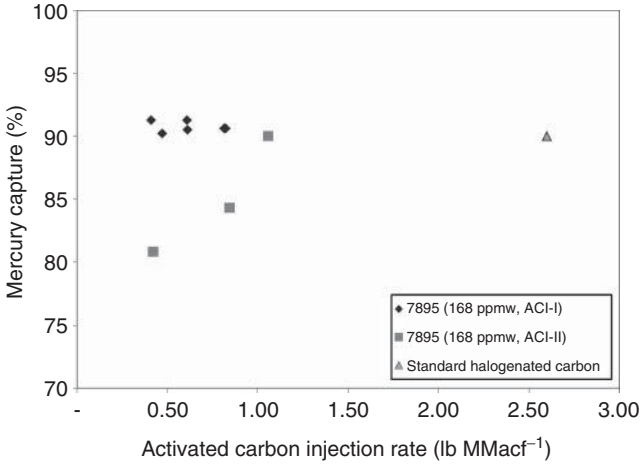

Figure 14.2 Mercury capture as a function of the activated carbon injection rate, with and without MerControl 7895 technology injection.

The 2.5 lb $MMacf^{-1}$ injection rate with the halogenated activated carbon did not meet the initial requirements of 90% mercury capture at <2 lb $MMacf^{-1}$ injection rates to preserve fly ash quality. The application of halogen-containing fuel additive and a greatly reduced activated carbon flow rate met both of the client's goals and resulted in the lowest annual compliance cost.

Case Study Two: Bituminous Coal with Performance Shortfalls and SCR/wFGD Typically, halogen-containing fuel additives are discussed with respect to application on low-chlorine, subbituminous, fuels [8]. The reason is that bituminous coals usually have sufficiently high levels of chlorine to oxidize most of the mercury. This is particularly true when there is also an SCR present. However, as shown earlier, even with high levels of chlorine, mercury oxidation is limited, and cannot reach as high a level of mercury oxidation as a bromine-based fuel additives.

Oxidized mercury is readably soluble in water, specifically in wFGD systems. Elemental mercury is not readably soluble in wFGD water. Units with a wFGD system are limited in mercury capture by their mercury oxidation rate. If 80% of the mercury entering the wFGD is oxidized and reemission is controlled, 80% mercury capture across the wFGD is expected. Because bromine-based fuel additives increase the oxidation of mercury, it also increases the unit overall mercury capture in a wFGD.

Case Study Two: Results The case study outlines the application of a bromine-based fuel additive on a 195-MWe high-chlorine bituminous-coal-fired boiler, equipped with an SCR for NO*x* control, a wFGD for SO_2 control, and a CS-ESP for particulate control. The typical coal chlorine level was around 1600 $\mu g\, g^{-1}$ of fuel, which in combination with the SCR should have resulted in excess of 90% mercury oxidation and subsequent capture in the wFGD. SCR catalysts typically increase the oxidation rate of mercury in the presence of high concentrations of chlorine.

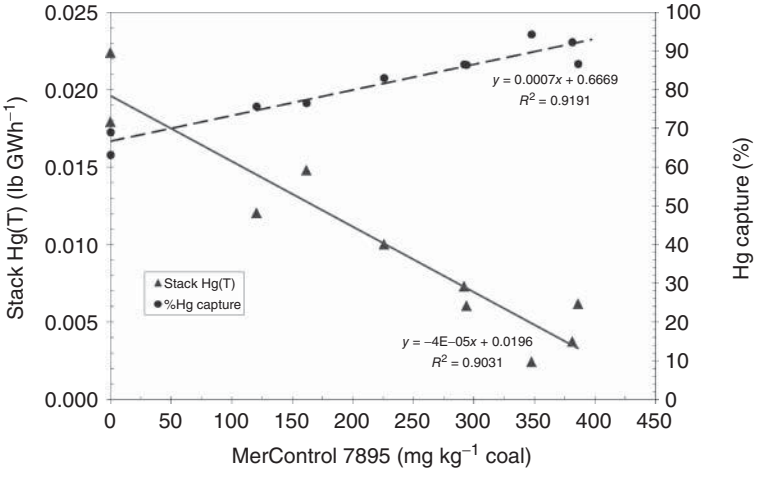

Figure 14.3 Decreasing stack emissions (left) and increasing mercury capture (right) shown for increasing MerControl 7895 technology concentration.

However, owing to the catalyst type and age, mercury oxidation was limited to 70% as observed in previous testing and validated with Ontario Hydro (OH) measurements [9] performed during the baseline observation.

In order to increase the mercury oxidation, a MerControl 7895 solution was applied using a temporary injection system. OH measurements were performed daily, and were validated against Environmental Protection Agency (EPA) Method 30B [10] carbon traps. As with CMMs, halogens can result in fouling of the OH impinger trains, so it is important to validate measurements with an alternative reference method to ensure data accuracy.

The results of the addition of MerControl 7895 technology are shown in Figure 14.3. The mercury oxidation rate during baseline measurements was suggested to be about 80% and the overall mercury capture rate was about 70%. The wFGD was estimated to be nearly 100% efficient in removing oxidized mercury and showed no evidence of reemission. The reason the mercury capture rate is less than the mercury oxidation rate is due to an estimated 5–10% of the flue gas bypassing the wFGD through a leaking flue gas bypass damper.

With increasing dosage rates of MerControl 7895 technology, there is a linear decrease in stack emissions, as shown in Figure 14.3. With the addition of at least 265 mg MerControl 7895 technology per kg coal, the client was able to maintain their required emission rate of 0.008 lb GWh^{-1}, equal to a net 85% mercury capture rate, which includes the bypass damper leakage.

Using the wFGD as the primary mercury removal mechanism was highly desired by the client relative to the injection of activated carbon. High-sulfur bituminous coal burning units with SCRs result in formation of high levels of SO_3 in the flue gas. The deleterious effect of SO_3 on activated carbon performance is well known, resulting in greatly increased ACI rates required to maintain high levels of mercury removal. We estimate that 5–7 lb $MMacf^{-1}$ of ACI would

be required to reach the same removal rate as 265 $\mu g\,g^{-1}$ of MerControl 7895 technology because of the CS-ESP as the primary particulate control device and the high levels of SO_3. Because of this, the MerControl 7895 technology application resulted in substantial savings compared to an option with ACI alone.

Case Study Three: Subbituminous Coal with High Fly Ash Unburned Carbon[†] For units that are not equipped with a wFGD, the primary mercury removal mechanism is formation of particulate mercury. Mercury absorbs on the surface of a carbonaceous material, such as injected activated carbon or unburned carbon from the combustion process. Units with high unburned carbon in the fly ash, typically >2% loss on ignition (LOI), do not require much, if any, activated carbon to be injected because the carbon in the fly ash is adequate to achieve high levels of mercury capture when in the presence of high levels of oxidized mercury. For units that produce a high fraction of elemental mercury (e.g., >20%), the addition of an halogen-containing fuel additive can increase total mercury capture through oxidation and adsorption onto the unburned carbon in the fly ash.

Not all unburned carbon is created equal in terms of oxidized mercury capture efficiency. Owing to high volatility and moisture content, subbituminous coals typically produce higher quality unburned carbon in terms of capturing mercury, relative to bituminous coals. Subbituminous fly ash has better performing pore size, better carbon distribution throughout the ash, more favorable alkali content, and higher surface area resulting from the thermal activation processes that occur during combustion.

If no activated carbon is required, the total capital cost for a halogen-containing fuel additive mercury can be 20% that of an ACI system. Typically, annual operating and maintenance (O&M) costs are substantially lower as well.

Case Study Three: Results The injection of a halogen salt solution was demonstrated on a tangentially fired, 400-MW boiler burning subbituminous coal. The boiler was equipped with low NO*x* burners and a CS-ESP, for particulate control. Before the demonstration, the unit was in compliance with their mercury regulation (0.008 lb GWh^{-1}) by injecting approximately 1.7 lb $MMacf^{-1}$ (~61 kg h^{-1} at full load) of a relatively concrete-friendly halogenated activated carbon. The injection location during normal operation occurred after the air heater through eight injection lances. The goals of the fuel additive demonstration were as follows:

- Reduce ACI flow rates to permit high-value fly ash resale for concrete manufacture. High amounts of activated carbon present in the fly ash causes discoloration when used for concrete manufacture, and also increases the amount of air entrainment chemicals required.
- Decrease overall compliance costs, while maintaining their regulated mercury emission limit.

Selling fly ash for concrete manufacturing can be a significant revenue stream for coal-fired utilities. If the fly ash is unsuitable for concrete, the utility will be

[†] These results have not yet been independently published.

forced to landfill their ash off site at considerable cost. Therefore, poor fly ash quality impacts the utility's profitability by both the loss of sale and the price to landfill. Two main concerns with the quality of fly ash are air entrainment and structural integrity. Activated carbon, while not the only factor, will negatively affect the quality of fly ash by preventing proper air entrainment of the concrete. By reducing the amount of activated carbon used during normal operations, halogen-containing fuel additives can help produce fly ash suitable for concrete manufacturing.

Given the client's goals, we implemented an approach to (i) determine the effect of MerControl 7895 technology on reducing activated carbon consumption rates and (ii) determine the effect of changing the injection location of the activated carbon to upstream of the air heater to further reduce the activated carbon flow with and without MerControl 7895 technology. Gas-phase measurements were provided by an independent third party using two CMMs, one placed at the inlet of the ESP and the other at the stack. CMMs can become fouled during the addition of halogen-containing fuel additives. In order to verify the CMM accuracy, EPA Method 30B carbon trap sampling should always be performed to validate the CMM.

We have found that inlet CMM measurements provide essential information related to process variation and changes in coal mercury concentration. By monitoring the inlet mercury concentration, we can account for process variables that otherwise could systematically affect the results and lead to incorrect conclusions. When coal analyses are solely used to determine inlet mercury concentration, we have found that this does not work as well and does not illuminate process variable effects.

We applied a liquid-based bromine salt solution (MerControl 7895) to all five of the coal feeders. The MerControl 7895 product was delivered to site in 240-gal Schutz totes. A pump-and-control skid provided product pressure, flow control, and flow rate measurements. Temporary injection lines were provided from the pump skid to the injection nozzles, installed on the coal mill feeders. As part of this project, we also provided movable ACI lances to be able to inject carbon before the air heater. The demonstration was completed in under 2 weeks.

Fly ash samples acquired during the demonstration showed LOI values over 2.0%. This level of LOI provided adequate sites for mercury adsorption during application of MerControl 7895 technology. As shown in Figure 14.4, the addition of $10\,\mu g\,g^{-1}$ of MerControl 7895 technology produced mercury emissions $<0.005\,lb\,GWh^{-1}$, below the required emission rate of $0.008\,lb\,GWh^{-1}$. The application of MerControl 7895 technology reduced overall compliance cost by over 90% compared to the application of activated carbon.

14.1.4 Case Studies where Conditions Are Disadvantageous to Fuel Additive

There are several conditions in which the utilization of fuel additives is unlikely to provide economic justification. These need to be considered on a case-by-case basis.

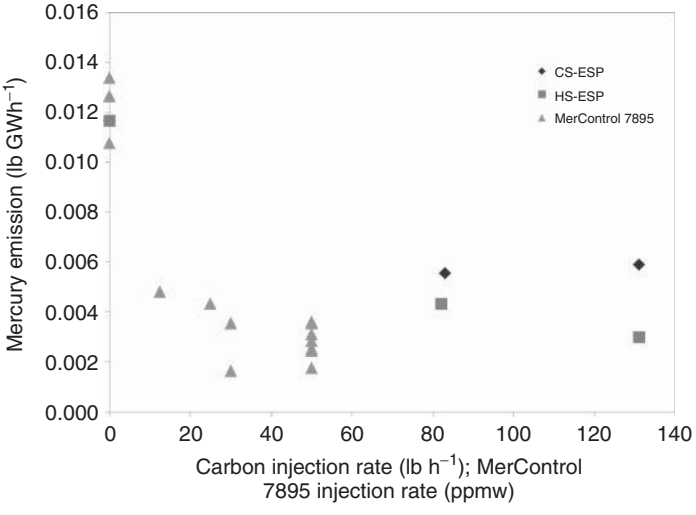

Figure 14.4 Decrease in mercury emissions for increasing carbon and MerControl 7895 technology injection rate.

14.1.4.1 Units Burning High Chlorine Fuel with an SCR

SCR systems have a synergistic effect with available chlorine in the combustion gas in oxidizing mercury. Units burning fuels containing chlorine over 800 μg g^{-1} and employing an SCR will typically result in over 90% mercury oxidation. Addition of halogen-containing fuel additives is unlikely to show benefit for these conditions because of the high inherent mercury oxidation rates. Some catalysts contained in the SCRs are less effective than others in oxidizing mercury, and application of fuel additives may still be beneficial.

Generally, the combination of high chlorine and an SCR should not require fuel additives. However, additives can be used to augment deficiencies in fuel chlorine content or SCR function.

14.1.4.2 Subbituminous Fired Units with Flue Gas Conditioning (SO_3 Injection)

A significant fraction of subbituminous fired units inject SO_3 into the ductwork to modify ash resistivity. This, in turn, increases the collection efficiency of the ESP. The injection of SO_3 reduces the performance of activated carbon, requiring relatively high levels of ACI compared to similar configurations without SO_3 injection. These high levels of ACI virtually always spoil the ash for resale.

We have found for these cases that the benefits from applying a bromine oxidizer are rarely economical. This is primarily due to specialty activated carbons that are better suited for high SO_3 applications without the co-benefit of using halogen-containing fuel additives.

For boilers that have high SO_3 concentrations, injected to improve ESP function, and also have a wFGD, the use of halogen-containing fuel additives would be economically justified. These configurations are infrequent because of low sulfur content traditionally found in subbituminous coals.

14.1.4.3 Units without Acid Gas Scrubbing and a Fabric Filter (FF)

Units employing a FF for particulate control, but without a spray dry absorber (SDA) or wFGD, will see little benefit from the application of a bromine-containing fuel additive. Compliance costs are generally low for this condition, typically requiring <1 lb $MMacf^{-1}$ halogenated ACI to reach around 90% mercury capture. Compliance costs are so low for this configuration that there is typically not enough economic opportunity to reduce the ACI rates to justify the use of a halogen-containing fuel additive.

There are other considerations that can make the addition of halogen-containing fuel additives attractive for these configurations, such as increased fly ash quality because of reduced ACI rates with addition of halogen-containing fuel additives or the inclusion of an SCR, reducing the typically required dosage rates of halogen-containing fuel additives.

14.2 Summary

Elemental mercury can be difficult to remove using existing air pollution control equipment. The addition of halogen-containing fuel or flue-gas additives to promote mercury oxidation can increase overall mercury capture, decrease compliance costs, and/or reduce activated carbon requirements. The efficacy of halogen-based oxidizers is subject to a number of operational parameters (e.g., flue-gas temperature, unburned carbon, and ash alkalinity), and as such, low-cost trial demonstrations are often used to show results.

15
Catalysts for the Oxidation of Mercury

April Freeman Sibley

15.1
Introduction

In December of 2011, the United States Environmental Protection Agency (EPA) issued an emissions standard aimed primarily at mercury but an extensive list of other hazardous air pollutants as well. The regulation was finalized in February of 2012. Targeted toward coal and oil-fired electric generating units, this rule requires applied and potentially newly installed emission control technologies to meet these standards using a maximum achievable control technology application as stemming from the Clean Air Act. In response to this regulation, it has been noted that an approach of utilizing existing emissions control systems retrofitted in the current fleet and capitalizing on a co-benefit strategy as a likely option.

This section discusses the applicability of selective catalytic reduction (SCR) catalysts in the oxidation of mercury contained within the flue gas from coal combustion as it pertains to mercury control using existing technology. Through various operating conditions, multiple responses to varying levels of mercury oxidation can be observed. Factors that affect mercury oxidation include temperature, halogen concentration in the flue gas (from the coal type burned), flow rate, and rate of deNO*x* (or ammonia concentration in the flue gas). By optimizing the rate of mercury oxidation, co-benefit capture can be observed downstream in the wet FGD (flue gas desulfurization) vessel and this could make it easier to comply with potential future mercury emissions regulations. Contained within this section are various tables, figures, and data to substantiate this application.

15.1.1
Process Overview

Mercury emissions from coal-fired boilers can be characterized into three main forms: elemental mercury (Hg^0), oxidized mercury (Hg^{2+}), and particle-bound mercury (Hg^p). The concentration of Hg^0, Hg^{2+}, and Hg^p primarily depends on coal composition and combustion conditions. During combustion, Hg^0 is liberated from coal. In the high-temperature regions of coal-fired boilers, mercury

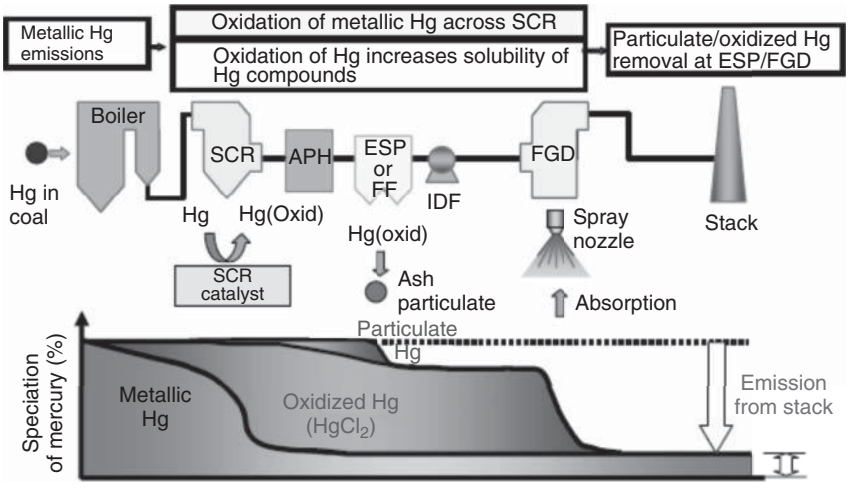

Figure 15.1 Typical behavior of mercury.

in coal is volatized and converted into the elemental form. However, depending on the coal type, a significant fraction of the mercury can be oxidized, as well as become associated with the fly ash particles in the post-combustion environment of a coal-fired boiler. Relative to Hg^0, Hg^{2+}, and Hg^p are more effectively captured in conventional pollution control systems, such as FGD systems, fabric filters, and electrostatic precipitators (ESPs). The identification of a process for converting Hg^0 to Hg^{2+} and/or Hg^p forms would improve the mercury removal efficiencies of existing pollution control systems. Mercuric chloride compounds are soluble and can be captured in FGD systems used for SO_2 removal. It is known that the catalysts used for SCR of NO*x* compounds can exhibit the co-benefit of promoting mercury oxidation. In addition to catalyzing the decomposition of NO*x* compounds to form nitrogen and water, the metal contents of the SCR catalysts have been shown to aid in the oxidation of elemental mercury into a water-soluble compound form. Figure 15.1 depicts the behavior of Hg through a typical eastern bituminous SCR-ESP-wFGD (wet flue gas desulfurization) system [1].

15.2
Hg Oxidation and Affecting Parameters

Upon focusing on the operations of the SCR and its affect on the oxidation of mercury, it is important to note some key areas. The potential contributing factors that can affect mercury oxidation across the SCR reactor include reaction with the catalyst, increased residence time, change in flue gas chemistry (including, but not limited to, the reduction in NO*x* concentration), and reaction with NH_3. Some tests conducted within various electric generating fleets show clearly that for low-halogen flue gases, increases in flue gas chlorine and/or bromine levels will have beneficial effects on SCR mercury oxidation. To capitalize on this effect, facilities

may consider the artificial adjustment of halogens, through direct injection or fuel additives. In addition, tests have shown that direct injection of hydrogen chloride before an SCR can enhance mercury oxidation across the SCR and this will likely enhance the overall mercury removal at sites equipped with an SCR-ESP-wFGD. The data show that lower temperature operation of the SCR will help maximize SCR mercury oxidation. Thus, in designing both retrofit and green-field facilities, lower SCR operating temperatures aid in mercury oxidation and capture. For green-field installations, boiler/SCR designs that provide for generally lower SCR temperatures will help maximize the achievable mercury oxidation through the SCR, at least with conventional catalysts. Lower operating temperatures also have potential benefits in terms of minimizing SO_2 oxidation to SO_3, but the benefits of lowering the SCR temperature must be weighed against the possible loss of catalytic activity for NO*x* decomposition (removal).

15.2.1
Hg^0 Oxidation Reaction Mechanism

On the basis of experimental data available, theories suggest that elemental mercury conversion can occur either through a homogeneous or heterogeneous oxidation. In terms of rate order, it appears that the heterogeneous reaction occurs at a faster rate than the homogeneous reaction. Both reactions, however, have a commonality of kinetics limitation. Factors affecting oxidation reaction kinetics include any of the following: fuel type, halogen content of coal, SCR catalyst age and/or type, SCR reactor temperature, and space velocity.

15.2.2
Homogeneous Oxidation of Mercury

During the homogeneous oxidation reaction, elemental gas-phase mercury reacts with other gas-phase constituents, primarily halogens, to achieve oxidation. There is a very specific temperature window of 400–700 °C in which this occurs. This temperature range is key to the abundance of halogen radicals, namely, chlorine, allowing for sufficient oxidation to occur. It is then that the mercury undergoes two steps to reach a more favorable oxidized state, in the form of water-soluble $HgCl_2$. The following equations represent what chemically occurs during the homogeneous oxidation of mercury.

$$Hg(g) + Cl(g) \rightarrow HgCl(g) \tag{15.1}$$

$$HgCl(g) + HCl(g) \rightarrow HgCl_2(g) \tag{15.2}$$

15.2.3
Heterogeneous Oxidation of Mercury over SCR Catalysts

We can propose numerous reaction mechanisms to describe heterogeneous catalytic reactions. The mechanism described as a catalytic reaction will

often fall into one of these three categories: (i) Langmuir–Hinshelwood; (ii) Mars–Maessen/Mars–van Krevelen; or (iii) Eley–Rideal.

The Langmuir–Hinshelwood mechanism involves reaction of two adsorbed species on the catalyst to form the product, as shown:

$$\mathrm{A(g)} \leftrightarrow \mathrm{A(ads)}$$
$$\mathrm{B(g)} \leftrightarrow \mathrm{B(ads)}$$
$$\mathrm{A(ads)} + \mathrm{B(ads)} \xrightarrow{k_{\mathrm{surf}}} \mathrm{AB(ads)}$$
$$\mathrm{AB(ads)} \rightarrow \mathrm{AB(g)}$$

where A could represent mercury and B could represent a halogen such as chlorine.

The Mars–Maessen or Mars–van Krevelen mechanism involves reaction between an adsorbed species (in our case, mercury) and lattice oxygen, or halogen from the catalyst to form the product. The oxygen or halogen is replenished from the gas. The mechanism is depicted here for oxidation of species A by lattice oxygen of the catalyst.

$$\mathrm{A(g)} \leftrightarrow \mathrm{A(ads)}$$
$$\mathrm{A(ads)} + \mathrm{M}_x\mathrm{O}_y \rightarrow \mathrm{AO(ads)} + \mathrm{M}_x\mathrm{O}_{y-1}$$
$$\mathrm{M}_x\mathrm{O}_{y-1} + \frac{1}{2}\mathrm{O}_2 \rightarrow \mathrm{M}_x\mathrm{O}_y$$
$$\mathrm{AO(ads)} \rightarrow \mathrm{AO(g)}$$

The Eley–Rideal mechanism involves a gas-phase species reacting with an adsorbed species to form the product. The mechanism is depicted here.

$$\mathrm{A(g)} \leftrightarrow \mathrm{A(ads)}$$
$$\mathrm{A(ads)} + \mathrm{B(g)} \xrightarrow{k} \mathrm{AB(g)}$$

where A could represent mercury and B could represent a halogen atom such as chlorine.

Niksa and Fujiwara [2] suggest that ammonia and HCl strongly adsorb to the surface of the SCR catalyst, thus creating an environment for surface site adsorption competition. The elemental mercury either in the gas phase contained within the flue gas itself, or as a weakly adsorbed species, eventually contacts the chlorinated sites and the oxidation reaction occurs. The form of this reaction follows the Eley–Rideal rate expression describing the mercury oxidation rate as a function of the ammonia/NO*x* ratio and concentrations of elemental mercury and HCl at the inlet of the SCR as well as catalyst pitch and channel shape, SCR temperature, and the gas space velocity [2]. Other mechanisms suggest that elemental mercury reacts with other constituents either in the gas phase or on the surface of the catalyst or some other solid particle (such as unburned carbon or fly ash), before converting to the more stable $HgCl_2$ form. No one mechanism, however,

has been verified as the primary reaction mechanism for mercury oxidation, possibly because of the multiple components comprising both the catalysts and the flue gas in a real power plant setting. For example, although we may speculate that the tungsten and vanadium species of the SCR catalyst comprise the active phase for mercury oxidation, we must note that there will also typically be catalytically active fly ash particles (containing carbon and numerous metal oxides) present on the catalyst. In addition, if we suggest that a halogen such as adsorbed chlorine on the surface of the catalyst is primarily responsible for the oxidation of mercury, we must note the possibilities (likelihood) of adsorbed oxygen and bromine participating in the oxidation of mercury as well.

15.2.4
SCR Operation-Hg^0 Reaction Effects

Because of the limited knowledge of the exact reaction that occurs during mercury oxidation, little information is available with regard to the effect of operational conditions within the SCR itself. To better understand operational effects, some data has been collected during an array of laboratory and pilot scale tests. One particular test conducted between Southern Company and Gulf Power, Electric Power Research Institute (EPRI) and W.S Hinton and Associates, investigated the mercury oxidation behavior of several different commercial SCR catalysts across various operating conditions. The testing occurred at the 5 MWe Mercury Research Center (MRC) located in Pensacola, FL. at Gulf Power's Plant Crist. Parameters such as halogen content in the flue gas, flue gas flow rate, temperature, and ammonia injection, were all varied to measure the mercury oxidation response to these changes.

Research has demonstrated the inhibitive effect of ammonia on the process of oxidizing mercury. Tests have demonstrated that in a low-ammonia concentration environment, the vast majority of the mercury oxidation was observed to have occurred across the first two layers of the three-layer SCR. In the instance of increasing and subsequent high-ammonia concentrations, the reaction zone for the mercury oxidation tended to shift further down in the SCR reactor occurring in the third layer. In one test program performed at the Mercury Research Center in particular, there was a marked increase in the amount of oxidized mercury further down in the SCR catalyst layers, particularly at lower ammonia injection rates.

Owing to the host unit's fuel source containing a very low level of native chlorine in the coal, opportunity existed to vary the levels of halogens into the flue gas to measure the response of mercury oxidation. For the sake of this particular test, chlorine was injected as HCl gas directly into the flue gas. Injection levels ranged from 0 to 150 ppm of chlorine and to ensure minimal interference from ammonia being injected, a constant alpha ratio of 0.9 (or 90% deNOx) was maintained. It was observed that there was indeed a positive response to mercury oxidation levels as the injection rate of chlorine increased.

A key component of any chemical reaction, temperature was varied to observe the response of the mercury oxidation levels. DeNOx activity tends to improve as

temperature increases. In addition, the conversion of SO_2 to SO_3 also increases with increasing temperature. Conversely, the rate of mercury oxidation decreases as the temperature increases. Typically, for a constant rate of gas flow, given a certain geometry of the catalyst pitch, the temperature change will also result in a volumetric flow change. High- and low-temperature operating conditions were created in conjunction with slightly different ammonia injection rates while increasing the chlorine concentration in the flue gas. Although there were varying conditions affecting data collection, the data do show a decline in mercury oxidation as the temperature is increased. It is noted that mercury is a semi-noble metal, and the thermal decomposition temperatures of its compounds, such as mercuric chloride, are relatively modest, possibly explaining this observed effect.

Although it is observed to not have as large an effect on mercury oxidation as other parameters, the flow rate through the SCR was varied and response to mercury oxidation measured. It was noted that flow rate changes in addition have an effect on residence time (gas contact time across the catalyst), mass transfer, and ammonia slip, thus ultimately affecting mercury oxidation. As the flow rate increased, the rate of mercury oxidation decreased, which could be linked to the lowered residence (contact) time and increased ammonia slip throughout the reactor.

On the basis of the research conducted, some general conclusions can be drawn from the data collected. They include (i) chlorine content has no apparent effect on deNO*x* rate, (ii) chlorine concentrations are effective from 0 to 50 ppm, (iii) mercury oxidation is a function of specific surface area of the catalyst, and (iv) lower temperatures within the SCR reactor increase mercury oxidation rates.

15.2.5
Hg^0 Oxidation and SO_2/SO_3 Conversion

In addition to the deNO*x* and mercury oxidation properties that SCR catalysts possess, there is the ability to oxidize SO_2 (present in the flue gas) to SO_3, with conversion being represented by the following equation:

$$SO_2 + 1/2\ O_2 \rightarrow SO_3 \tag{15.3}$$

The SO_3 produced can then combine with water vapor in the flue gas to produce sulfuric acid. Other potential side reactions that can occur in the presence of excess ammonia include the formation of ammonium sulfate and ammonium bisulfate, which can have adverse reactions on both catalyst performance as well as downstream equipment performance (namely, the air preheater). Through proper operation of the SCR (including minimizing ammonia slip, minimizing SO_2 conversion through catalyst formulations, controlling temperature, etc.), ammonium sulfate and ammonium bisulfate formation can be reduced. Formation reactions are described here:

$$2\ NH_3 + SO_3 + H_2O \rightarrow (NH_4)_2SO_4(\text{Ammonium Sulfate}) \tag{15.4}$$

$$NH_3 + SO_3 + H_2O \rightarrow NH_4HSO_4(\text{Ammonium Bisulfate}) \quad (15.5)$$

In an ideal situation, the SCR catalyst would promote the oxidation of mercury and removal of NO*x* in the flue gas while minimizing the conversion of SO_2 to SO_3. Typical SCR operating conditions have made this balance difficult, especially when it has been observed that SO_2 strongly reduces elemental mercury oxidation at high temperatures (>662 °F) [4]. In laboratory operations, catalyst manufacturer Hitachi has observed that while SO_2 conversion rates of conventional SCR catalysts have decreased, corresponding rates of mercury oxidation have decreased. This suggests a close correlation between both mercury oxidation activity and SO_2 conversion activity. It is noted that vanadium oxides are well-known commercial catalysts for the oxidation of sulfur dioxide to sulfur trioxide, and are also a key component of the SCR catalysts.

By changing the active composition of catalysts, one could also control activity of the catalyst, which would affect all of the chemical reactions. Research has shown that the active metal components contained in the SCR catalyst have demonstrated this direct effect on both the conversion of SO_2 to SO_3 and mercury oxidation. In a test conducted by Schwaemmle *et al.* [5] V_2O_5 and WO_3 concentrations were varied to measure the effects on deNO*x* and $SO_2 - SO_3$ conversion. By reducing the amount of V_2O_5 in the catalyst, a decrease in SO_2 conversion was observed. In addition, the removal of WO_3 and subsequent addition of Cu to the catalyst composition resulted in an increased $SO_2 - SO_3$ conversion and a higher deNO*x* activity. By altering the active catalyst compositions while noting performance, such data can aid manufacturers in catalyst development, achieving high deNO*x* and high mercury oxidation while keeping SO_2-SO_3 conversion relatively low. Both the removal of NO*x* as well as oxidation of elemental mercury occur on the surface of the catalyst, and the SO_2 conversion is a diffusion-limited reaction that occurs within the catalyst itself. According to Gretta *et al.* [4], the reaction rate of SO_2 to SO_3 conversion is slower than the diffusion velocity of SO_2 through the catalyst and the reaction rate of mercury oxidation is faster than the diffusion velocity of the mercury through the catalyst owing to its molecular weight. This means that the SO_2 conversion is controlled by the oxidation rate, which is controlled by the active composition of the SCR catalyst. In order to develop the area of optimizing mercury oxidation using SCR catalysts, design must take into account the amount of active components in the catalyst. By altering the catalyst based on the reaction mechanism, allowing the more active sites to oxidize mercury instead of converting SO_2 to SO_3, higher oxidation rates can be achieved while maintaining low conversion rates [4].

15.3
Conclusions and Future Research

While much research has been done to understand the impacts of SCR operations on mercury oxidation, there is still a need to gain better insight on the actual

reaction mechanism. This need is the key to being able to predict oxidation performance given a plethora of catalyst types and formulations. Given certain SCR inlet conditions as well as catalyst properties, one could essentially predict the fate of the mercury across the SCR as well as in downstream equipment, namely, the ESP and eventually the wFGD.

In terms of operations, it is noted that changes in flow rate did not appear to have significant impact upon mercury oxidation. This is important to note because in the case of a load change, the change in temperature is expected to have the greatest impact, rather than any effects due to flow rate. This holds given a moderate turndown in load (roughly 60%). More extreme turndowns may see larger effects in which flow rate does play a significant role, but facilities should not assume that low load conditions are necessarily beneficial in terms of mercury oxidation, especially in cases where the flue gas temperatures do not change significantly [3]. The data also indicate that changes in ammonia will affect the amount of mercury oxidation through the SCR. From the results found, the total effect of SCR reactor conditions is not well noted, but the relationship between ammonia concentration and mercury oxidation performance has been identified.

Available data can be used in a relative sense to determine how various operational changes will affect mercury-related parameters; however, the industry would benefit from information from other catalyst formulations, such as newer formulations designed to enhance the oxidation of elemental mercury, ultralow SO_2 conversion catalysts, and regenerated and spent catalysts. New information will help utilities develop catalyst management strategies to maximize and maintain high levels of oxidized mercury from outage to outage. From a compliance perspective, being able to predict and optimize mercury oxidation using current air pollution control equipment, namely, the SCR, would provide cost-effective options for electric generating fleets, avoiding higher installation costs of more capital-intensive control technologies in an effort to meet a stringent standard.

Mercury Capture in Wet Flue Gas Desulfurization Systems

Gary Blythe

16.1
Introduction

This section discusses mercury removal by wet flue gas desulfurization (FGD) systems installed to remove sulfur dioxide (SO_2) from coal flue gas. This is often called *co-benefit* mercury removal because wet FGD systems are generally installed to remove SO_2, but many achieve a substantial amount of mercury removal from the flue gas as well.

Wet FGD systems work by circulating an alkaline slurry that contains lime or limestone, or a sodium-based alkaline solution, through a flue gas contactor or "absorber vessel" to remove SO_2 and other acid gases from the flue gas. Figure 16.1 is an illustration of a limestone forced oxidation (LSFO) wet FGD process, showing the main components of reagent preparation, flue gas handling and SO_2 absorption, and by-product dewatering. While most wet FGD systems were not originally designed to remove mercury from flue gas, there can be considerable co-benefit capture of mercury under favorable conditions.

As described in earlier sections, mercury in the gas phase of coal flue gases is present in two main forms: elemental or metallic mercury (Hg^0) and oxidized or ionic mercury (Hg^{2+}), with a small amount present as particulate-bound mercury. Oxidized mercury is believed to be present primarily as mercuric chloride ($HgCl_2$) under most circumstances, but may include mercuric bromide if bromide is added to the coal or flue gas to enhance mercury oxidation.

Of the two major mercury forms in flue gas, the elemental form is exceedingly insoluble in aqueous solutions and therefore is not removed at significant percentages in wet FGD absorbers. In contrast, the oxidized forms, as mercuric chloride or mercuric bromide, are very soluble and absorbed into the FGD scrubbing slurry at high efficiency – at or near the gas-film mass transfer limit of the FGD absorber. In most modern FGD systems, the gas-film limit represents 95–99+% capture of soluble gas-phase species from the FGD inlet flue gas.

Thus, ideally, of the oxidized mercury in the FGD inlet flue gas, a high percentage should be absorbed into the scrubbing slurry. For example, if the total mercury at the FGD inlet is 60% in the oxidized form, approximately 57% to greater than

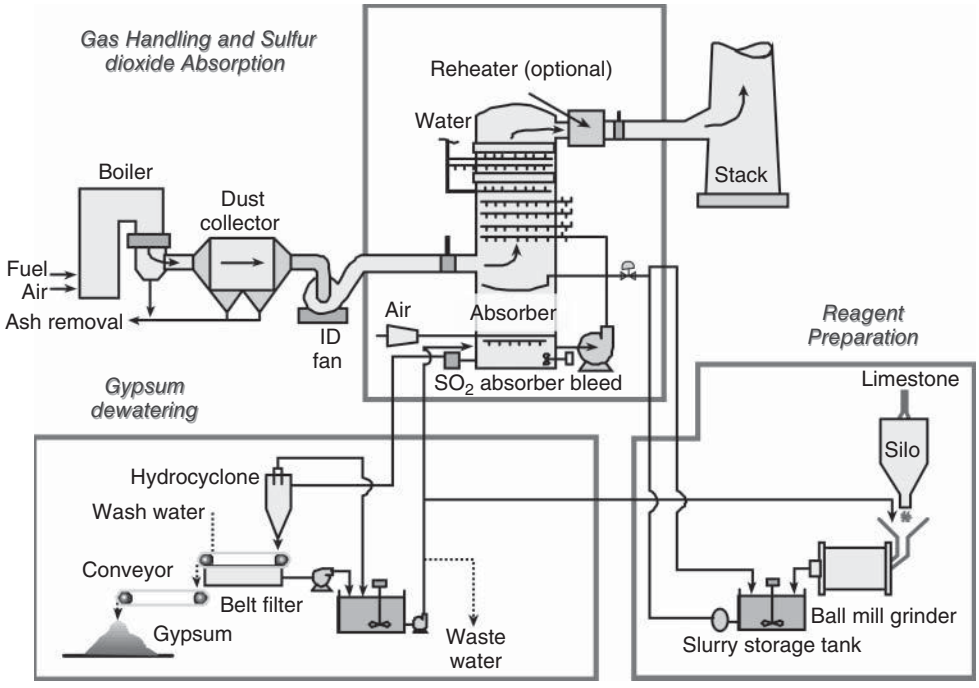

Figure 16.1 Typical limestone forced oxidation wet FGD process.

59% of the total mercury should be absorbed. However, the net removal of oxidized mercury across the FGD system is often limited to lower percentages by a phenomenon called *mercury reemission*, or *reemissions*. In this phenomenon, a portion of the absorbed oxidized mercury undergoes chemical reduction reactions while dissolved in the aqueous phase, and is converted to the relatively insoluble elemental form. Once converted, it is released from the aqueous phase back into the flue gas. Evidence of reemission is seen when the FGD outlet or stack flue gas elemental mercury concentration is measured to be greater than the FGD inlet elemental mercury concentration. Reemissions are discussed in greater detail later in this section.

In the remainder of this section, the capture of oxidized mercury by wet FGD systems is described using two different terminologies to account for the effects of reemissions in limiting net mercury removal. Mercury "absorption" or "capture" is used to describe the transfer of oxidized mercury in the flue gas into the dissolved state in the absorber recirculating slurry, before any reemission reactions. This could be considered the gross capture or removal of oxidized mercury by the FGD system. In contrast, the term *net removal* describes how much oxidized mercury is removed from the inlet flue gas across the FGD system after considering the limitations imposed by reemissions. The initial mercury absorption or capture into the FGD slurry liquor is typically in the range of 95–99+% of the oxidized mercury in the FGD inlet flue gas, while the net removal could be

anywhere in the range of 0–99+%, depending on how significant the reemissions might be. In some cases, the mercury removal across an FGD system can appear to be negative, when in a transient circumstance the inlet mercury concentration to the absorber(s) is lower than the concentration produced by the reemission of mercury from the FGD slurry liquor.

16.2 Fate of Net Mercury Removed by Wet FGD Systems

16.2.1 Phase Partitioning

Mercury is initially absorbed from the flue gas into the liquid phase of the absorber slurry. Once absorbed, it can either remain in the liquor, undergo reemission reactions and be released back into the flue gas as elemental mercury, or be adsorbed or precipitated into the slurry solids.

After being absorbed and dissolved into the aqueous phase of a wet FGD recirculating slurry, oxidized mercury becomes a cationic (positively charged ionic) species. Considering the mercuric salts of the major FGD anionic (negatively charged ionic) species such as sulfate, sulfite, chloride, and carbonate, mercury would be expected to remain in the liquid phase of an FGD slurry; all of these mercuric salts are very soluble. However, the many trace elements present in FGD slurries enter the FGD system by absorption from the flue gas, by capture of fly ash from the flue gas, or from the lime or limestone reagent. Some of these, such as iron (Fe^{3+}) precipitate in FGD slurries, form fine (small particle size) ferri-hydroxides ($Fe_X(OH)_Y$) that can adsorb and/or coprecipitate heavy metals such as mercury. Others such as reduced forms of sulfur (sulfide) and selenium (selenide) form very insoluble salts with oxidized mercury and can result in the precipitation of mercury salts from the aqueous phase into the slurry solid phase. Any or all of these species could be present in FGD slurries in concentrations sufficient to cause a significant phase change of oxidized mercury from the aqueous phase to the solid phase.

The actual mechanism for mercury adsorption/coprecipitation into the solids is not well understood. A number of theories have been considered, and include mercury adsorption/coprecipitation with iron hydroxide fines [1], precipitation as mercuric sulfides [2], or precipitation as mercuric selenides (Bloom, N. (2011) URS Corporation. Personal communication with Gary Blythe, August 2011) and others.

Whether the mercury is found in the slurry solids or liquor is often called the *mercury phase partitioning*. Electric Power Research Institute (EPRI) investigated the phase partitioning of mercury in U.S. wet FGD systems and found that the absorbed mercury can be partitioned over a wide range, from primarily in the slurry liquor to primarily in the slurry solids [3]. Two decades ago, Gutberlet *et al.*, observed that mercury was found primarily dissolved in the liquor phase of LSFO

or gypsum ($CaSO_4 \cdot 2H_2O$) producing wet FGD systems, but primarily in the solid phase of low-oxidation FGD systems that produce calcium sulfite hemihydrate ($CaSO_3 \cdot {}^1/_2H_2O$) as a by-product [4]. At first, this was puzzling to EPRI researchers collecting mercury phase partitioning data on U.S. wet FGD systems, because as mentioned a wide range of mercury partitioning was measured in LSFO systems.

However, on further analysis of the data collected, it was observed that the mercury phase partitioning in forced oxidation FGD systems correlated with the oxidation-reduction potential (ORP) measured in the absorber recirculating slurry. ORP is measured in millivolts and provides a measure of how electrochemically oxidizing or reducing is the chemical environment in an aqueous solution. The more positive the ORP the more oxidizing the environment, while the more negative (or closer to zero) the ORP the more reducing the environment.

ORP measurements are relative to a reference electrode also inserted into the aqueous environment, and each electrode type has its own characteristic electrochemical potential. A "standard hydrogen electrode" (SHE) is defined as having a potential of 0 mV, and this is the defined basis for ORP measurements. Field measurements require a more rugged reference electrode than the SHE, so most FGD ORP measurements are made with a silver/silver chloride electrode in a solution of potassium chloride (Ag/AgCl in KCl), with the KCl solution either 4-M or saturated in concentration. The ORP measurements discussed in this section were all made relative to an Ag/AgCl reference electrode in 4-M KCl, and are reported as measured. These measurement results should have approximately 200-mV added to them to make them equivalent to measurements with a SHE.

Figure 16.2 shows EPRI data for mercury phase partitioning in U.S. wet FGD systems as a function of ORP measured in the absorber slurry. The data for LSFO systems show a consistent trend of increasing percentage of mercury in the liquor phase of the slurry as the ORP increases, although with a few outliers. The linear least-squares fit of the data shown in the plot has an R^2 value of 0.9, indicating a relatively good fit. The LSFO systems show a wide range of mercury partitioning, from virtually all in the solids to greater than 80% in the liquor, over a relatively wide range of ORP from less than 100 to over 600 mV. The underlying mechanism for this apparent correlation with ORP in LSFO systems is not yet fully understood.

The data for low-oxidation (calcium sulfite producing) FGD systems show ORP values of approximately +50 to −50 mV, and the mercury is found primarily in the solid phase. However, the data do not fit the linear correlation made for the LSFO systems, and the reason for the different response to ORP is not apparent.

16.2.2 Mercury in FGD By-product Streams

The recirculating slurry in wet FGD systems contains mostly by-product solids (gypsum in LSFO systems and calcium sulfite in low-oxidation systems) with a small amount of lime or limestone reagent present to provide alkalinity. The reactions with flue gas SO_2 produce solid by-products that must be purged periodically

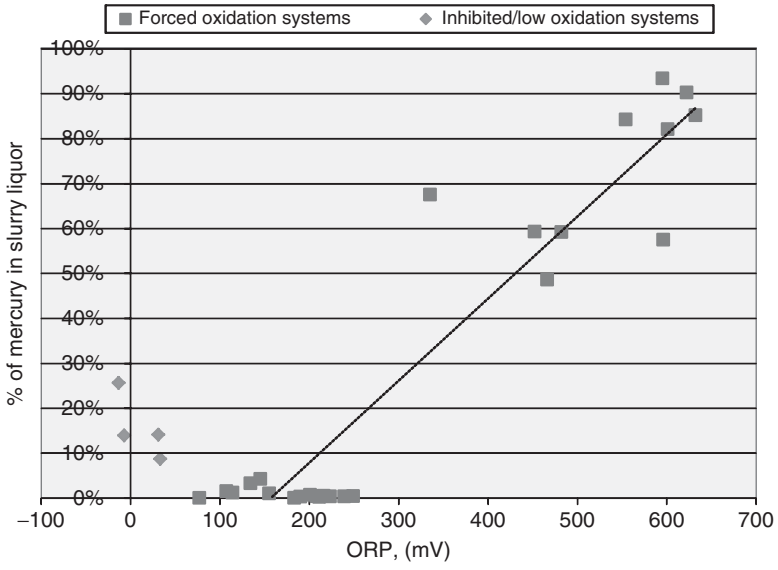

Figure 16.2 Apparent relationship between ORP and phase partitioning of mercury in an FGD absorber slurry. (Reference [5].)

to limit the concentration of suspended solids in the recirculating slurry. This absorber purge stream is dewatered in up to two stages, to produce a damp solid by-product and a low-solid-content liquor stream. In LSFO systems, a portion of the low-solid-content liquor stream is commonly purged to bleed soluble chlorides from the FGD system to prevent excessive chloride concentrations, while the remainder is returned to the absorber. In sulfite-producing wet FGD systems, the sulfite by-product does not dewater as well as gypsum; a separate chloride stream may not be needed, as the water leaving with the dewatered calcium sulfite by-product may adequately control chloride concentrations.

Generally, LSFO systems use hydrocyclones for the first dewatering step, whereas sulfite-producing systems use thickeners (sometimes called *clarifiers*) for the first dewatering step. Figures 16.3 and 16.4 illustrate these two primary dewatering processes. Some early LSFO systems use thickeners for the first step, but hydrocyclones are almost never used in sulfite-producing systems. Both device types produce a low-solid-content liquor overflow and a high-solid-content underflow that can be further dewatered in secondary dewatering processes such as horizontal vacuum belts, drum vacuum filters, or centrifuges. Hydrocyclones produce an overflow that contains approximately 1–5 wt% fine suspended solids, whereas well-performing thickeners produce an overflow with only part-per-million levels of very fine suspended solids. Correspondingly, the two devices produce a different distribution of solids between their overflow and underflow streams.

Hydrocyclones tend to send most of the fine solids in the feed stream to their overflow and most of the coarser solids to their underflow. In contrast,

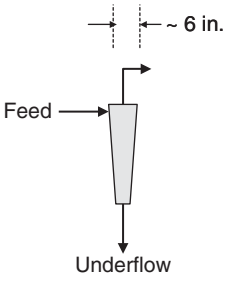

Figure 16.3 Illustration of a hydrocyclone-type FGD primary dewatering system (one of ~10 to 20 per unit is illustrated).

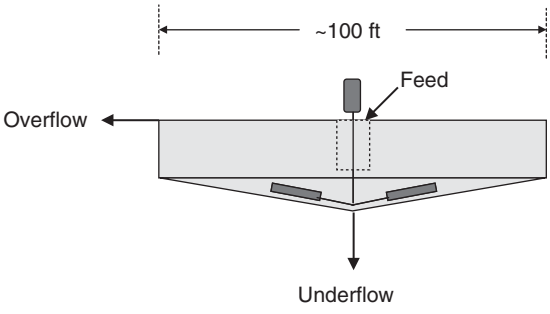

Figure 16.4 Illustration of a thickener-type FGD primary dewatering system (typically one per unit).

well-performing thickeners send almost all of the solids in the feed stream, both fine and coarse, to the underflow. Thus, FGD systems with hydrocyclones tend to recycle an appreciable percentage of fine solids back to the absorber, whereas in systems with thickeners the solids are essentially once through (i.e., no recycle of fine solids).

The sulfite oxidation mode and the types of dewatering devices used in wet FGD systems are described here because they can have a significant impact on how mercury distributes among the solid and liquid by-product streams leaving a wet FGD system. It has generally been observed that mercury is enriched in fine (<20-μm-diameter) solids and is found in a lower concentration in larger solids [5]. This means that in FGD systems with hydrocyclones, the mercury in fine solids tends to get recycled back to the absorber. Because the fine solids have a higher concentration of mercury, the absorber slurry tends to have a higher mercury concentration than the gypsum by-product (hydrocyclone underflow). In systems with thickeners for primary dewatering, the absorber solids tend to have nominally the same mercury concentration as the solid by-product, as the solids are essentially passed through with no size separation.

In systems where most of the mercury is found in the slurry liquor (mostly LSFO systems operated at high ORP), there can be considerable mercury recycle back to the absorber in the hydrocyclone overflow slurry, which is mostly liquor rich in mercury and mostly returned to the absorber. Such a recycle is less common in FGD systems with thickeners, because most are sulfite-producing FGD

systems that operate at low ORP where mercury mostly partitions to the solids, and because it has been observed that liquid-phase mercury concentrations tend to decrease across the thickener. This is likely due to the long residence time in a thickener, during which mercury adsorption and/or precipitation into the solids (or possibly reemission to the atmosphere) can occur.

Correspondingly, in systems that use thickeners for primary dewatering, particularly sulfite-producing wet FGD systems, nearly all of the mercury removed by the wet FGD system leaves with the solid by-product stream. This is largely because in sulfite-producing wet FGD systems, most of the mercury captured by the FGD system is found in the solids. Also, calcium sulfite hemihydrate does not dewater as well as gypsum, so sulfite-producing FGD systems may not require a separate chloride purge stream to control chloride concentrations in the FGD absorber slurry liquor. Thus, there is not a second by-product stream in which mercury can leave the FGD system.

In gypsum-producing wet FGD systems, the mercury removed can be distributed between the gypsum by-product, the chloride purge liquor, and the chloride purge suspended solids. The distribution of mercury among these by-products depends primarily on the ORP at which the absorber(s) operate, the type of primary dewatering device employed, and the weight percent solids in the chloride purge stream. For example, in LSFO systems with a thickener as the primary dewatering device and that operate at low ORP, nearly all of the mercury leaves the FGD system in the gypsum by-product. In contrast, in FGD systems with hydrocyclones for primary dewatering, which operate at high ORP, and/or contain significant fine solids content in the chloride purge stream (e.g., several weight percent solids), the solid and/or liquid portion of the chloride purge stream can represent a significant percentage of the mercury discharge.

16.3 Mercury Reemissions

16.3.1 Definition and Reporting Conventions

As described earlier in this section, mercury reemission describes a phenomenon where oxidized mercury in the flue gas is absorbed in the wet FGD scrubbing slurry, then chemically reduced to the relatively insoluble elemental form and released back into the FGD outlet flue gas. Evidence of reemission is seen when the FGD outlet elemental mercury concentration is greater than the inlet flue gas elemental mercury concentration, when the two concentrations are expressed on a comparable basis (e.g., lb $TBtu^{-1}$ or μg Nm^{-3}@ 3% O_2).

However, it should be noted that making mercury concentration and speciation measurements is sometimes difficult, and FGD inlet and outlet flue gas conditions are much different in terms of temperature and moisture content. Reemissions

are quantified by subtracting one measurement result from another, which often involves subtracting one large number from another to quantify a smaller number by difference. This measurement by difference between two significantly different flue gas matrices can lead to measurement errors. Consequently, it is the author's opinion that reemission levels $<0.5\,\mu g\,Nm^{-3}$@3% O_2 (less than about $0.3\,lb\,TBtu^{-1}$) difference between the FGD inlet and outlet elemental mercury concentrations may be within measurement error. Only if such apparent reemission levels are seen consistently in a series of measurements might such levels be considered "real." Even if the measurement data are consistent, it is possible that apparent reemissions are actually measurement bias artifacts.

Several conventions are used to express reemission levels across an FGD system besides the elemental mercury concentration increase across the FGD system, as described earlier. One is to calculate an observed elemental mercury removal percentage based on FGD inlet and outlet elemental mercury concentrations:

$$\text{Reemission percentage} = (\text{inlet } Hg^0 - \text{outlet } Hg^0) \div \text{inlet } Hg^0 \times 100$$

with reemission being represented by a negative value. However, this percentage can be deceiving because the size of the result is dependent on how large is the inlet elemental mercury concentration. Instead, the author prefers to express reemission levels as a percentage of the inlet oxidized mercury concentration, as it is the oxidized mercury that is removed by the wet FGD system and reduced to the elemental form:

$$\text{Reemission percentage} = (\text{outlet } Hg^0 - \text{inlet } Hg^0) \div \text{inlet } Hg^{2+} \times 100$$

Also, this percentage is a reasonably accurate measure of how much reemission has reduced the overall net mercury removal across the FGD system. However, this percentage result can be misleadingly high when the inlet flue gas contains mostly elemental mercury and/or the inlet oxidized mercury concentration is low. In general, it is best to show reemission levels both as a concentration increase and as a percentage of the inlet oxidized mercury concentration. The two conventions for reporting together provide the best overall measure of how significant the observed reemissions might be.

Table 16.1 illustrates mercury measurements made across an LSFO wet FGD system that was experiencing significant levels of reemissions, both when expressed as an elemental mercury concentration increase across the absorber and as a percentage of the inlet oxidized mercury [6]. In this example, the FGD inlet mercury is 76% in the oxidized form; therefore, in the absence of reemissions approximately 72% to nearly 76% overall mercury capture across the FGD system would be expected. The measured capture percentage of oxidized mercury was high at 95%. However, the measured reemissions (by the Ontario Hydro method [7]) were significant, representing an increase in elemental mercury concentration across the FGD system of $3.4\,\mu g\,Nm^{-3}$ @ 3% O_2, or reemission of 49% of the inlet oxidized mercury. Thus, the net overall mercury capture across the FGD system was limited to only 34% of the FGD inlet total mercury instead of the expected 72–76%.

Table 16.1 Example of reemissions from an LSFO wet FGD system.

Parameter (all Hg concentrations corrected to 3% O_2)	FGD inlet flue gas	Stack flue gas
Hg^0 ($\mu g\,Nm^{-3}$)	2.2	5.7
Hg^{+2} ($\mu g\,Nm^{-3}$)	6.9	0.38
% Oxidized Hg	**76**	—
Total Hg ($\mu g\,Nm^{-3}$)	9.2	6.1
Hg^{+2} capture (%)	—	**95**
Hg^0 reemissions ($\mu g\,Nm^{-3}$)	—	**3.4**
Hg^0 reemissions, % of inlet Hg^{+2}	—	**49**
Overall Hg removal (%)	—	**34**

16.3.2 Reemission Chemistry

The primary reaction that produces reemission from FGD systems is believed to be an aqueous oxidation-reduction reaction between absorbed SO_2 and absorbed oxidized mercury. The overall reaction is shown as follows:

$$Hg^{2+}(aq) + HSO_3^-(aq) + H_2O(aq) \leftrightarrow Hg^0 \uparrow (gas) + SO_4^{2-}(aq) + 3\,H^+$$

where HSO_3^- (bisulfite ion) represents absorbed SO_2 in an ionic form at lower pH. However, this reaction is actually the net result of a number of reactions that appear to be kinetically limited at FGD conditions (i.e., they do not always proceed to chemical equilibrium).

The U.S. Department of Energy and EPRI funded a research project to investigate the kinetics of mercury reactions in the aqueous phase of wet FGD slurries, and fundamental studies were conducted in both an ultraviolet/visible spectrophotometer and in a bench-scale wet FGD simulator [8]. Those results showed that in simple simulated FGD solutions, reemission rates slowed as sulfite concentrations increased. This was determined to be the result of the formation of a disulfite complex with oxidized mercury that is more stable than a monosulfite complex with oxidized mercury, according to the following reactions:

$$Hg^{+2} + SO_3^{-2} \leftrightarrow HgSO_3$$
$$HgSO_3 + SO_3^{-2} \leftrightarrow Hg(SO3)_2^{-2}$$

It was determined that the monosulfite complex decomposes to produce the reemission reaction, as follows:

$$HgSO_3 + H_2O \rightarrow Hg^0 \uparrow + SO_4^{-2} + 2\,H^+$$

However, with the addition of chloride to the synthetic FGD liquor, the reemission reaction rates slowed markedly, in proportion to the chloride concentration in the liquor. The effect is apparently the result of the formation of mercuric chloride complexes that are more stable (less likely to produce reemission reactions)

than the mercury-sulfite complexes. Figure 16.5 provides an illustration of the proposed reactions involved in mercury reemissions in a relatively simple aqueous environment containing only mercuric ion, sulfite, and chloride. Bromide and iodide anions were found to form increasingly stronger complexes than chloride (in that order) when compared on a molar concentration basis, but these halogens are much less abundant in U.S. coals than chloride, and are correspondingly found in lower concentrations in wet FGD liquors.

Other FGD variables such as pH were found to have a complex relationship with sulfite and chloride concentration in their effects on reemission rates (i.e., no consistent trends over the typical range of values for FGD systems). Some species found in FGD systems were found to have a direct impact on reemission rates, most likely because they are reducing species themselves and may directly reduce oxidized mercury in the FGD liquor. Examples of this phenomenon include thiosulfate ion (present in inhibited oxidation FGD systems) and some sulfur-nitrogen species (present in many FGD systems, particularly those that do not have a high-efficiency NO_X control system upstream of the FGD).

This research also identified that reemission rates are directly proportional to FGD liquor mercury concentrations. As described, there are mechanisms that result in the transfer of mercury from the liquid phase to the solid phase of the FGD slurry. Reemission reactions occur predominantly in the liquid phase, so mercury precipitated or adsorbed into the solid phase is less likely to reemit. Current research funded by EPRI is focused on developing kinetics for mercury precipitation or adsorption from the liquid phase to the solid phase in FGD slurries, and on identifying the mechanisms for this phase transfer [5].

The species that cause mercury to transfer to the solid phase (e.g., iron hydroxides, sulfide, or selenide) have limited capacity to precipitate or adsorb mercury.

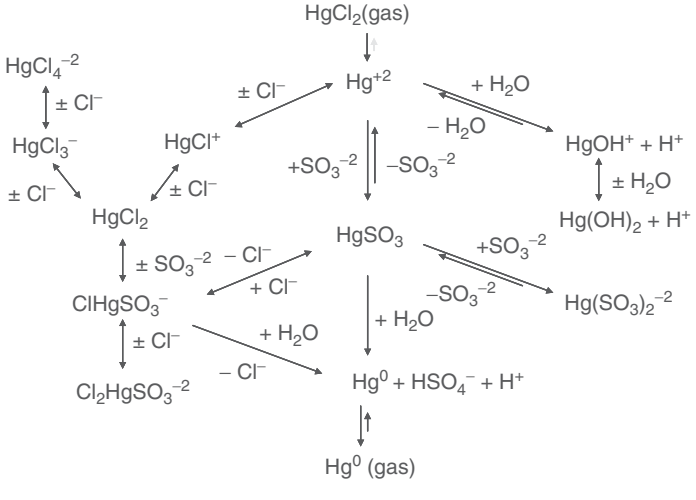

Figure 16.5 Illustration of proposed chemical reactions for mercuric ion, sulfite, and chloride in an aqueous environment [8].

Thus, the ratio of oxidized mercury concentration in the FGD liquor to the concentrations of these species may impact the amount of mercury that remains in the FGD liquor rather than transferring to the solid phase.

The phase change from the liquor to the solids serves as the basis for the so-called FGD reemission additives, which are added to FGD slurries to control reemissions and improve overall co-benefit capture of mercury. Reemission additives are discussed subsequently.

16.3.3 Reemission Additives

A number of vendors offer additives that can be used to limit or even completely eliminate reemissions. Most reemission additives are compounds that contain sulfide (R–S) or thiol (R–S–H) groups (where R represents the remainder of the molecule). Some are based on sodium or calcium molecules, while others have an organic base molecule. Of the organic-based molecules, the base species can either be a single molecule or a polymer.

The principle of operation of reemission additives is that they either precipitate or form very strong complexes with ionic mercury in aqueous solutions. Several of these additives are commonly used in industrial wastewater treatment processes to remove mercury and other metals from waters, and have been adapted for use directly in FGD processes to precipitate mercury. An example is Evonik Degussa's TMT-15, a 15 wt% solution of trimercapto-s-triazine, which has a molecular weight of 243 and has three sulfide groups attached. Evonik Degussa literature cites how extremely insoluble mercuric sulfides are, and that this is the principle of operation of their additive. The additive has been used for some time in industrial wastewater treatment and Evonik Degussa reported its use in European wet FGD systems for reemission control in 2003 [9]. Sulfide-based additives can also precipitate other metals, mostly divalent transition metals, but mercuric sulfide is the least soluble sulfide salt. Degussa cites the relative solubilities of several metal sulfides in the following order:

$$PbS > CdS > CuS >> HgS$$

Besides lead (Pb), cadmium (Cd), copper (Cu) and mercury, nickel (Ni) and zinc (Zn) are also precipitated as low-solubility sulfides. All of these metals tend to be present in FGD liquors, many in concentrations higher than mercury. Thus, these metals can compete with the reemission additives when they are first injected into an FGD system. Over time, with mercury being the least soluble sulfide salt, mercury in the liquor will preferentially precipitate with the additives. But, depending on how fast the reemission reactions occur, these reactions could still produce reemissions before the mercury is precipitated. Therefore, additive dosage and location of injection must be optimized to ensure rapid precipitation of oxidized mercury as it is absorbed into the FGD liquor.

Besides TMT-15, other vendors have reported considerable testing results on U.S. coal plant FGD systems, including Babcock and Wilcox, and the Nalco

Company [10, 11]. Several other companies offer sulfide- or thiol-based reemission additives; one such example is Pravo [12]. Other approaches for controlling reemissions are being offered. For example, Steag offers a technology to add activated carbon to FGD systems to adsorb mercury as it is absorbed from the flue gas [13]. CH2MHill has a patent for a technology to add iron salts to FGD absorbers to remove mercury from the liquor by iron coprecipitation [14]. All of these technologies are adaptations of technologies commonly used to remove mercury and other heavy metals from industrial wastewaters.

Another approach for controlling reemissions from FGD systems may be to optimize FGD operating conditions to minimize reemission rates. However, more research and development is needed to establish this as a well-defined and controllable approach. FGD parameters that could be optimized to control reemissions might include (but may not be limited to) the following:

- ORP (Mitsubishi Heavy Industries has a patent covering ORP control to optimize net mercury capture [15]),
- Iron content in the limestone reagent, and/or process configurations that maximize iron fines recycle to the absorber as part of the slurry dewatering process,
- Chloride concentrations in the FGD liquor (impacts mercury complexation, indirectly impacts the recycle of iron-based mineral fines in FGD reclaim water in systems that employ hydrocyclones),
- Concentrations of other halogens (bromide and iodide) in the FGD liquor that form strong complexes with mercury, and
- Weight percent suspended solids in the absorber slurry (impacts fines concentrations and surface area available for mercury adsorption).

16.4 Effects of Flue Gas Mercury Oxidation Technologies on FGD Capture of Mercury

One way to increase the co-benefit removal of mercury by wet FGD systems is to increase the percent oxidation of the mercury in the flue gas. Other chapters discuss the effects of fuel and flue gas additives, several of which enhance mercury oxidation, and the effects of catalysts, which also can enhance mercury oxidation. Of course, these technologies are not as effective if reemissions limit the net removal of oxidized mercury across the FGD system.

One additive that has been demonstrated to increase mercury oxidation in flue gas is the bromide ion, which can be added to the coal as a salt or injected into the flue gas as a salt or an acid. One impact of bromide injection is that bromine compounds in the flue gas are scrubbed at high efficiency in the FGD system, and the bromide ion is highly soluble in calcium- and sodium-based solutions. Thus, bromide builds up in the FGD system in a manner similar to chloride, to a concentration at which the bromide rate leaving in the water purged from the FGD system equals the rate entering with the coal and the bromide additive.

As the bromide builds to steady-state concentrations in wet FGD systems, it can affect mercury chemistry in the system. One effect was mentioned earlier in this section: bromide forms a relatively strong aqueous complex with oxidized mercury. This complexation can have further effects. As the bromide concentration builds, the mercury tends to remain in the liquor phase rather than transfer to the solids, and is available to participate in aqueous reemission reactions. However, the strength of the mercury–bromide complex tends to slow reemission reaction rates. The net effect of increased bromide concentrations on mercury reemission tendencies can be site specific – in some cases, reemissions are significant, while in one account the presence of elevated bromide concentrations appears to have stopped reemissions [16].

FGD system operators should keep in mind their system's liquid residence time when conducting tests with the bromide additive, as the true performance of the FGD system for net mercury capture may not be realized until steady-state bromide concentrations are achieved. The data plotted in Figure 16.6 show that it took almost 1 week of bromide addition testing at one full-scale wet FGD system to experience a change in mercury partitioning between the FGD liquor and solids. The change was not realized until the liquor bromide concentration exceeded 100 mg l^{-1}. FGD systems with hydrocyclones for primary dewatering, which operate with relatively low chloride concentrations in the FGD liquor and do not have a lot of slurry or liquor storage volume incorporated (e.g., no filter feed tanks or no large reclaim water tanks), tend to reach steady state rapidly, within a matter of days. The FGD liquid residence time is affected by factors such as the total volume of process water in the FGD system, the chloride concentration in the coal, and the chloride concentration in the FGD liquor at blow down. Systems that fire low-chloride coal but operate with elevated chloride concentrations in the absorber liquor, have thickeners for primary dewatering (which have a large liquid volume), and/or systems with other large volumes of water that get returned to the FGD system (e.g., from ponds) can take many days, weeks, or months to reach steady-state bromide concentrations.

Oxidation catalysts that enhance mercury oxidation percentages in the FGD inlet flue gas have generally not been observed to impact mercury behavior in wet FGD systems. That is, catalytically oxidized mercury is generally captured from the flue gas at as high an efficiency as is native oxidized mercury, and is no more or less likely to be reemitted.

However, one possible adverse effect is that by increasing the concentration of oxidized mercury in the flue gas, the ratio of oxidized mercury to species that enhance the transfer of mercury to the solid phase is increased. As this ratio increases, mercury may tend to remain in the liquor, and thus be available for reemission reactions. In contrast, selective catalytic reduction (SCR) catalysts can also oxidize mercury and may have a beneficial effect on mercury chemistry in wet FGD systems. By lowering NO_X concentrations in the FGD inlet flue gas, SCR systems may reduce the formation of "sulfur-nitrogen" compounds in FGD liquors [18]. Some of these compounds are chemically reducing species, and in bench-scale tests have been observed to contribute to mercury reemission

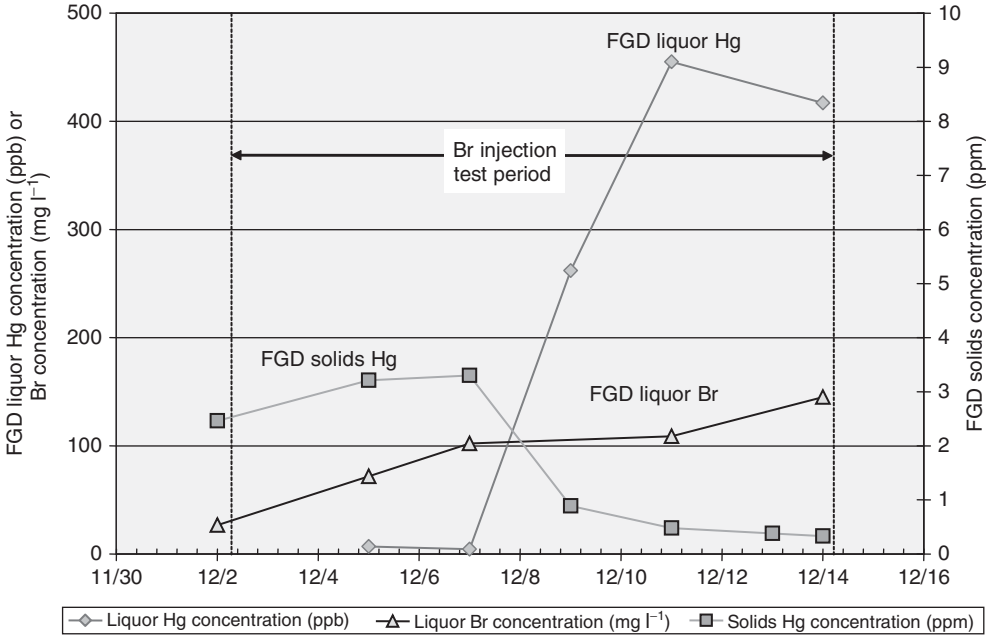

Figure 16.6 Example data showing time dependency of bromide concentration and effects on mercury partitioning in a full-scale wet FGD system. (Reference [17].)

reactions [8]. Thus, SCR catalysts may indirectly lower mercury reemission rates by lowering sulfur-nitrogen compound concentrations.

Some researchers are developing technology to enhance mercury capture by wet FGD systems by *in situ* oxidation of the small amount of elemental mercury that is soluble in wet FGD solutions [19]. Another technology being investigated would use replaceable carbon composite panels in the upper portion of an absorber vessel to absorb mercury from the flue gas [20]. These development efforts may represent future directions for maximizing co-benefit mercury capture by wet FGD systems. At present, these technologies are being investigated at laboratory to demonstration scale.

Introduction to Carbon Sorbents for Pollution Control

Joe Wong

17.1
Carbon Materials

Carbon materials occur in various forms owing to the arrangement of the carbon atom in the structural lattice, which can be characterized as either crystalline or amorphous. Crystalline carbons represent a class of materials whereby the carbon atoms are highly ordered and show a high degree of symmetry in their structural features (Figure 17.1). Crystalline carbon materials include diamond, graphite, and fullerenes. Diamond is considered the most highly ordered crystalline carbon material, having tetrahedrally bonded carbon atoms (sp^3) that form a face-centered cubic structure (Figure 17.2) [1]. Graphite is a highly ordered layered carbon structure with "sheets" of graphene planes (Figure 17.3) [1]. Carbon bond lengths and structural features of crystalline carbons are very regular and well defined.

In contrast, amorphous carbons are carbon materials with less order and/or more defects in the carbon structures. As there is never total disorder of the structure, there exist micro-regions of order or micro-crystallinity in the structure. The irregular carbon arrangement and structural defects give rise to the carbon material's pore structure, surface, and surface area features. Amorphous carbons are further classified into materials derived from coal, charcoal, or lamp black. Activated carbons possess many of the crystal structural features of amorphous carbon materials, and thus are characterized as predominantly amorphous solids.

17.2
Carbon Activation

Activated carbon can be produced from a variety of raw materials, including coal (predominantly bituminous and lignite), lignocellulose (sawdust, nut shells, lignin, pits, etc.), peat, plastics, resins, and petroleum residue. Essentially, any raw material that can be converted to a carbonaceous form can be activated.

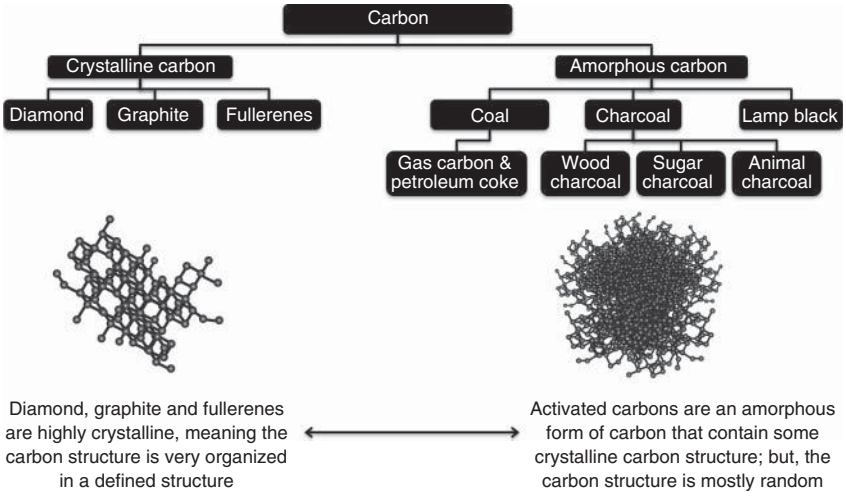

Figure 17.1 Crystalline and amorphous carbon materials.

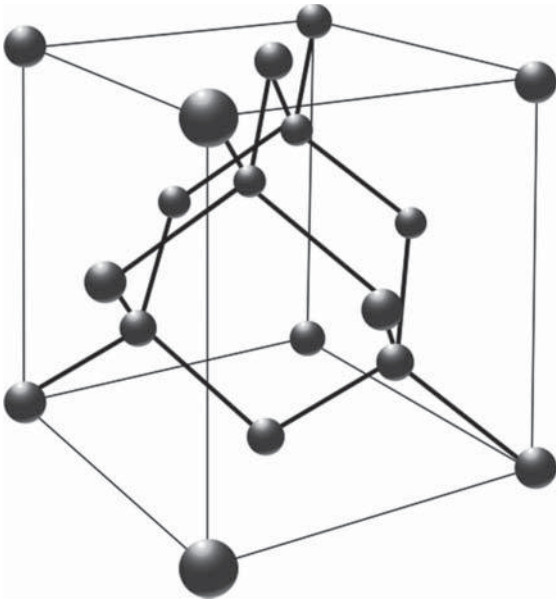

Figure 17.2 Crystalline structure of diamond.

Activation of the carbonaceous raw material is typically conducted either by thermal means or with chemical reactants. Heat treatment equipment ranging from rotary kilns, multihearth furnaces, fluid bed reactors, and batch ovens are employed under a variety of temperature, residence time, and gas composition conditions to achieve desired activated carbon properties. As one can imagine,

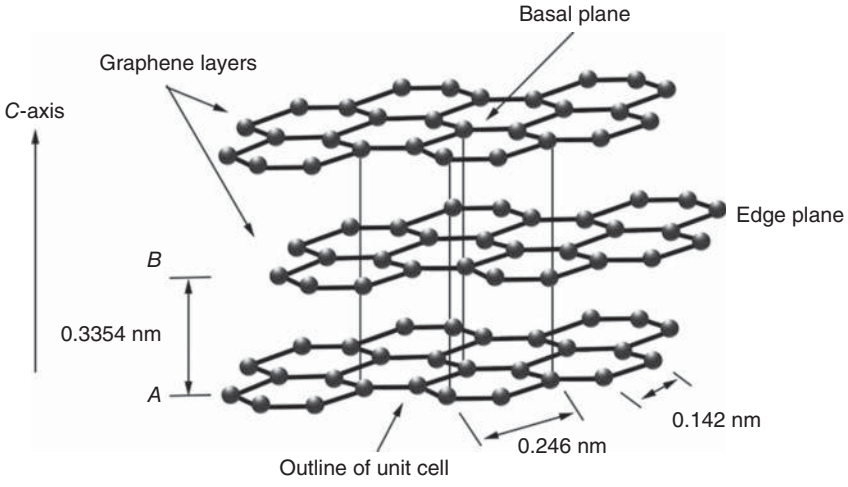

Figure 17.3 Crystalline structure of graphite.

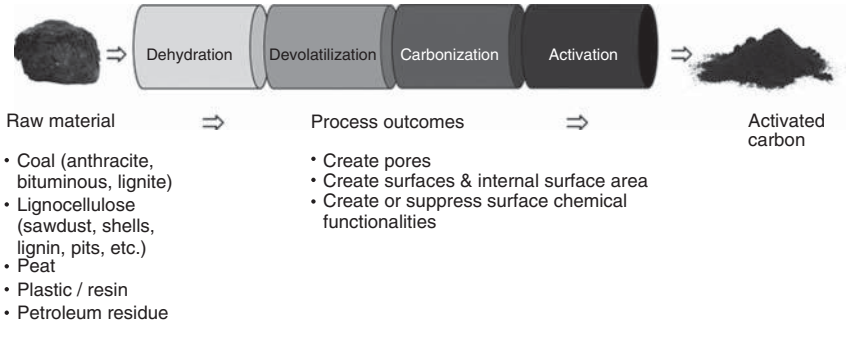

Figure 17.4 Carbon activation.

those in academia and industry and entrepreneurs have defined many activated carbon processing conditions. An Internet search of "Activated Carbon Activation" will return over 37 million hits. Baker, *et al.* [2] describe the various commercial manufacturing processes.

Despite the plethora of activation conditions, there are predominant basic processes occurring in activation, consisting of dehydration, devolatilization, carbonization, and finally activation itself. Figure 17.4 depicts a generalized view of these basic process steps in a thermal activation process. These basic steps are not necessarily discrete steps with fine lines of demarcation, but instead can overlap each other significantly. The first step consists of "dehydration." Most raw materials contain moisture, essentially in the form of free and some bound water, that is initially removed upon heating to about 100–150 °C. The next step is termed *devolatilization* and occurs above 150 °C, whereby free or weakly bound volatile organic constituents begin to evolve from the raw material into the gas phase.

"Carbonization" begins to occur around about 350 °C and proceeds to slightly below 800 °C in an inert or nonoxidizing atmosphere [3]. During carbonization, the non-carbon constituents containing heteroatoms, including oxygen, hydrogen, sulfur, and nitrogen, decompose or volatilize. Some of the organic constituents are not removed and remain in the carbon material as partially charred matter. Elemental carbon is essentially concentrated in the carbon material during carbonization. In addition, the carbon atoms begin to arrange into semirandom amorphous structures. Spaces or interstices of various sizes and shapes begin to form, giving rise to the beginning formation of the material's pores and surfaces. This carbonized material is sometimes referred to as *char*.

Typically, above about 800 and below 1000 °C in the presence of air, steam, carbon dioxide, or another oxidizing agent, the char begins to "activate." During activation, the initial pore structure from carbonization is further developed through oxidation or "burn-off" of the carbon structure and charred organics. Depending on the desired activated carbon "activity," pore development is a trade-off to carbon yield.

During activation and in subsequent cooling steps, the surface chemical functionalities can be manipulated. The oxidative atmosphere during activation typically results in a high oxygen-containing carbon surface. The injection of a "reductive" gas is sometimes employed to cap these oxygen functional groups to obtain desired carbon surface properties.

17.3 Carbon Particle Shapes and Forms

Activated carbons produced from thermal or chemical activation are typically in a combination of powdered and granular particulate form with particle sizes of less than about 2–3 mm in diameter. Additional processing employed by manufacturers can provide smaller or larger particles or shaped forms. Figure 17.5 describes typical activated carbon shapes and forms, which can consist of powdered activated carbon (PAC), granular activated carbon (GAC), shaped carbon, and carbon cloths.

17.3.1 Powdered Activated Carbon (PAC)

The American Society for Testing and Materials (ASTM) classifies PAC as activated carbon material passing through an 80-mesh sieve (0.177 mm or 177 μm) [4]. PAC is produced commercially by comminuting larger activated carbon particles produced during the activation process through one or more types of grinding equipment, including roller mill, hammer mill, ball mill, jet mill, and so on. The comminuted particle is sometimes classified to attain desired sieve mesh size fractions for different application requirements.

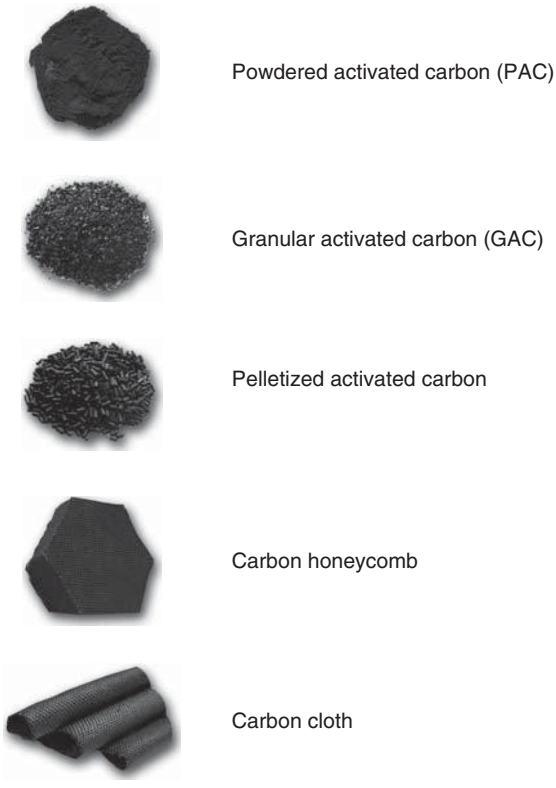

Figure 17.5 Activated carbon shapes and forms.

PAC is used prevalently in liquid-phase purification applications, such as in water treatment and food purification. By the nature of its small particle size, PAC is also a leading candidate for dispersed gas-phase applications. PAC can be designed to be highly dispersible in the gas phase, which allows for enhanced probability of contacting with dilute concentration gaseous pollutants and for rapid capture and uptake of pollutant molecules.

17.3.2 Granular Activated Carbon (GAC)

GAC particles are larger in size than PAC. ASTM classifies GAC as activated carbon particles that are retained on an 80-mesh sieve. The larger particle sized GAC is often used in gas- and liquid-phase applications, whereby the process stream flows through a packed bed of activated carbon. The GAC provides a lower pressure drop, thus allowing higher process stream flow rates, simpler equipment design, and lower energy requirements.

17.3.3
Shaped Activated Carbon

PAC can be mixed with a binder and shaped into different forms, including pellets, beads, honeycombs, and so on. Typical binders include carboxyl methylcellulose, clays, phenolic resins, ceramics, coal tar pitch, or combinations thereof. Depending on the manufacturing process, the binder addition and shaping of the raw material may occur before or after activation.

The manufacture of shaped carbons requires additional equipment and processing beyond carbon activation, thus adding cost to the final activated carbon product. Additional steps include (i) mixing and mulling of the PAC and binder, (ii) extrusion/briquetting/shaping, (iii) low-temperature heat treatment to achieve "green" strength, and (iv) high-temperature heat treatment to "set" the binder.

Shaped activated carbons, including honeycombs (Figure 17.5), are used extensively in gas-phase purification and catalyst support applications. The binder system provides the activated carbon its shape integrity, high mechanical strength, and low dust properties.

17.3.4
Other Activated Carbon Forms

Activated carbons can be impregnated into cloths and fabric, either physically bound or via a coating. These cloths find utility in air filters, chemical warfare suits, or applications requiring a conformal shape.

Other activated carbon forms include fibers and aerogels, which typically tend to be used for high-value, specialized applications.

17.4
Activated Carbon Applications

Activated carbon is a proven, versatile technology for a host of purification and other applications. The ability to tailor performance properties is a key, enabling feature of activated carbons. Although not an encompassing list, Baker, Global Industry Analyst, Freedonia and Roskill [2, 5–7] each describe industrial markets for activated carbon. Figure 17.6 lists some of the larger established and emerging market areas for activated carbon.

The use of activated carbons is well established for waste and potable water treatment, food and pharmaceutical separations and purifications and industrial processes, including solvent recovery. Other specialty applications are also well established, such as for catalyst and catalyst supports. The versatility of activated carbons has garnered much interest in applications for electrode materials for electrical energy storage markets. Other applications in the medical and consumer products arena are also prevalent. Carbon dioxide capture and sequestration are rapidly expanding R&D sectors for activated carbon sorbents.

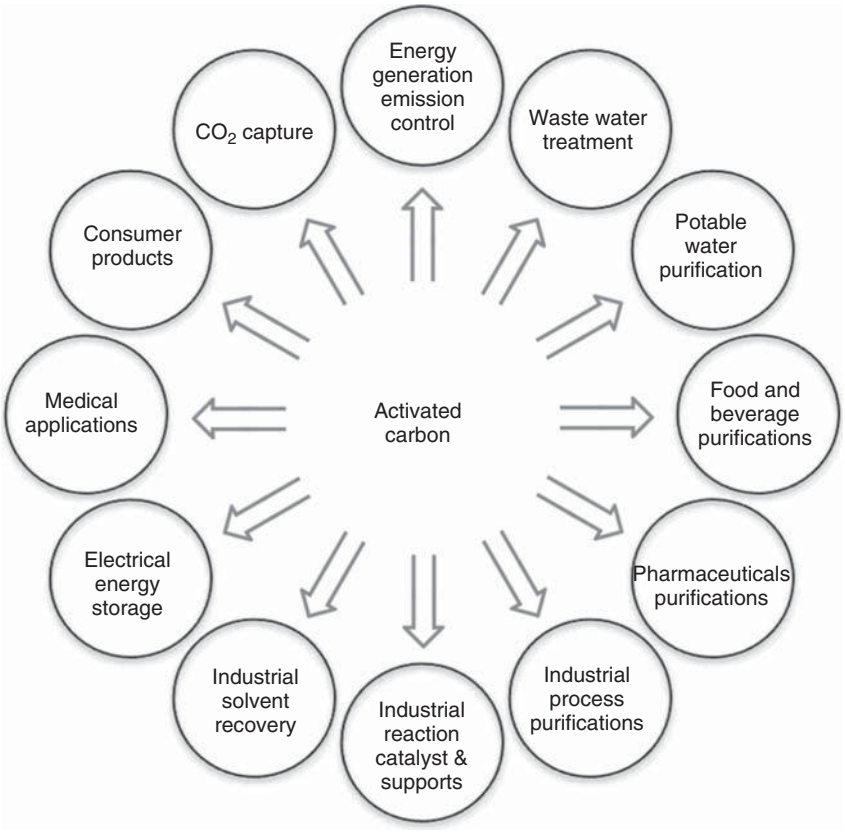

Figure 17.6 Activated carbon market applications.

A significant market interest in activated carbon has come from the energy generation industries, such as coal- and waste-fired power plants, industrial boilers, and cement kilns. These industries are in their initial commercial stages of applying activated carbons in their flue gas treatment steps and are conducting plant trials of improved, specialty activated carbons for mercury and other emission controls. This specialized application of activated carbon technology is establishing ground as the best available, cost-effective technology for mercury capture from flue gas.

17.5
Activated Carbon Properties in Emission Systems

Activated carbons are highly adaptable and can serve multiple purposes in removing organic and inorganic pollutants. Their innate ability to attract and capture

targeted molecules has made activated carbon a viable solution for removing mercury from flue gas streams.

The removal of mercury from power plant flue gas is a complex process, with consideration, to name a few, of the effects of chemical reaction kinetics, flue gas constituents and activated carbon surface interactions, and carbon adsorption capacity, diffusion kinetics, and adsorptive energy distribution. In addition, power plant flue gas emission trains are typically set up differently and thus present a variety of operating conditions from which the activated carbon must perform. Unfortunately, there is no reliable computational model to estimate the individual or collective nature of these factors on mercury removal. However, much work has been conducted to start painting a scientific-based fundamental picture of an ideal model system from which to build upon [8]. Later chapters in this book describe in detail the recent work on mechanisms and models for mercury interaction with carbon surfaces.

It is acknowledged widely that the removal of mercury from flue gas is represented by three predominant mechanisms.

- Conversion of elemental mercury, Hg^0, to an electron-receptive, oxidized state, either Hg^+ or preferably Hg^{2+} to enhance mercury's receptivity to activated carbon;
- Contact of the mercury compound, which is in a very dilute concentration in the flue gas, with the activated carbon;
- Diffusion and capture of the mercury compound in the activated carbon structure by physical adsorption and chemisorption.

The order and influence of these mechanisms and the rate-limiting step have been studied, proposed, and debated; however, it is plausible that all occur in a parallel manner, with one being more pronounced than the others in certain emission train conditions.

Given these mechanisms, activated carbon has three key properties or capabilities that make it effective for emission control applications (Figure 17.7). A meaningful specification for activated carbon for mercury removal in flue gas should factor in each of these characteristics.

- Activated carbons provide a **SURFACE** to host chemical reactants and other functionalities that interact with or affect the pollutant species, both chemically and physically.
- Carbons have **PORES** that adsorb, meaning attract, transport, and capture, molecules to be removed.
- Carbons are **PARTICLES** that are highly dispersible and provide a transport medium to deliver all the desired properties to the right place and at the right time in the emission system.

Each of these properties is discussed here.

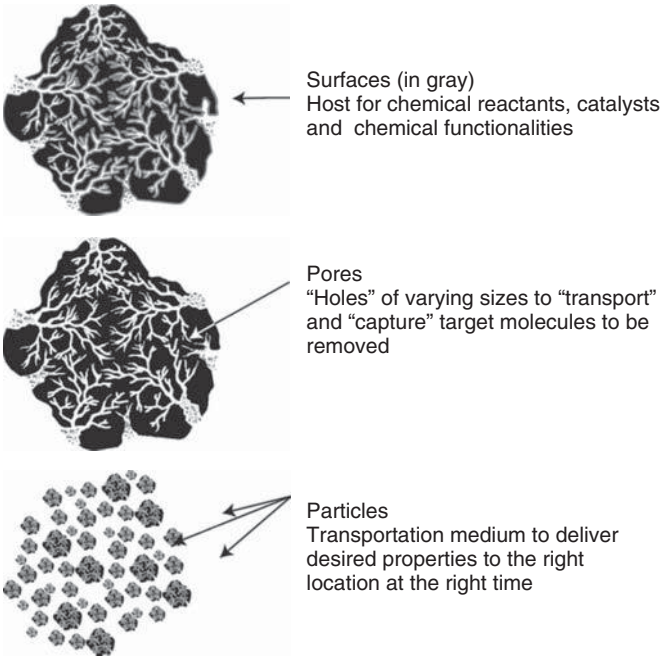

Figure 17.7 Activated carbons are multifunctional.

17.5.1 Activated Carbon Surface

A typical activated carbon designed for power plant flue gas mercury capture contains 500–700 m^2 of surface area per gram of activated carbon. In other words, 1 lb of activated carbon per million actual cubic feet of flue gas (lb/actual cubic feet per minute (ACFM)) injection rate provides enough carbon surface area to cover about 50 football fields if each carbon particle is unfolded completely flat to expose all surfaces. At this level of potential surface area, it is evident that not all of the activated carbon's surfaces are accessible to the mercury and that there are other factors involved. Accordingly, in developing activated carbon specifications specific to mercury capture, specifying surface area alone is insufficient.

Consideration of the role of an activated carbon surface in mercury removal reveals other key surface activities that occur (Figure 17.8).

The carbon surface provides bromine or other halogen forms or an oxidant to facilitate oxidation of elemental mercury to an oxidized, more "adsorbable/soluble" state.

The surface contains and exposes minerals to catalyze the oxidation of mercury. It is well documented that heterogeneous catalysis of mercury in the presence of halogens by precious metals and other minerals is on order of 100 000 times faster than the oxidation of mercury by halogens in a homogeneous gas phase [9, 10]. Having certain minerals present is particularly important when there are only

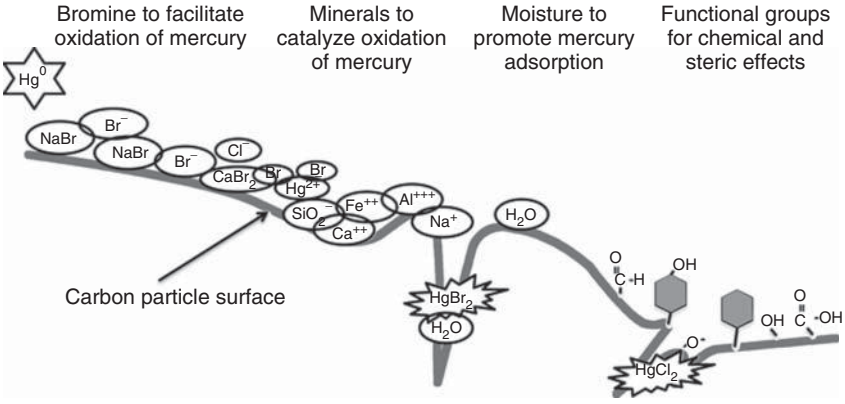

Figure 17.8 Activated carbon surfaces.

seconds of exposure time of the mercury to the halogen in most plant emission systems.

The surface contains moisture to promote mercury adsorption into the pores. The effects of carbon moisture levels have been studied and cited in literature [11]. Moisture plays a role in improving the adsorption of oxidized mercury.

The surface exposes certain chemical functional groups. It is well known that activated carbon surfaces contain a variety of chemical functions, including acidic carboxylic acid functions, phenyl and phenol groups, reactive free radicals, and polar hydroxyl and carbonyl groups [12, 13]. These surface functionalities can enhance or reduce the affinity of the activated carbon for the mercury species [14].

Evaluation of the binding energies of mercury and oxidized mercury species with simulated carbon surfaces has offered insights as to potential surface complex mechanisms, but a definitive or dominate pathway has not been elucidated [15]. However, it has been demonstrated that activated carbon surface features can be tuned to enhance or block specific surface mechanisms to enhance pollutant capture.

17.5.2
Activated Carbon Pores

The pores of an activated carbon are an intricate arrangement of "holes," "passages," and "caves," providing a carbon with its adsorptive properties and the resultant ability to capture targeted mercury molecules in flue gas systems. The characterization of pore structure often includes microscopic analyses and molecular simulations of the morphological (pore shape and size) and topological (pore connectivity) character of carbons [16].

Carbon pores are defined by their shape and size. Pores have been represented in various geometries, ranging in shapes from tapered cylinders to elongated slits. It is commonly acknowledged that the elongated slits provide the best representation of pore shape and function [17–21]. Carbon pore sizes (width) are

Table 17.1 IUPAC classification of pore size.

Classification	Pore diameter (nm) (10^{-9} m)	Pore diameter, Å (10^{-10} m)
Micropore	<2	<20
Mesopore	2–50	20–500
Macropore	>50	>500

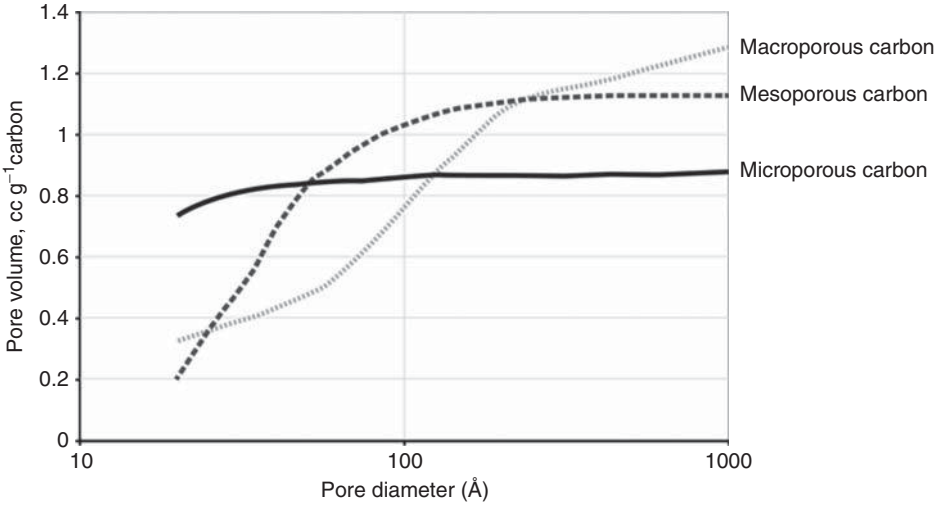

Figure 17.9 Cumulative pore volume and pore size of activated carbons. (Reproduced with permission from MeadWestvaco Corporation.)

classified by the International Union of Pure and Applied Chemistry (IUPAC) as shown in Table 17.1 [22]. Pores with width <2 nm are designated as *micropores.* Pores between 2 and 50 nm are *mesopores.* Pores with width >50 nm are termed *macropores.*

Pore size distributions can be interpreted from gas porosimetry measurements using nitrogen or argon as the adsorbate. Figure 17.9 [23] shows a plot of cumulative pore volume in various pore size ranges for activated carbons possessing high degrees of micropores, mesopores, and macropores. For the microporous carbon, essentially all of the 0.8 cc g^{-1} pore volume is in pores <2 nm in diameter. The mesoporous carbon has minimal pore volume in micropores, and pore volume starts building progressively around 2 to about 30 nm. The macroporous carbon has the majority of its pore volume in pores >25 nm in diameter, building in macropore volume to 100 nm. What is apparent is that activated carbon is not one-size-fits-all, as the pore size distribution can be tuned to some extent to favor one size distribution over another.

Moreover, the molecular size of the target molecule in a particular end-use plays a key role in optimizing the pore size distribution of activated carbon. Because of

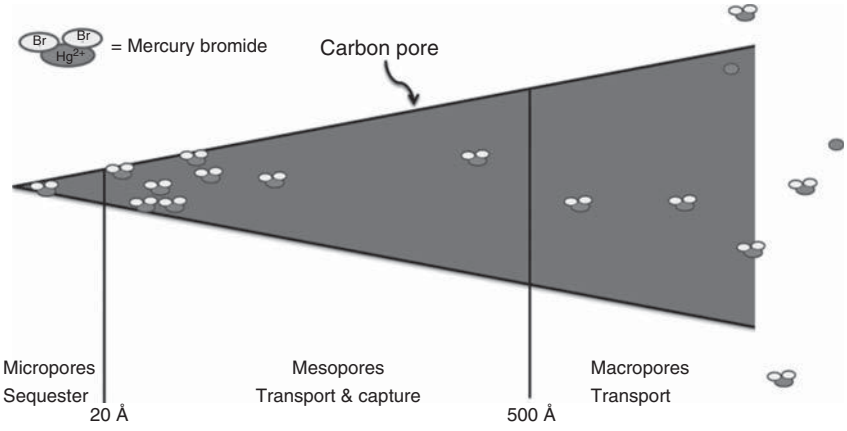

Figure 17.10 Activated carbon pore geometry and size range.

the prevalence of water treatment and food purification applications, traditional liquid- and gas-phase activated carbon pore size design is based on the adsorption performance of small iodine molecules (0.3–0.6 nm or 3–6 Å in molecular size) and large tannins, molasses, or methylene blue color bodies (>2 nm or 20 Å in molecular size). However, in the case of oxidized mercury, a mercury bromide molecule has a molecular size in between those two benchmarks on order of 1.0–1.3 nm (10–13 Å). From that simple analysis, it follows that using traditional activated carbon specifications based on adsorption of smaller molecules or larger color bodies would not be expected to result in the optimal mercury removal performance [24].

Figure 17.10 shows a graphical depiction of the role of each pore size required in capturing mercury. Starting from the right side of Figure 17.10 – in the high-temperature flue gas, highly energetic mercury species need to come in contact with the carbon particle and enter the larger macropores. Once in contact, the macropores transport the molecules into large mesopores. The molecules are eventually captured and sequestered in the small meso and micropores. Because this diffusion, transport, capture, and sequestration occur in a very short amount of time in the emission system, larger pores are required to increase the probability of capturing the gas-phase molecule and enhance pore diffusion/transport, while smaller micropores with high adsorptive energies are required to capture the mercury molecule and prevent diffusion back into the flue gas.

Commercial carbon manufacturers employ a variety of raw materials to produce activated carbon. Invariably, the starting raw material affects the porosity characteristics of the final activated product (Table 17.2). For example, raw coconut shells are hard and dense and produce activated carbons that are typically very high in micropores and have low amounts of mesopores and macropores. Cellulosic precursors, such as wood, are inherently low density and porous, leading to highly meso- and macroporous carbons. Bituminous coal-based carbons lean more toward micropores, while lignite coal carbons are highly mesoporous. It is

Table 17.2 Raw material impact on pore characteristics.

	Coconut activated carbon	Coal activated carbon	Lignite activated carbon	Wood activated carbon
Pore characteristics				Micropores	High	High	Medium	Low
Mesopores	Low	Medium	High	High
Macropores	Low	Medium	Medium	High

recognized that these are typical porosity descriptions, and that enhanced activation conditions and/or additional processing steps can be added to shift the porosity characteristic from any raw material source. For example, Baker *et al.* [25] developed highly microporous carbons from wood by an intensive second-stage activation of a wood-based carbon with an alkali salt, such as potassium hydroxide.

17.5.3 Activated Carbon Particles

Another important feature of activated carbon is that it is a particle or form that transports key functional properties in and out of the emission system. Specifically, the carbon particle or carbon grain serves an important function as a carrier and disbursement mechanism for bromine or halogen as the mercury oxidant, minerals as oxidation catalyst, surface for other desired chemical functionalities, pores for mercury capture, and a medium to transport mercury out of the emission system through the electrostatic precipitator or filter fabric baghouse.

Knowing the operating conditions of the emission system is critical to maximizing the performance of the activated carbon particle. With such information, the properties of the activated carbon can be tuned to achieve the best performance in various operating configurations. For example, the activated carbon may need to function at high temperatures, such as in the case when injected "hot-side" before the air preheater (as opposed to "cold-side" after the air preheater or after the electrostatic precipitator) or may need to be compatible with other emission control devices (Figure 17.11).

In addition, activated carbon injected into the flue gas may have less than a second of time in order to capture the mercury before being removed from

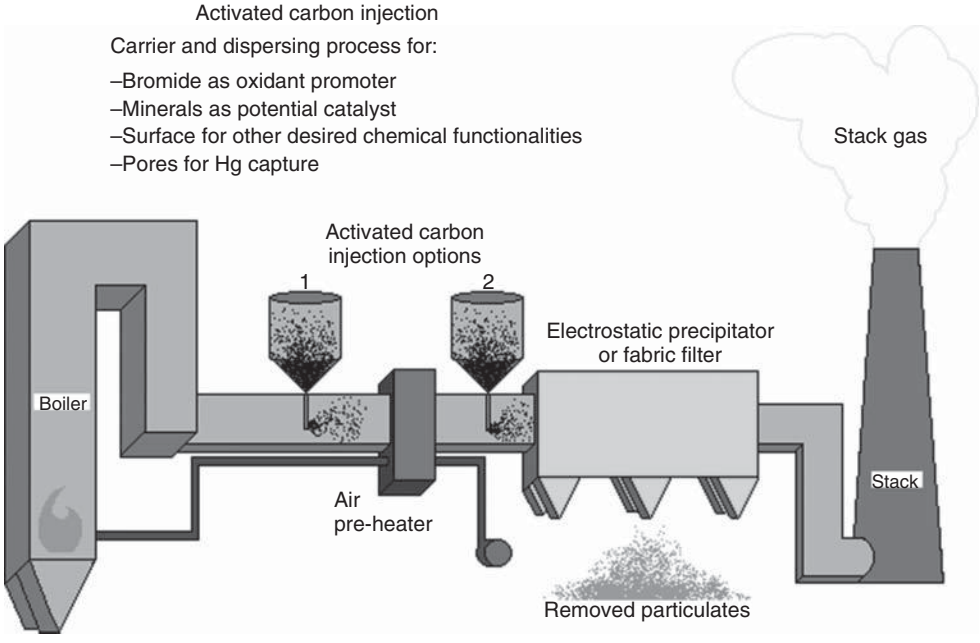

Figure 17.11 Activated carbon particles in emission systems.

the system. Consequently, its effectiveness is highly dependent on diffusional and kinetic considerations with the short residence time of contact between the carbon and the mercury. Much modeling has been conducted to discern drivers and rate-limiting mechanisms, including carbon pore diffusion and restrictions, as well as temperature effects [26].

In view of the kinetic considerations, the industry is trending toward the use of fine activated carbon particles with mean particle diameter $<25-30\,\mu m$. These smaller particles provide a higher propensity of surface for contacting the flue gas than larger carbon particles. However, the handling of these fine carbon particles in a power plant environment requires new particle handling protocols because of different flow characteristics in the injection equipment and removal dynamics in the emission train. Durham and Martin [27] developed a process for onsite size reduction of activated carbon particles to mitigate fine particulate handling issues, but this approach has not yet been adopted widely.

Another benefit of activated carbon particles is that once the mercury species is captured and sequestered on the carbon surfaces and pores, the particles can be readily removed from the emission train. Typical equipment used for this removal includes an electrostatic precipitator or filter fabric baghouse, whereby the spent activated carbon is removed along with the coal fly ash. This fly ash and PAC mixture can be safely land filled or used in producing cement.

17.6 Summary

Activated carbons are customizable adsorbent materials that are key enablers for controlling mercury emissions in power plant flue gas. Advances in understanding and tailoring activated carbon surface, pore, and particle features are providing insights and solutions to tackling the complex adsorptive, catalytic, and diffusional challenges faced in removing mercury in harsh, variable flue gas environments. These insights will help the coal-fired power energy industry move toward more pertinent carbon property specifications, much like the advances that have been made in defining activated carbon specifications for the well-established water treatment, sugar decolorization, and automotive gasoline emission control industries.

Activated Carbon Injection

Sharon M. Sjostrom

18.1
Introduction

Activated carbon (AC) is effective in adsorbing mercury from the flue gas produced by many coal-combustion sources. AC can be installed as a fixed bed of carbon downstream of other pollution control equipment, or ground into a powder and injected upstream of a particulate collection device. This chapter provides information on activated carbon injection (ACI) into flue gas, factors limiting the effectiveness of ACI, and balance-of-plant considerations.

ACI is the most established commercial technology for reducing mercury emissions from coal-fired boiler flue gases. It has been proven through numerous full-scale demonstrations to be an effective, cost-efficient way to reduce mercury emissions from most plants that fire lower sulfur coals. Depending on the type of coal being burned and the type of air pollution control equipment installed on the plant, ACI can reduce mercury emissions by more than 90%, and can offer options for mercury trim at most plants. For plants firing low-halogen fuels, ACI can be used in conjunction with halogen-based coal additives to enhance performance.

ACI technology, which is shown in Figure 18.1, is relatively simple in comparison to typical emission control equipment. An ACI system is shown in Figure 18.1 to the right of an SO_2 scrubber and fabric filter (FF) in the photograph. An ACI system consists of a storage silo for the AC and a pneumatic conveying system that injects the AC at a controlled feed rate at the desired locations in the ductwork before the particulate control device. The mercury reacts with the AC sorbent and then is removed from the flue gas along with the fly ash by the plant's particle control device. Tests have shown that the mercury is not leachable from the sorbent [1] so that it can be disposed of in a landfill without concern for contamination of waterways. Because of their simplicity and small size, ACI systems can be retrofit on virtually any power plant with minimal engineering.

Mercury Control: for Coal-Derived Gas Streams, First Edition.

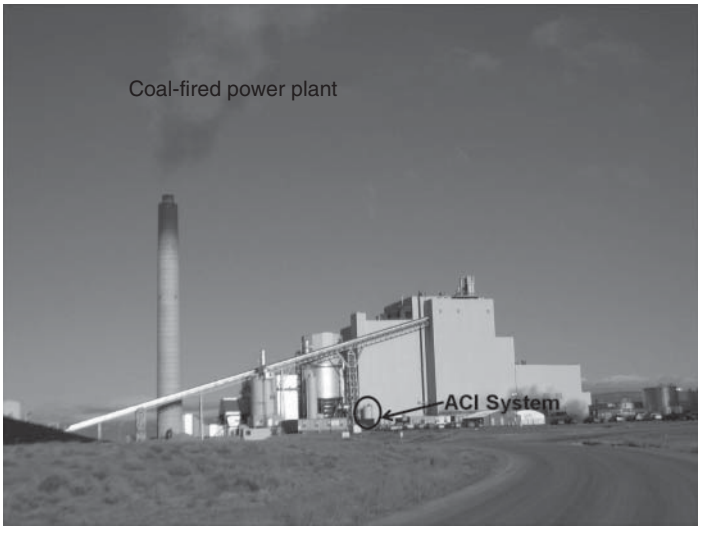

Figure 18.1 Perspective on ACI system in relation to other air pollution control equipment at a coal-fired power plant.

18.2 The Activated Carbon Injection System

Typical ACI system components include a silo to store the powdered activated carbon (PAC) before injection, process equipment to meter and convey the PAC to the injection location, and a distribution grid that includes manifolds and individual injection lances. Figure 18.2 shows a cutaway of a typical ACI system, including the storage module and process equipment, and a photograph of an ACI system installed at a coal-fired power plant. The ACI system shown has a storage silo with an enclosed process equipment room at grade level and a separate motor control building. Although the system appears relatively simple, there are critical aspects of the design that can result in poor control performance or poor reliability if attention is not paid to the details.

18.2.1 Powdered Activated Carbon Storage

The size of the PAC storage system is dependent on the unique needs of the plant. Factors include the projected PAC usage rate and the total days of storage that are required to assure continuous availability. PAC is usually delivered to the plant in a closed truck. The smallest silo for a commercial system typically holds more than a full delivery truck of PAC so that the truck can be unloaded without completely emptying the silo before unloading. This allows continuous availability of the material without demurrage or delays in availability of PAC.

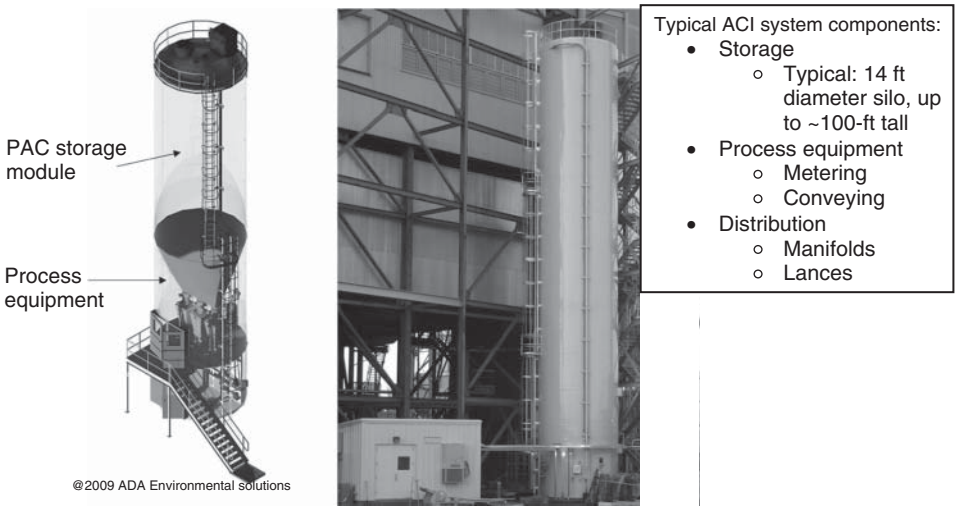

Figure 18.2 Cutaway and photograph of typical ACI system installed at a coal-fired power plant.

18.2.2 Process Equipment

18.2.2.1 Metering

The amount of PAC fed over time can be monitored in real time using either gravimetric or volumetric feeders. Gravimetric feeders are more accurate than volumetric feeders, but are two to three times the cost. One of the main disadvantages of volumetric feeders is that without use of a feedback control loop they may need to be recalibrated whenever a different sorbent with different properties is used. This can be a problem for sites that use multiple sorbents on a frequent basis. For plants that control the PAC feed rate to a set point, accurate calibrations are critical to cost control and to assuring sufficient PAC is being fed to meet mercury emission compliance. Plants that use feedback control from a mercury continuous emissions monitor can often benefit from a gravimetric feeder for inventory control.

18.2.2.2 Conveying

Both regenerative and positive displacement (PD) blowers are used in ACI systems for dilute phase conveying of PAC. The choice of blowers depends on how much PAC is being fed, conveying distance, number of elbows, and change in elevation. PD blowers are more expensive and have a larger footprint, but can provide higher flow and motive force, which is important for installations with long piping runs and many turns. The downstream components must be sized appropriately for the blower to minimize both sorbent fallout and pluggage from low velocities as well as component failures from abrasion due to the high velocities.

18.2.3
PAC Distribution

PAC is conveyed from the silo and feed system through main conveying lines. These are typically hard piped for permanently installed systems to minimize leaks associated with abrasion. The conveying lines terminate at a manifold that distributes the PAC into separate injection lances. These manifolds must be carefully designed to assure that the appropriate amount of PAC is delivered to each lance. There are typically several lances installed at the injection location to assure good distribution across the entire gas path. It is important to assure that all of the flue gas is being treated, especially for plants with electrostatic precipitators (ESPs) where most of the mercury adsorption takes place in-flight. Lance placement can be affected by several factors including access constraints that may limit the ability to install ports.

18.3
Factors Influencing the Effectiveness of Activated Carbon

Coal-combustion facilities that produce steam for electricity or heat fire a range of coals and are configured with a variety of pollution control devices. The effectiveness of ACI for mercury control at these facilities is contingent on several factors. Key factors can be categorized as

1) *Site specific*, including coal characteristics, flue gas temperature, SO_3 concentration in the flue gas, particulate control configuration,
2) *PAC specific*, including characteristics such as PAC quality, chemical treatment, and size distribution, and
3) *ACI system design specific*, including PAC injection location, grid design, and lance design.

18.3.1
Site-Specific Factors

Aside from the difference in heating value between bituminous and subbituminous coals, there are obvious differences in the sulfur and chlorine concentrations, as described in more detail in Chapter 2. In general, ACI is most effective for mercury control on flue gas derived from combustion of coals with lower sulfur contents, such as subbituminous coals, low-sulfur bituminous coals, and many lignite coals. In the United States, most subbituminous coal is mined in the Powder River Basin (PRB). PRB coal typically contains <1% sulfur and $<50\,\mu g\,g^{-1}$ chlorine. Furthermore, ACI is more effective when used in conjunction with an FF, where flue gas must pass through a collected layer of sorbent, than in other particulate collectors, such as ESPs where in-flight capture is more critical. Some plants are installing FFs downstream of an existing ESP, a configuration developed by EPRI (Electric Power Research

Institute) called *TOXECON™* to provide higher efficiency mercury control and particulate trim.

18.3.1.1 Flue Gas Characteristics: Halogens and SO_3

URS Group, University of North Dakota Energy & Environmental Research Center (UNDEERC), and others have studied the effect of hydrogen chloride (HCl) and sulfur in the flue gas on the adsorption capacity of fly ash and AC for mercury in laboratory studies (see, for example, Refs [2, 3] as well as Chapter 25). In general, results from laboratory studies suggest that

- HCl and sulfuric acid (H_2SO_4) accumulate on the surface of carbon.
- HCl increases the mercury removal effectiveness of AC and fly ash for mercury, particularly as the flue gas HCl concentration increases from 1 to nominally 10 ppmv. The relative enhancement in mercury removal performance is not as great above 10 ppmv HCl. In the absence of HCl, the ability of carbon to remove elemental mercury is minimal. Other strong Brønsted acids such as the hydrogen halides HCl, HBr, or HI should have a similar effect. Halogens such as Cl_2 and Br_2 should also be effective in enhancing mercury removal effectiveness, but this may be a result of the halogens reacting directly with mercury rather than the halides promoting the effectiveness of the AC.
- Sulfur dioxide (SO_2) reduces the equilibrium capacity of AC and fly ash for mercury. AC catalyzes the oxidation of SO_2 on the surface of the carbon. Because the concentration of SO_2 is much higher than that of mercury in flue gas, the overall adsorption capacity is likely dependent on the SO_2 concentration in the gas as it forms H_2SO_4 on the surface of the carbon. Thus, the capacity of AC for mercury is higher in flue gas with lower concentrations of SO_2 in the flue gas.

When coal is combusted, mercury contained in the coal is volatized. In the absence of halogens, the resulting vapor-phase mercury will be present primarily in the elemental form. If sufficient halogen is present in the coal, some of the mercury will react with the available halogen and form oxidized mercury. The fraction of oxidized mercury in the gas will be influenced by several factors including the presence of unburned carbon, whether the plant is configured with a selective catalytic reduction system (SCR) for NO_x control, the temperature of the gas where the mercury is measured, and the time–temperature history of the mercury.

Variations in the mercury control effectiveness of injected AC at different plants will be influenced by the speciation of the mercury and variations in the SO_2 and HCl in the flue gases. In 2001, AC-sorbent-based mercury control technology was first applied to full-scale plants burning PRB coals [4]. As noted, PRB fuel typically has very low-halogen content. With ACI, mercury removal for units configured with ESPs was generally limited to roughly 70%. This limitation likely represented the point where available HCl was removed from the gas stream by injected carbon. Excess carbon did not result in additional removal because insufficient HCl was available to promote oxidation and chemisorption of the remaining elemental mercury in the flue gas.

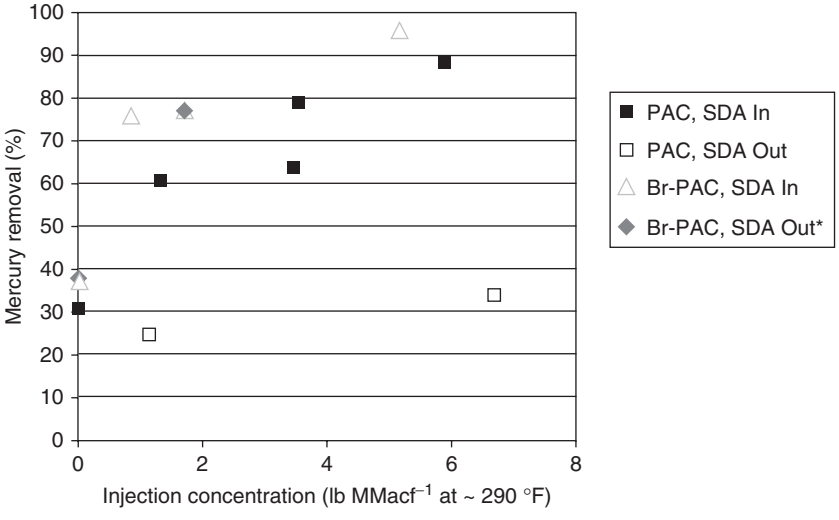

Figure 18.3 Results of injection location tests, Holcomb Station [5] (1 lb MMacf^{-1} = 16 mg m^{-3}).

Results from sites firing PRB and North Dakota lignite coals (low sulfur, low chlorine) configured with a spray dryer absorber (SDA) and an FF also indicate the importance of halogens for capturing elemental mercury using AC. In a typical SDA, slurry of lime is atomized to react with and control emissions of SO_2 and other acid gases. SDAs are very effective in removing HCl. In 2002, tests were conducted at Sunflower Electric's Holcomb Station [5]. The HCl measured at the inlet to the SDA was 0.13–0.61 ppmv. Results from ACI testing at Holcomb is shown in Figure 18.3. During the test, when PAC (DARCO®-Hg) was injected upstream of the Holcomb SDA, the mercury removal was much lower than would have been expected on a site without an SDA. An injection concentration of 91.2 g per actual cubic meter (5.7 lb MMacf^{-1}[1)]) was required to achieve 90% mercury removal. It is likely that the PAC did not fully react with the HCl between the PAC injection location and the SDA inlet before the remaining HCl was removed from the flue gas in the SDA. When PAC was injected downstream of the SDA, the mercury removal suffered further. The mercury removal was limited to <35% at injection concentrations up to 5.7 lb MMacf^{-1}, compared to 90% mercury removal at the inlet location. Most of the HCl was removed in the SDA and was not available to support mercury removal at the SDA outlet injection location [5–7].

On the basis of some of the studies conducted in the early 2000s, PAC vendors developed AC sorbents treated with halogens, typically bromine, to improve mercury control in low-halogen environments. Chapter 20 discusses brominated PAC in more detail. A PAC treated with bromine, DARCO Hg-LH (Norit Americas), was also tested at Holcomb. More than 90% mercury removal was achieved

1) 1 lb/10^6 ft^3 = 16 mg m^{-3}; sorbent loading is typically measured per "actual" volume at the temperature of the particulate control device and is usually denoted as lb MMacf^{-1}.

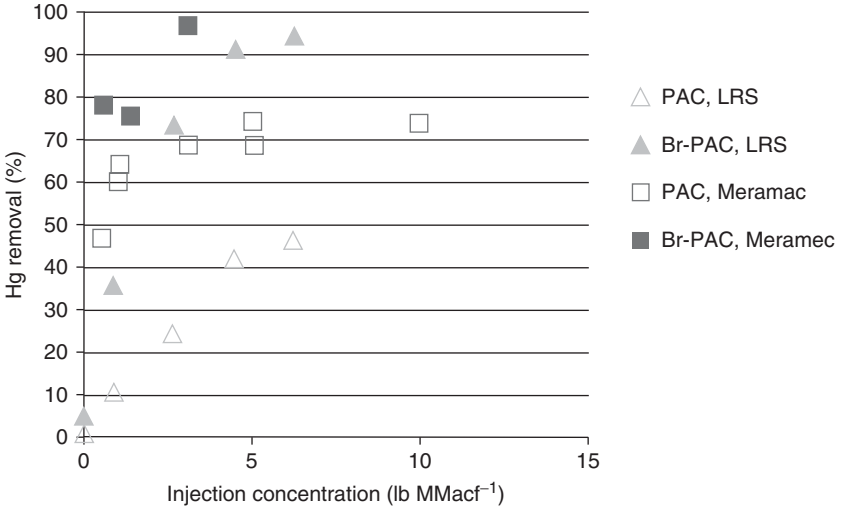

Figure 18.4 Comparison of PAC treated with bromine to nontreated PAC at two PRB-fired sites [8] (1 lb MMacf^{-1} = 16 mg m^{-3}).

at bromine-treated PAC concentrations <2 lb MMacf^{-1} and there was no difference in the performance of the bromine-treated PAC whether injected upstream or downstream of the SDA. These data are also included in Figure 18.3 [5].

Results from tests conducted with ACI at Ameren's Meramec Station and Basin Electric's Laramie River Station (LRS) are presented in Figure 18.4 [8]. Both Meramec and LRS were firing PRB coal during the testing period when both PAC treated with bromine-treated and nontreated PAC was tested. The results indicate that the mercury removal improved dramatically with the treated sorbent. At present, bromine-treated PAC is the standard sorbent for sites firing low-halogen coals. As an alternative, some sites treat the coal with halogens to improve the effectiveness of both unburned carbon and PAC.

Full-scale field tests indicate that standard AC is less efficient in high-sulfur environments. ACI tests were conducted at the University of Illinois' Abbott Power Plant in Champaign, IL in 2001 [9, 10]. This site fires high-sulfur (3.8%) bituminous coal with 2500 μg g^{-1} chlorine. Equilibrium adsorption capacity measurements were conducted on non-bromine-treated PAC samples at this site at temperatures of 191 °C (375 °F) and 163 °C (325 °F). The equilibrium adsorption capacity is measured by flowing flue gas through a fixed bed of PAC, typically mixed with sand to manage the pressure drop through the bed of powder, until the mercury at the inlet to the bed is equal to the outlet, or full breakthrough has been achieved. The equilibrium capacity is calculated as the mass of mercury in the bed to the mass of carbon. The value is often normalized to a mercury concentration in the gas of 50 μg m^{-3} by assuming a linear correlation between capacity and flue gas mercury concentration (i.e., the capacity at 50 μg m^{-3} is five times the capacity at 10 μg m^{-3}). At 191 °C (375 °F), the equilibrium adsorption

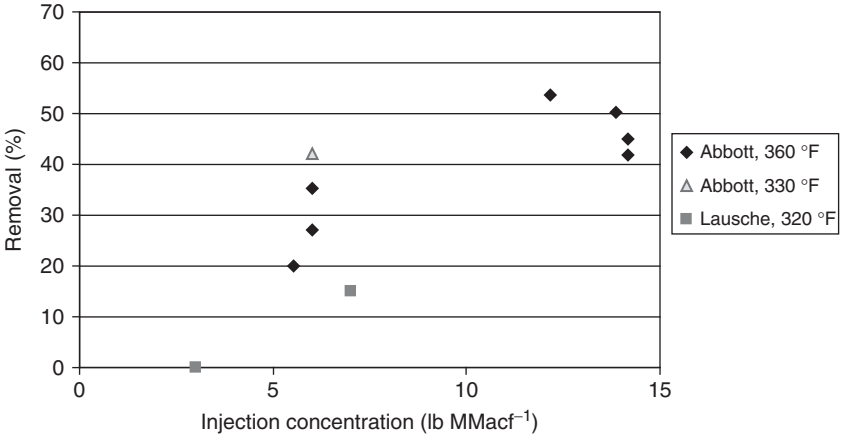

Figure 18.5 Injection test results from Abbott and Lausche Power Plants [9] (1 lb MMacf^{-1} = 16 mg m^{-3}).

capacity was 184 μg g^{-1}. At 163 °C (325 °F), the equilibrium adsorption capacity was 486 μg g^{-1}. Injection tests were conducted at Abbott at two flue gas temperatures: 182 °C (360 °F) and 166 °C (330 °F), and the results suggest a slight increase in the mercury removal performance of non-bromine-treated PAC at the lower temperature. Injection tests were also conducted at the Lausche plant of Ohio University (1000 ppmv SO_2 and 20 ppmv SO_3 in flue gas). Test results from both Abbott and Lausche, shown in Figure 18.5, indicate limited mercury removal performance of non-bromine-treated PAC.

Plants firing low-sulfur fuel may also face mercury control challenges from impacts related to sulfur compounds. For example, SO_3 is used to "condition" the flue gas to improve particulate capture in ESPs. This poses a unique problem because, across the United States, ~25 GW of power is produced by units that fire PRB and low-sulfur bituminous coals and that inject SO_3 to improve ESP performance. Many low-sulfur-fueled sites are also installing SCRs to control NO_x. The SCRs convert a portion of the flue gas SO_2 to SO_3. Low-conversion catalysts are available, but are typically more expensive and are often not considered necessary on low-sulfur applications unless mercury control is a consideration.

We Energies' Pleasant Prairie Power Plant (P4) utilizes SO_3 for flue gas conditioning. Equilibrium adsorption capacity measurements were made at locations upstream and downstream of SO_3 injection [6]. These data indicate a significant impact on the mercury capacity of non-bromine-treated PAC due to both SO_3 and temperature. However, when the PAC was injected into the duct, no difference in performance was noted. In addition, decreasing the temperature at P4 using spray cooling from 149 °C (300 °F) to 121 °C (250 °F) did not improve the mercury removal measured across the ESP when injecting non-bromine-treated PAC for mercury control. This suggests that the threshold capacity, or the capacity at which a change in performance is expected during injection testing, was <425 μg g^{-1} at P4, the equilibrium adsorption capacity measured at 149 °C (300 °F) in the

Table 18.1 Equilibrium adsorption capacities measured at two sites with SO_3 present in flue gas [6].

Site	SO_3	Temperature (°C)	Equilibrium Adsorption Capacity (μg g^{-1}) Normalized to 50 μg Nm^{-3}
P4	None	121	8823
P4	FGC	121	3355
P4 (PAC + lime[a)])	FGC	121	2091
P4	None	149	880
P4	FGC	149	425
P4 (PAC + lime[a)])	FGC	149	>1504
Abbott	Coal	191	148
Abbott	Coal	163	486

FGC, flue gas conditioner.
a) Lime to sorbent ratio was 60 : 1.

presence of SO_3. The equilibrium data also suggests that the capacity can be significantly improved at higher temperatures (149°C) in the presence of SO_3 if the sorbent is mixed with an alkali material such as lime. No improvement was noted at the lower temperature (121 °C). The P4 and Abbott results are presented in Table 18.1.

Full-scale injection testing conducted at Southern Company's Plant Daniel indicated that, unlike Pleasant Prairie, SO_3 used for flue gas conditioning had a negative impact on sorbent performance [11]. Daniel was firing a low sulfur western bituminous coal during the tests and is configured with an ESP for particulate control.

Results from testing conducted at Ameren's Labadie Power Plant [12] clearly show the impact of SO_3 on the mercury control effectiveness of AC. The mercury removal trends for brominated are summarized for 0, 5.4, and 10.7 ppmv SO_3 (0%, 30%, and 60% setting on SO_3 injection system) in Figure 18.6.

SO_3 levels may also be elevated if a selective catalytic reduction system (SCR) is in service to reduce NO_x and if the catalyst converts sufficient SO_2 to SO_3. Public Service of New Hampshire Merrimack Station is configured with an early-vintage SCR. Although the plant was not firing high-sulfur coal, the SO_2 to SO_3 conversion across the SCR was relatively high, resulting in SO_3 concentrations often above 10 ppmv. During long-term ACI testing [13], trona was injected for SO_3 control through four lances between the SCR and the air preheater (APH) at a rate of 550 lb h^{-1} with Br-PAC for mercury control at a rate of 5 lb $MMacf^{-1}$. Under these conditions, 50–55% mercury removal was achieved but could not be sustained because of balance-of-plant impacts. While injecting trona at 550 lb h^{-1}, the APH differential pressure increased 1.2 in. H_2O during the 30 days of injection, indicating deposition of a sodium compound in the APH. These results are shown in Figure 18.7.

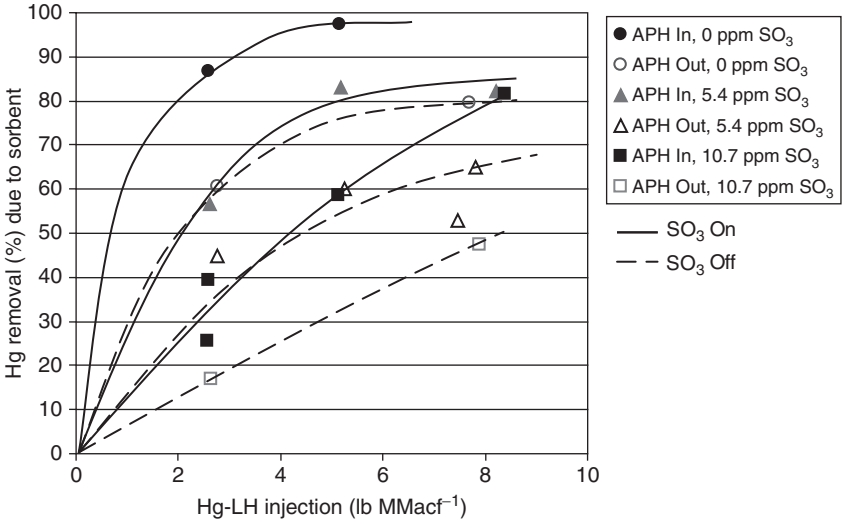

Figure 18.6 Comparison of APH inlet and outlet injection results for Br-PAC [12] (1 lb MMacf^{-1} = 16 mg m^{-3}).

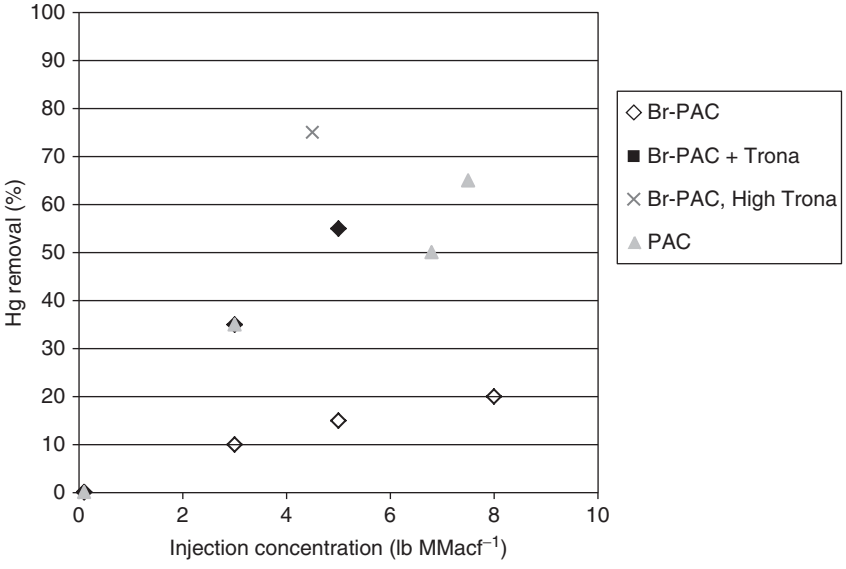

Figure 18.7 Merrimack test results [13] (1 lb MMacf^{-1} = 16 mg m^{-3}).

During a 3-day test, the trona injection rate was increased to 1000 lb h^{-1} to assess the ability to improve mercury removal by lowering the SO_3 concentration. This resulted in an increase in mercury removal up to 75% at a Br-PAC injection concentration of 4.5 lb MMacf^{-1}. These short-term results show that optimizing the trona injection lances for better distribution could improve both SO_3 and

mercury removal, but the data are insufficient to determine long-term balance-of-plant impacts or sustainability.

Techniques to limit the impact of other pollution control devices on PAC effectiveness for mercury control are being developed. For example, chemicals to replace SO_3 for flue gas conditioning are under development and evaluation. For sites firing high-sulfur coal, or when SCR catalysts that convert sufficient SO_2 to SO_3 are in use, the most effective option evaluated to date is lowering the SO_3 concentration using techniques such as trona (sodium sesquicarbonate) or hydrated lime injection. As a result of decreased SO_3 levels, the mercury removal can be significantly increased. Unfortunately, the introduction of trona at some sites has also resulted in other balance-of-plant issues such as an increase in the pressure drop across the APH [13].

18.3.1.2 TOXECON™

The first commercial operation of a mercury-specific control system to the power industry was a TOXECON system installed at the We Energies' Presque Isle Power Plant in Marquette, Michigan [14]. This was as part of a DOE (Department of Energy) Clean Coal Program and significant tests were conducted to characterize performance. Typical of many first installations of emission control technology, some operating problems were encountered during startup. The Presque Isle system achieved 90% mercury control levels for more than a year of continuous operation during the testing program. The operating procedures developed are being implemented with all of the new TOXECON systems being installed.

18.3.2 PAC-Specific Factors

Although ACI is a viable commercial process, technology developers continue to evaluate options to reduce costs and increase removal levels. For example, results from modeling and full-scale ACI tests indicate that reducing the PAC particle size can result in significant improvements in PAC effectiveness. For example, reducing the PAC diameter by a factor of 2 will result in an increase in the particle density of 8 (2^3), and double the available surface area. In 1999, Meserole [15] developed a model for mercury removal with sorbent injection, and the beneficial impact of reduced particle size, given sufficient sorbent capacity, was reported.

PAC milled from a mean diameter of nominally 18–6 μm was evaluated at Ameren's Labadie Station. The milled PAC resulted in a reduction in PAC requirements of more than 50% at a constant mercury reduction percentage, as shown in Figure 18.8 [16].

Most PAC injection systems are designed to feed standard PAC, which typically has a mean diameter between 15 and 25 μm. Fine material has different handling characteristics and may result in ACI system reliability issues. Fine PAC may also reagglomerate, especially if it is stored in the silo for prolonged periods.

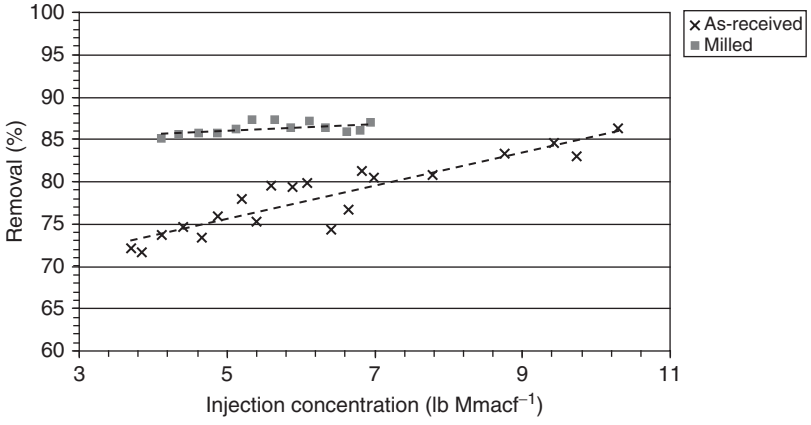

Figure 18.8 Improved mercury control using fine PAC [15] (1 lb MMacf^{-1} = 16 mg m^{-3}).

18.3.3 ACI System Design-Specific Factors

18.3.3.1 Injection Location

Injection location can make a significant difference in the residence time of the PAC in the gas stream, and improve the likelihood of good distribution. For some configurations, the biggest improvement in performance can be attained by moving the injection location from downstream of the APH, where the flue gas temperature is typically between 121 and 205 °C (250 and 400 °F), to upstream of the APH, where temperatures are typically 400–315 °C (750–600 °F). An example of improved mercury removal with PAC injection upstream of the APH is shown in Figure 18.9 [12]. In this case, higher mercury removal was achieved at half the injection rate when injected upstream of the APH. Note that although the *x*-axis presents the data as pound per million actual cubic feet, the actual flue gas volume for the calculation was at the APH downstream temperature in both cases. Although the effectiveness of a carbon for mercury degrades quickly as the temperature increases, injecting PAC upstream of the APH often results in overall improvements in PAC removal effectiveness. This effect is a result of several influences including increased residence time, which can promote both better distribution of the PAC in the duct, reactions between flue gas halogens and PAC, and increased time for reaction as the PAC moves through the APH.

18.3.3.2 Distribution

Either physical flow or computational fluid dynamics (CFD) modeling can be used to predict whether an injection grid is capable of getting PAC into all of the flue gas passages. Flue gas flow and temperature biases are often present. These can develop as a result of boiler design, duct structural members such as turning vanes, or for many plants that use rotary APHs, the rotation of the APH can

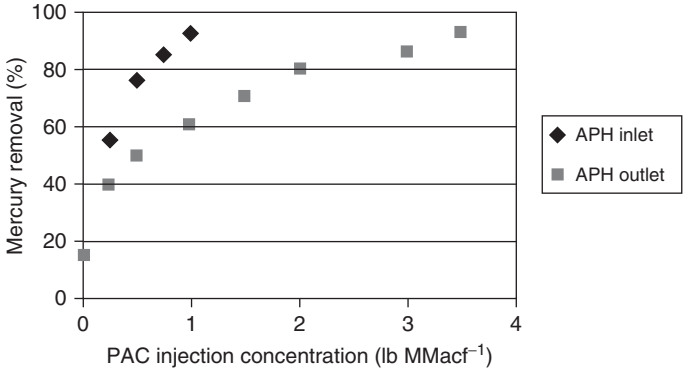

Figure 18.9 Mercury removal when AC was injected upstream and downstream of APH [11] (1 lb MMacf^{-1} = 16 mg m^{-3}).

cause temperature nonhomogeneity. CFD modeling can assist in determining whether additional lances are needed or if PAC injection should be biased into select lances to assure good distribution before the particulate collection device.

Caution should be exercised when designing PAC injection lances to assure that incremental improvements in short-term PAC distribution resulting from complex lance designs do not overshadow long-term maintenance and reliability concerns. Complicated lances, such as those with multiple injection nozzles, may provide enhanced distribution initially, but coal-combustion flue gas is not a forgiving environment. Nozzles can quickly become plugged, resulting in decreased overall distribution compared to simpler, more robust designs.

18.4
Balance-of-Plant Impacts

18.4.1
Coal Combustion By-Products

Fly ash has been used as a replacement for Portland cement in concrete since the 1920s when it was used in the construction of the Hoover Dam, then the largest concrete structure in the world. Air entrained in the concrete matrix improves the durability of the concrete over freeze–thaw cycles. In 2006, more than 72 million tons of fly ash were produced in the United States, 46% of which was used in concrete, concrete products, and grout, with another 6% used to make cement [17]. The remainder was placed in landfills or used in other applications. Fly ash landfilling costs are significant and can become one of the largest operating costs for plants after labor and fuel [18].

Air entrained in the concrete matrix improves the durability of the concrete over freeze/thaw cycles. Air-entraining agents are typically soaplike organic additives.

PAC in fly ash absorbs the organic air-entraining additives and can change the fly ash from a saleable product to a potential landfill liability.

Options to preserve ash sales while using ACI for mercury control include separating the PAC-laden ash from the bulk of the fly ash by using EPRI-patented techniques such as TOXECON, reducing the amount of PAC required through techniques such as using fine PAC, or use of a specialized ash-compatible AC. Chapter 21 discusses concrete-compatible carbons in more detail.

18.4.1.1 Autoignition of PAC in Ash Hoppers

There have been several reports of burning embers in baghouse and ESP ash hoppers collecting ash/PAC mixtures that have relatively high ratios of PAC to ash, such as TOXECON configurations where the majority of ash is removed before injecting PAC into the system [14, 19]. PAC is a relatively good insulator. If a hopper full of PAC is exposed to a localized heat source, such as a hopper heater or a welding spark, it can begin to smolder. PAC can also be oxidized via exothermic reactions in an air- or oxygen-rich environment. When the heat of oxidation increases faster than it can be liberated, temperatures increase, and can ignite the carbon.

Key factors contributing to autoignition are size of the bed or amount of ash/PAC in the hopper, temperature surrounding the bed from hopper heaters or high flue gas temperatures, concentration of carbon in the ash, and oxygen concentration.

Plants where autoignition has occurred have implemented maintenance procedures to prevent future occurrences of autoignition. Successful maintenance procedures include the following:

- Eliminate use of hopper heaters or lower the set point.
- Empty hoppers more frequently to minimize ash in the hopper.
- Ensure complete emptying of ash hoppers because AC becomes sticky when hot.
- Minimize fluidization.

Laboratory oven tests were conducted on different size square containers filled with PAC/ash mixtures collected in the hoppers of the TOXECON baghouse during PAC injection at Presque Isle. Thermocouples were placed in the oven and inserted into the bed of material at different levels to track temperature profiles over time. These tests confirmed that although the ignition temperature of the PAC was 850 °F, sufficient heat was internally generated at 430 °F for the PAC to increase the temperature of the mixture to ignition temperatures.

18.4.1.2 Impacts on Particulate Emissions

PAC is typically injected into flue gas at a rate that typically does not exceed 5% of the fly ash loading, and is often nearer to 1%, except for polishing applications such as TOXECON. There have been few reports of PAC injection negatively impacting particulate emissions [20], and some have reported that Br-PAC injection can improve the operation of the installed ESP [21].

18.4.1.3 Corrosion Issues

Injecting AC for mercury control is not expected to have adverse impacts on corrosion within the ductwork. However, when halogen-treated ACs are used, there is a possibility of inducing corrosion. Recent bench-scale corrosion tests have shown that bromine is capable of accelerating corrosion on metal surfaces [22]. Further investigations into long-term impacts of continuous halogen-treated ACI are under way.

18.5 Future Considerations

Advancements continue to be made in mercury control to assure compliance and minimize costs. PAC vendors are developing materials that are more effective, more tolerant to SO_3 and temperature, less corrosive, and concrete compatible. Equipment providers are required to provide equipment that can assure near-continuous reliability. Integrated solutions that incorporate multiple technologies such as coal additives to provide supplemental halogen, reagents to reduce the SO_3 concentration, catalysts to increase the fraction of oxidized mercury, and chemicals to improve the co-benefit mercury removal in SO_2 scrubbers are being refined. On the basis of its simplicity and cost, ACI will continue to be an important component of the installed mercury control technology base for the US coal-fired fleet.

Halogenated Carbon Sorbents

Robert Nebergall

19.1
Introduction

Activated carbon has been shown over the past several decades to be an effective adsorbent for the removal of mercury from flue gas. The technology was developed in Europe during the late 1980s where municipal waste combustion was a large contributor of anthropogenic (human produced) mercury emissions to the environment. In addition, hazardous waste and medical waste incinerators are also large contributors of mercury emissions to the environment [1]. Municipal, medical, and hazardous wastes typically contain sources of chlorine and hence form chlorine compounds in the flue gas. The chlorine compounds present in the flue gas provide an excellent oxidant in the gas stream for the conversion to oxidized mercury. Standard or untreated activated carbons only effectively remove oxidized mercury from the flue gas. The mercury concentration in the flue gas in these applications was typically relatively high. Owing to the prevalence of mercury in municipal waste and hazardous waste, concentrations of mercury $>200\,\mu g\,m^{-3}$ of flue gas were not uncommon. Activated carbon treatment dosages of 3–6 pounds per million actual cubic feet (lb/MMacf)[1)] or $30–60\,mg\,m^{-3}$ of flue gas were also common [2].

19.2
Application of Activated Carbon for Mercury Control

When injecting activated carbon for mercury control, the mercury capture occurs in the particulate collection device. The two most common particulate collection devices installed at-coal fired power plants are an electrostatic precipitator (ESP) and a fabric filter.

1) $1\,lb/10^6\,ft^3 = 16\,mg\,m^{-3}$; sorbent loading is typically measured per "actual" volume at the temperature of the particulate control device and is usually denoted as lb/MMacf.

Mercury Control: for Coal-Derived Gas Streams, First Edition.

ESPs electrically charge the ash and powdered activated carbon (PAC) particles in the flue gas to collect and remove them [3]. The unit comprises a series of parallel vertical plates through which the flue gas passes. Centered between the plates are charging electrodes that provide the electric field. The collecting plates are typically electrically grounded and are the positive electrode components. The discharge electrodes in the flue-gas stream are connected to a high-voltage power source (typically 55–75 kV DC) with a negative polarity. An electric field is established between the discharge electrodes and the collecting surface. As the flue gas passes through the electric field, the particulate takes on a negative charge, which, depending on particle size, is accomplished by field charging or diffusion.

Dust that has accumulated to a certain thickness on the collection electrode is removed by one of two processes, depending on the type of collection electrode. Collection electrodes in precipitators can be either plates or tubes, with plates being more common. Tubes are usually cleaned by water sprays, while plates can be cleaned either by water sprays or a process called *rapping*. Rapping is a process whereby deposited, dry particles are dislodged from the collection plates by sending mechanical impulses, or vibrations, to the plates. Precipitator plates are rapped periodically while maintaining the continuous flue-gas cleaning process. In other words, the plates are rapped while the ESP is online; the gas flow continues through the precipitator and the applied voltage remains constant. Plates are rapped when the accumulated dust layer is relatively thick (0.03–0.50 in.). This allows the dust layer to fall off the plates as large aggregate sheets and helps eliminate dust re-entrainment.

A fabric filter collects the dry particulate matter and PAC as the cooled gas passes through the filter material [4]. The fabric filter is comprised of a multiple-compartment enclosure, with each compartment containing up to several hundred long vertically supported, small-diameter fabric bags. The gas passes through the porous bag material, which separates the particulate and PAC from the flue gas.

With the typical coal-fired boiler, the PAC-laden flue gas enters the filter inlet plenum, which in turn distributes the gas to each of the compartments for cleaning. An outlet plenum collects the cleaned flue gas from each compartment and directs it toward the induced draft fan and stack. Each compartment has a hopper for particulate and PAC collection. The individual bags are closed at one end and connected to a tube sheet at the other end to permit the gas to pass through the bag assembly. The layer of dust and PAC accumulating on the bag is referred to as the *cake*. As the cake builds and the flue-gas pressure drop across the fabric filter increases, the bags must be cleaned. This occurs after a predetermined operating period or when the pressure drop hits a set point. Each compartment is sequentially cleaned to remove the excess cake and to reduce pressure drop. A residual cake coating is preferred to enhance further collection. Owing to the longer contact time when employing fabric filters, the dosage is up to 75% less than that needed for ESPs.

Table 19.1 Key coal properties [6].

Coal rank	Dry basis	Hg (μg g^{-1})	Cl (μg g^{-1})	S (wt%)	Ash (wt%)	Higher heating value, HHV (MJ kg^{-1})
Bituminous	Average	0.11	1033	1.69	11.10	31

19.3 Development of Halogenated Activated Carbon

19.3.1 Motivation

In the United States, the federal Clean Air Mercury Rule (CAMR) was vacated by a Federal Court in February 2008, and a new federal standard for regulation of mercury emissions from power plants (the Mercury and Air Toxics Standards or MATS) has just been finalized. The MATS will not go into effect until 2015, at the earliest; however, as of 2011, 16 states had their own mercury emission regulations [5]. Before the vacatur of CAMR there was a need for the development of mercury control technologies from coal-derived flue-gas streams, and a new challenge for activated carbon. Low-rank coal fuels, including lignite and subbituminous fuels, typically have very low halogen content. As a result, mercury present in the flue gas from low-rank coal combustion is mostly elemental mercury, which provides a challenge for the standard activated carbons.

As discussed in Chapter 2, coal is ranked by age and key characteristics (calorific value, volatile matter, and carbon content). The three main coal ranks, lowest to highest, that power plants in the United States utilize as fuel are lignite, subbituminous, and bituminous. Each of these ranks contains subgroups that provide further differentiation of the key characteristics. Table 19.1 summarizes coal properties by rank relevant to mercury control in coal-fired boilers.

The relationship of coal rank to chlorine content is not easily explained and there are several factors involved over the lifetime of the formation of the coal. In the United States, bituminous coals have higher chlorine content by weight than lower rank coals,[2] with lignite having the least amount of chlorine content by weight.

2) The exception is that beginning with the higher ranked bituminous coals (low volatile and medium volatile), a decrease in chlorine content is seen because of the decreasing sorption capacity of the highly carbonized coal organic matter [17].

Leading up to the 2005 CAMR, much test work was completed in coal-fired power plants with support from the National Energy Technology Laboratory (NETL) division of the Department of Energy (DOE), as discussed in Chapter 10. It was demonstrated early in the plant testing programs that standard activated carbons had limited mercury removal capabilities in flue-gas streams from combustion of low-rank coal fuels. In all, the DOE NETL funded over 40 full-scale field tests for mercury removal with various APCDs (air pollution control devices) [7].

The DOE-sponsored testing program at Pleasant Prairie Power Plant in the early 2000s showed a distinct limitation of standard activated carbons for mercury emission control with Powder River Basin (PRB) subbituminous fuels [8]. Certain levels of mercury removal were possible, but reaching 80% or 90% removal was not achieved with standard PAC. Reduction curves demonstrating diminishing return on additional carbon dosage were developed from that work.

Similar results were achieved at Stanton Station in the same time period on lignite fuel [8, 9]. It was determined that the low halogen level in the low-rank coals was responsible for the low level of oxidized mercury in the flue gas, which prevented effective removal of mercury from the flue-gas stream with PAC.

In the Sunflower Electric testing of 2005 at Holcomb Station, this concept (elemental vs oxidized mercury) was tested at a facility that burned a PRB subbituminous coal and had a pollution control train including a spray dryer absorber and a fabric filter [10]. In this trial, 90% mercury removal efficiency was achieved at ~6 lb of untreated activated carbon injection per million actual cubic feet (MMacf) of gas flow. Correspondingly, 90% removal efficiency was achieved at just over 1 lb $MMacf^{-1}$ of an experimental halogenated activated carbon.

This step forward in technology was later duplicated at Meramec Station near St. Louis, Missouri, in a demonstration that also used a PRB coal fuel [10]. This site had an ESP and also an unusually high level of unburned carbon in the fly ash. Mercury removal levels of 90% were achieved at 3 lb $MMacf^{-1}$ activated carbon injection rate with a halogenated activated carbon. When standard activated carbon (not halogenated) was tested, mercury removal levels did not reach 80%, even at carbon injection rates as high as 15 lb $MMacf^{-1}$.

Since before the beginning of the DOE field test work, there was a great deal of speculation and research on the mechanism of mercury removal from flue gas when utilizing halogenated and nonhalogenated activated carbon. In general, activated carbon is a highly porous adsorption material with a complex structure composed primarily of carbon atoms (see Chapter 17). The structure consists of graphitic-like sheets of carbon atoms joined together by random cross-linkage. Unlike the orderly stacking of layers of carbon atoms in true graphite, an activate carbon has sheets or groups of atoms that are stacked unevenly and disorganized. This randomized bonding of the graphite sheets creates a highly porous structure with myriad nooks and crannies, cracks, and crevices between carbon layers. It is this molecular-size porosity and resulting enormous internal surface area that makes activated carbon such an effective material for adsorbing mercury. Activated carbon's pore surface is a defect structure with a cloud of unpaired electrons.

It contains an array of chemical functional groups containing oxygen that form active sites where adsorption occurs. It is not unreasonable to visualize an active carbon particle as one enormous carbon molecule. It is capable of reacting with, and bonding to, mercury as well as trapping it within its internal structure by electrostatic attraction.

19.3.2 Manufacture

Activated carbons are manufactured by one of two processes: high-temperature steam activation or chemical activation using a strong dehydrating agent. Steam activation is the most commonly used method for activated carbon production. It is performed in a furnace and consists of the following steps:

1) *Drying* – All of the raw materials currently in commercial use contain some residual moisture which must be removed before activation can take place.
2) *Devolatilization* – The lighter boiling organics are driven off the carbon raw material. These volatiles have some fuel value and may be used to reduce the overall energy requirements of the process.
3) *Charring* – The higher molecular weight organics are reduced to carbonaceous char residue. This char becomes the active carbon product during activation.
4) *Activation* – The activation step is generally conducted in a steam atmosphere at temperatures that vary depending on the type of carbon to be produced. Typically, half of the carbonaceous char material entering the activation step will be volatilized during activation to create the desired internal pore structure.

The International Union of Pure and Applied Chemistry IUPAC differentiates carbon pores by size; micropores have diameters <2 nm, mesopore has diameters between 2 and 50 nm, and macropore has diameters >50 nm. The iodine number, bromophenol blue number (BPB), moisture, bulk density, surface area, mesh size as well as bromine concentration are physical properties used to characterize halogenated activated carbon. The iodine number is a relative measure of microporosity. The BPB is a relative measure of range of mesoporosity. The moisture is the weight percent of moisture contained in the activated carbon. The bulk density is defined as the mass of many particles of the material divided by the total volume they occupy. The total volume includes particle volume, interparticle void volume, and internal pore volume. Surface area is the area contained in the particle including pores per gram of the material.

The size of an activated carbon is described by referring to a certain mesh size. By itself, this type of description is somewhat ambiguous. More precise specifications will indicate that a material will pass through some specific mesh (that is, have a maximum size; larger pieces will not fit through this mesh) but will be retained by some specific tighter mesh (that is, a minimum size; pieces smaller than this will have passed through the mesh). This type of description establishes

a range of particle sizes. Bromine percentage is the weight percent of bromine in the activated carbon.

The mechanism by which halogenated activated carbons adsorb elemental mercury is not completely understood at present, and it is a very complex question when considering the differences in activated carbons made from different raw materials and different processes. Chapters 23 and 25 discuss the underlying mechanisms in more detail.

Several different base raw materials including bituminous coal, subbituminous coal, lignite coal, peat, wood, and coconut shells may be used in the production of activated carbon for mercury removal from flue gas. All these raw materials will produce activated carbons with different pore structures, carbon lattices, ash compositions, and internal pore surface functional (oxygen) groups. Furthermore, any individual raw material will also create different surface groups when processed under different activation and cooling conditions.

19.3.3 Performance

It is well known in the industry that halogenation of the activated carbon increases the ability of the activated carbon to adsorb elemental mercury. Figures 19.1 and 19.2 show full-scale data on the removal of mercury across cold-side ESPs (Figure 19.1) and spray dryer plus fabric filter (Figure 19.2). In these figures, Darco Hg is a non-brominated carbon (Norit Americas). The brominated carbons are Darco Hg-LH (Cabot Norit Activated Carbon) and B-PAC (Albemarle).

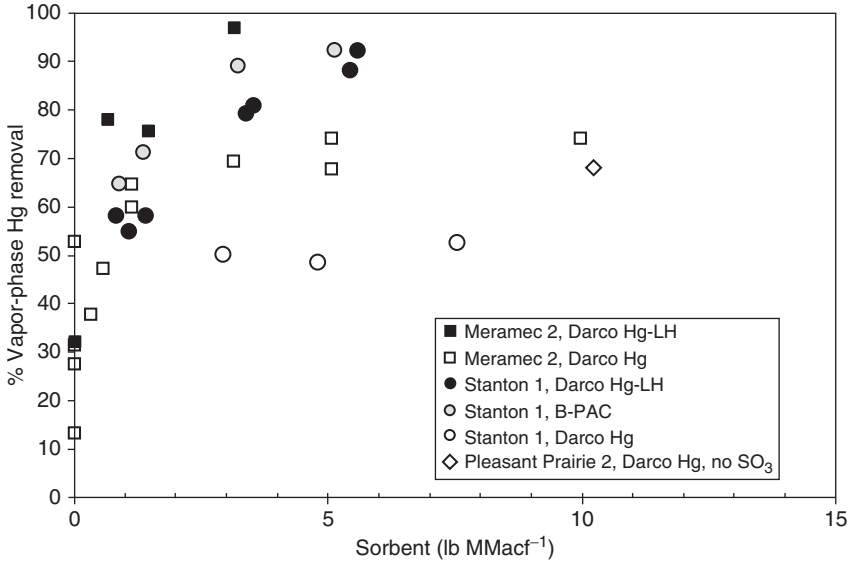

Figure 19.1 Mercury removal across cold-side ESPs at subbituminous-fired boilers; see text for discussion of carbon types [9, 10].

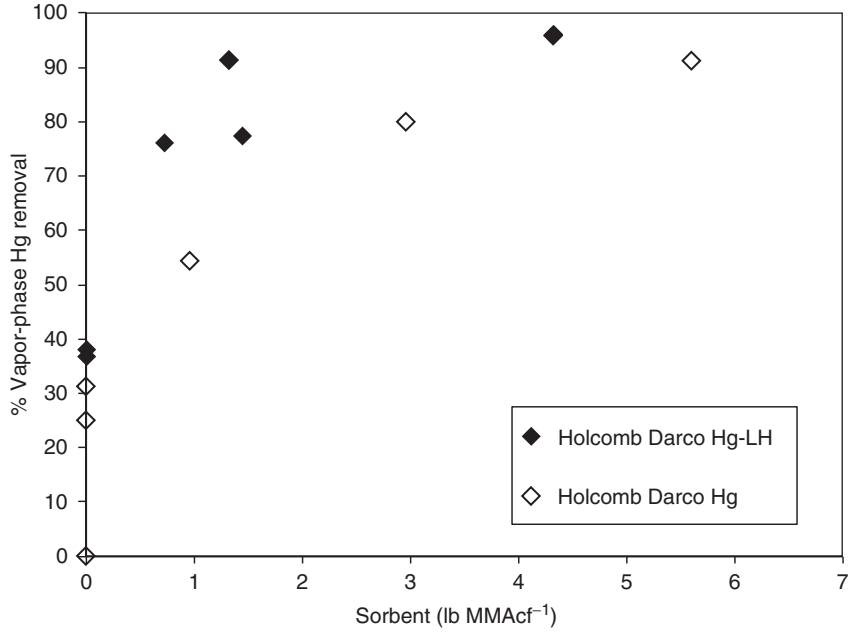

Figure 19.2 Mercury removal across spray dryer–fabric filter at subbituminous-fired boiler; see text for discussion of carbon types [10].

There are different theories as to the actual mechanism principally responsible for the adsorption. Elemental mercury is a highly polarizable atom because of its large number of electrons, which, by theory, should be subject to London dispersion forces [11]. In many activated carbon applications, it is generally believed that van der Waals forces of attraction are part of the mechanism of adsorption. Other theories have their basis in the idea that the surface of the activated carbon effectively acts similar to a Lewis acid through the formation of charge-transfer compounds on the surface of the carbon through halogenations [12].

Studies performed at Energy and Environmental Research Center have examined the effects of flue-gas acid species such as HCl, SO_2, NO, NO_2, on mercury capture as well as mercury binding and oxidation mechanism. In the model they propose, electrons must be accepted by a Lewis acid on activated carbon and then Hg^{2+}, which is a Lewis acid that can bind to Lewis base sites on the surface competing with other acidic species. Chapter 25 provides more detail on this work.

To add to the difficulty of surely identifying the mechanism behind elemental mercury adsorption, one must first address what form the halogen has taken while being applied to the activated carbon. In terms of application, information in the public domain indicates two primary methods of application. Halogen salts (primarily chlorine, bromine, and iodine) have been identified as both fuel additives and treatments for activated carbon. Studies have indicated that the larger the atom added to the surface of the activated carbon, the more effective it would be in oxidizing elemental mercury on the surface of the activated carbon. A lesser used

but also effective method of application is gas-phase impregnation of the activated carbon with gaseous bromine compounds. It is unlikely that the halide salt addition is captured on the internal pore surfaces of the activated carbon in a manner identical to that of a gas-phase treatment. According to X-ray studies, it has been shown that adsorbed mercury is indeed bound on the carbon pore surface in an oxidized form [13]. In addition, adsorbed mercury bound on the activated carbon pore surface appears to be located at halogenated sites, according to the other X-ray studies [14].

As one considers the complexity of a power plant fuel mix, boiler configuration, and its APCDs, it becomes apparent that many variables affect the ability of activated carbon to remove mercury from flue gas. As an example, it is commonly known that relatively high concentrations of sulfur trioxide (SO_3) have a substantial and negative impact on the activated carbon's ability to effectively remove mercury.

The presence of high concentrations of sulfur trioxide in the flue gas can be attributed to two main applications. Intuitively, higher sulfur fuels (typically bituminous) create higher sulfur dioxide flue gases, and hence higher sulfur trioxide levels in the flue gas. In addition, if the APCDs include an SCR (selective catalytic reduction), sulfur trioxide levels will typically be higher, because the SCR catalyst oxidizes some fraction of SO_2 to SO_3 (Chapter 15). In some newer coal-fired power plants burning bituminous fuels, levels of 50 ppmv of sulfur trioxide are found in the flue gas [15]. More commonly, bituminous facilities will have sulfur trioxide levels in the range of 10–20 ppmv.

The other situation in which sulfur trioxide becomes an issue is in flue-gas conditioning for ESP performance improvement. Sulfur trioxide is injected into the flue gas to improve ESP particulate collection performance. Sulfur trioxide is injected into the flue gas to improve ESP particulate collection performance typically at a level of 4–10 ppmv of sulfur trioxide. The flue-gas conditioning treatment, as of this writing, is a very common challenge to the implementation of current mercury control programs using activated carbon injection.

The state of Illinois has implemented the most stringent mercury control regulations to date. Many units located in Illinois were designed for burning high-sulfur, Illinois-basin bituminous coal. These coals have high sulfur and moderate ash contents. Subbituminous coals, although lower in ash than eastern bituminous coals, have much less sulfur and the resistivity of the fly ash is higher.

Resistivity is a measure of the particle's ability to transfer charge. Fly ash resistivity is a function of the particle composition and also the conditions in the flue gas: temperature, moisture, and sulfur trioxide concentration. If the resistivity of fly ash is too high, the ESP will not be able to collect it efficiently. The resistivity of fly ash from a low-sulfur coal is generally higher than that from a high-sulfur coal. Switching from a high-sulfur coal to a low-sulfur coal, therefore, can degrade the efficiency of an ESP. Flue-gas conditioning involves injecting a chemical upstream of the ESP; the chemical lowers the resistivity of the fly ash and improves the collection efficiency of the ESP.

Most units are equipped with ESPs, and thus face the challenge of particulate capture efficiency. Many units need to apply flue-gas conditioning to improve their performance, and sulfur trioxide is a common technology used for this enhancement. Although the mechanism for adsorption of sulfur trioxide has not been well studied, as is the case in many gas-phase applications for activated carbon, capillary condensation is thought to be an important mechanism for the removal of condensable constituents from flue gas. As sulfur trioxide molecules accumulate in the pore structure of the activated carbon, the molecules become closer and closer in proximity and are effectively compressed and condense in the pore. This phenomenon has a higher probability of taking place in smaller diameter pores such as micropores. Correspondingly, it is less likely to take place in mesopores or macropores.

In commercial application, halogenated activated carbons show improved resistance to the mechanism contributing to decreased activated carbon efficiency. The mechanism for this improvement is not well understood.

Another flue-gas variable that affects removal efficiency of activated carbon in general is the temperature. As activated carbon adsorption processes are an equilibrium based on the concentration of the contaminant in the stream, higher temperatures tend to favor desorption rather than adsorption. This has been demonstrated in many of the DOE trial programs. Halogenated activated carbons have demonstrated better mercury capture at higher temperatures [16]. It is speculated that the improved resistance is due to imparting higher charge imbalance on the surface of the activated carbon and hence improving the kinetic equilibrium in favor of adsorption.

19.3.4 Balance-of-Plant Impacts

Mention was made earlier in the chapter about the potential halogens that may be used in this process. Chlorine, bromine, and iodine have all been evaluated through the development of halogenated carbons for mercury removal from flue gas and all are used commercially to at least some degree. Owing to both effectiveness (ability to oxidize mercury) and commercial considerations (price, availability, supply chain reliability), most commercial products have been formulated with the use of bromine or bromine compounds as the preferred halogen. Given the great diversity of flue-gas constituency and potential interactions of a strong oxidant within other compounds in the gas, at least some concern needs to be given to the potential reactions to avoid other undesirable side effects. As an example, ammonia slip in excess may react with sulfur trioxide and form ammonium sulfate precipitate on APCD equipment upon cooling. When SCR work first began, this was not an expected outcome, but had material impacts.

All halogens can have the potential of being corrosive if handled improperly or handled in inappropriately designed equipment. For the handling of halogenated activated carbons, the use of high-grade stainless steel is not uncommon,

particularly in the feeder portion of the systems, to ensure that the equipment is not degraded.

Halogenated activated carbons have been a major technological advance for the mercury removal from coal-derived flue gas. Advancements in the efficiency and method of application are ongoing and sure to be followed by step changes to come.

Concrete-Compatible Activated Carbon

S. Behrooz Ghorishi

20.1
Introduction

The fly ash generated from coal combustion is virtually identical in its composition to volcanic ash and is ideal for concrete use. According to the American Coal Ash Association, the United States produced 65.6 million metric (MM) tons of fly ash in 2008. Replacing cement in concrete is the primary use of fly ash. About 11.5 MM tons of fly ash went to concrete market in 2008 [1]. This is the highest value use of coal combustion fly ash. Reuse of fly ash to partially substitute for cement in concrete is a major success in waste recycling in the US and has significant economic, environmental, and technical benefits. The economic benefits of using fly ash to replace a fraction of the cement in concrete include increased revenue from the sale of the ash, reduced costs for fly ash disposal, and savings from using the ash in place of the more costly cement. Concrete performance benefits include greater resistance to chemical attack, increased strength, and improved workability. Environmental benefits include reduced greenhouse gas emissions, reduced land disposal, and reduced virgin resource use.

Recently the U.S. EPA finalized new federal regulations on coal-fired power plant mercury emissions based on Maximum Achievable Control Technology (MACT). Twenty states have also started controlling the mercury emissions from utilities in their state by 70–90% [2]. For the majority of the coal-fired power plants, the leading technology to comply with the new mercury regulations is activated carbon injection (ACI) [3]. Power plants inject powdered activated carbon (PAC) based mercury sorbents into the flue gas to capture mercury. The carbon sorbent is injected upstream of the plant's existing particulate control device, usually either an electrostatic precipitator (ESP) or a fabric filter (FF) baghouse. Currently, 150 ACI systems have been installed by the coal-fired power plants across the country [4].

The main concern for power plants that sell their fly ash for cement replacement is that PAC-based sorbents make the fly ash incompatible with concrete, causing the fly ash to be landfilled. This is doubly negative, because not only must the fly ash be disposed of rather than beneficially used, but also the opportunity is missed

to physically and chemically sequester the mercury from release and interactions with the environment by encasing it in the concrete. Mercury that is sequestered in concrete is very stable. Golightly *et al.* [5] measured mercury release during curing of concrete that contained fly ash or fly ash/carbon that had mercury adsorbed on it. The mercury flux from the concrete samples resembled those from natural soils indicating no increase in baseline mercury emission from concrete that is made by inclusion of coal combustion fly ash/PAC. Because of the high surface area of typical PACs and their high adsorption capacity, if even the smallest amount gets mixed in with fly ash, the fly ash can no longer be used in concrete [6]. As shown by Senior *et al.* [6] in their field studies of class C fly ash mixed with activated carbon, the PAC adsorbs the air-entraining admixtures (AEAs) later added to the concrete slurry. These surfactants enable incorporation of the precise amount of air bubbles needed to create the air voids required for concrete workability and freeze-thaw capabilities.

Mercury emissions from cement kilns are also increasingly recognized as a problem. ACI offers the cement kilns a very cost-effective mercury control technology. PACs could similarly be injected into these exhaust gases and be collected in the particulate removal devices that separate the cement kiln dust (CKD) from the exhaust gases. However, because the collected CKD would then contain AEA-adsorbent PACs, it could no longer be sold as cement for air-entrained concretes.

To preserve the sale of fly ash and to continue the use of CKD, "concrete compatible" PAC needs to be developed. Concrete compatible activated-carbon-based mercury sorbent allows power plants to continue to sell their fly ash and cement kilns to continue the use of CKD while also having very good mercury capture performance. There are a number of concrete compatible activated carbon products, one of which is Albemarle Corporation's Concrete-Friendly™, C-PAC™, which is now commercially available. Calgon Carbon Corporation and Norit Americas also offer concrete-compatible products referred to as *FLUEPAC®-CF PLUS* and *DARCO® Hg-CC*, respectively.

Topics covered in this chapter are as follows: new and innovative metrics to define the concrete-compatibility of mercury sorbent, production of concrete-compatible products including C-PAC™, C-PAC™ specifications, commercial application of C-PAC™ in various plants, and the results of concrete test with the resultant fly ash containing C-PAC™.

20.2
Concrete-Compatibility Metrics

Traditionally, the foam index method has been used to determine the concrete compatibility of different fly ashes. The foam index test is a relatively crude method used to predict the relative degree of adsorption of AEAs that a fly ash sample's components, primarily carbon, will have in a concrete slurry. As described before, AEAs are surfactants that are added to concrete mixes to form fine, stable bubbles

that are needed for void volume so that concretes do not crack when interstitial water freezes. Foam index tests are usually done by titrating an AEA solution into a mixture of fly ash and water until a stable foam forms on the surface after agitation. The number of drops of AEA that it takes to saturate the fly ash components so that some is available to form a foam denotes the sample's foam index (FI). Dividing the FI by the amount of carbon in the sample provides a Specific Foam Index (SFI). Unfortunately, there is significant variability and, sometimes, a lack of repeatability in performing foam index measurements. These are the results of operator discretion, the use of different and variable reagents, varying laboratory equipments and "drop" sizes, non-standardized procedures, and the dynamic, nonequilibrium nature of the test. Also the foam index is specific to the AEA used in the particular measurement.

Pederson *et al.* [7] introduced a new method based on dynamic surface tension measurements (using a bubble pressure method) on filtrate from a fly ash and cement suspension. This method is claimed to have less variability as the foam index method. A pure surfactant is added to the suspension as a substitute for a commercial AEA. The surface tension method and the foam index test have been compared on fly ashes acquired from power plants in Denmark and the United States. The results revealed a good relationship between the two methods. This new method and the foam index technique are affected by changes in temperature. The authors stated that the surface tension method requires further work before a finished procedure is accomplished. Stencel *et al.* [8] introduced an automated foam index testing based on detecting acoustic waves emanating from a container in which cement-ash mixture is tested. AEA in water is dosed in the container and agitation is performed using precise computer control. The real-time nature of the acoustic emissions from the container provides dynamic assessment of foam stability. This method removes operator error in the foam index test, but it is still suffers from other drawbacks of this method as mentioned above.

In its development of a concrete-compatible mercury sorbent, Albemarle Corporation needed a standard, repeatable method to gauge the effect that different PACs would have on AEAs in a concrete mix. PACs are similar to the unburned carbon found in fly ash, but they have significantly higher surface area. The lack of reliability and precision encountered when trying to use foam index testing on PAC or PAC/fly ash blends proved unsatisfactory.

Consequently, a standardized and repeatable method for measuring the effect of fly ash carbon or mercury sorbent carbon on AEAs was developed to replace foam index test. This new method is a more accurate indicator of AEA interference than the traditional foam index test. It uses a standard reagent, tested at an equilibrium condition, and eliminates operator discretion in determining when a sample begins to "foam" by utilizing instrumental measurements. Based on this new method, Albemarle Corporation developed its Concrete-Friendly™ mercury sorbent known as *C-PAC™*.

20.2.1
The New and Innovative Concrete-Friendly™ Metrics; the Acid Blue Index

The new method is based on a standard reagent, acid blue 80 (AB80) (CAS 4474-24-2), rather than a non-standard AEA. Numerous dyes were evaluated for their correlations of adsorption with the foam indexes of various AEAs. AB80 provided the best results. Moreover, AB80 has a chemical structure and molecular size similar to some AEAs. Among the other tested dyes, one was methylene blue (CAS 7220-79-3; see Figure 20.1)

Methylene blue has been tried by other researchers for this role, however results indicates that the methylene blue adsorption of several commercially-available PACs does not correlate well with their foam index values, as indicated in Figure 20.2, while AB80 does.

AB80 is one of the anthraquinone type acid dyes (Figure 20.3).

The adsorption spectrum of an AB80 aqueous solution is shown in Figure 20.4. It has three peaks at 626, 581, and 282 nm, respectively. The appearance of several adsorption peaks for a given chromophore is common for a highly conjugated system.

The overall procedure of AB80 adsorption that was developed is very similar to ASTM D 3860-98 Standard Practice for Determination of Adsorptive Capacity of Activated Carbon by Aqueous Phase Isotherm technique. First, the PAC sample is oven-dried at 150 °C for 3 h prior to the test. Different dosages of dried carbon are then added to 50 ml of 100 mg l^{-1} AB80 solution and well stirred. After

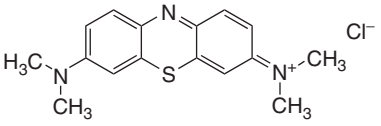

Figure 20.1 Structure of methylene blue.

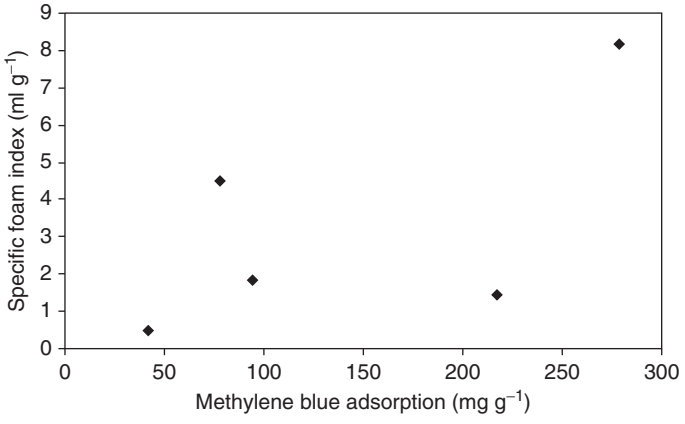

Figure 20.2 Correlation between specific foam index and methylene blue adsorption.

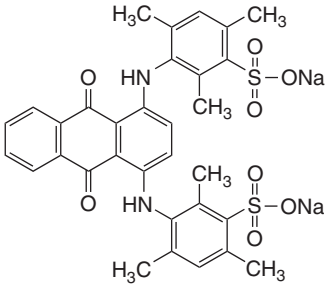

Figure 20.3 Structure of AB80.

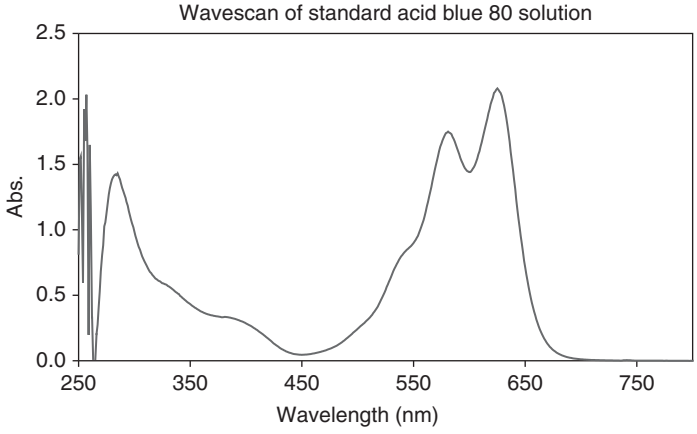

Figure 20.4 Adsorption spectra/wave scan of standard acid blue 80 solution.

the adsorption reaches an equilibrium, the carbon is separated from the AB80 solution by filtration. The concentration of the filtrate is determined, for example, by using Perkin Elmer Lambda EZ201 Spectrophotometer. The amount of AB80 removed by the activated carbon is determined by the relative change of AB80 solution prior to and after contact with activated carbon. The AB80 adsorption of the dosage carbon is then plotted with the equilibrium concentration of AB80 solution. The adsorptive capacity is calculated from a Freundlich isotherm plot at the original concentration of the AB80 solution, which is defined as Acid Blue Index (ABI) in the Albemarle-developed method.

During this method development, it was found that some chemically treated carbons interfere with AB80 adsorption. In order to eliminate this interference, such samples should be prewashed and extracted by deionized or distilled water until none of the impregnation chemicals is detected in the solution. For example, 5 g of B-PAC™ (an Albemarle Corporation's mercury sorbent; a non-concrete compatible brominated PAC) was washed with 250 ml of water, then filtered and rinsed with 1 l of water to properly prepare this brominated carbon for an ABI measurement. The sample weights of the activated carbons used in the

adsorption test may have to be adjusted depending on the adsorptive capacity of the activated carbon. A general guideline is that the concentration of the AB80 solution after contacting activated carbon should fit into the linear range of the AB80 working curve obtained based on the adsorption spectra at different concentrations (see Figure 20.5).

Based on the absorbance at 626 nm, the working curve for AB80 solutions was determined and is displayed in Figure 20.6. It can be used to calculate AB80 concentrations in solutions after adsorption by various activated carbons at various dosages.

The adsorption of AB80 by activated carbon fits well into a Freundlich Adsorption Isotherm, as shown in Figure 20.7. The AB80 adsorption of various activated carbons was determined based on Freundlich isotherms with the original AB80 solution concentration (100 mg l^{-1}) and the adsorption is defined as the ABI.

Depending on the different activation conditions, the pH of PACs can vary from very acidic to basic. Consequently, the effect of pH on the absorbance at 626 nm

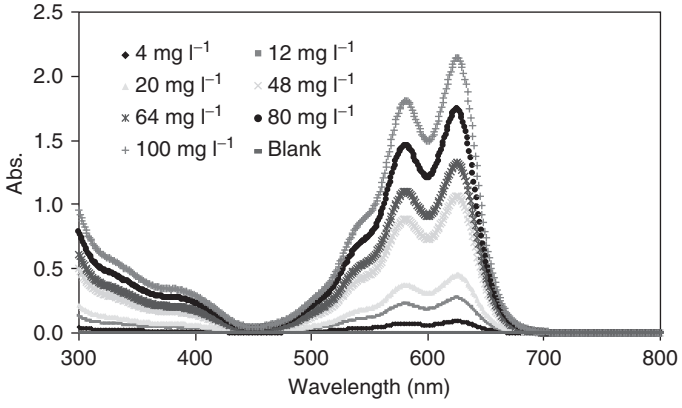

Figure 20.5 AB80 adsorption spectra at different concentrations.

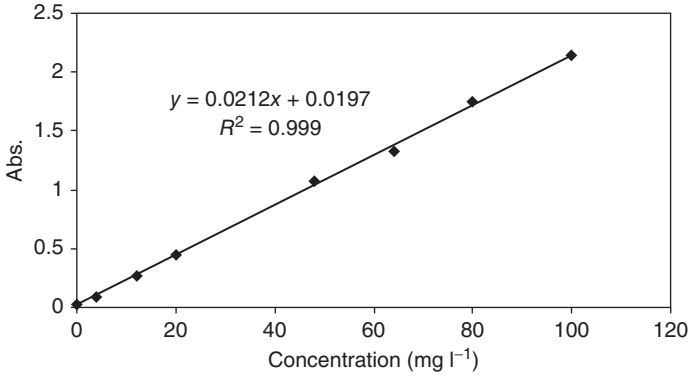

Figure 20.6 Working curve for AB80 solution.

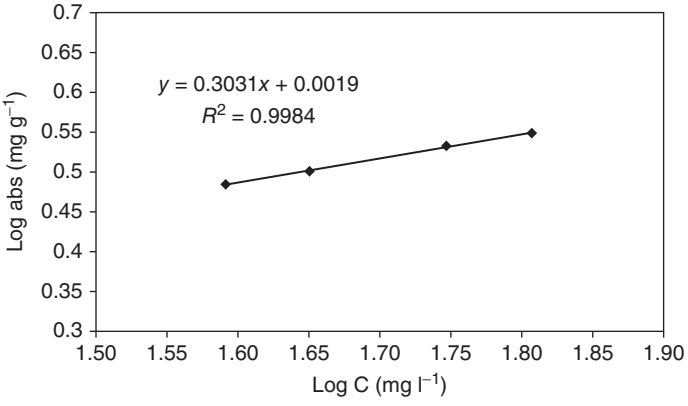

Figure 20.7 Freundlich isotherm for a tested activated carbon.

of AB80 solutions was investigated. The pH of the AB80 solutions was adjusted by H_2SO_4 or NaOH in order to obtain a series of AB80 solutions with different pHs. Within the test pH range of 2–12, the absorbance of the AB solutions vary about ±2%, which suggests that the absorbance of AB80 solution is independent of the pH of solution. The time needed for the adsorption to reach equilibrium is another important parameter in this method. AB80 adsorption progresses relatively quickly, with the adsorption capacity reaching a plateau at about 30 min. This is the recommended time for carrying out the AB80 tests.

The Albemarle-developed ABI method has been extensively tested using a broad variety of carbon-containing materials. These include a series of laboratory-made activated carbons, a range of commercially-available activated carbons from different precursors, and different chemically treated activated carbons, including Albemarle Corporations' B-PAC™ and C-PAC™. A comparison of the ABIs and SFIs of some of these activated carbons using various commercially-available AEAs is shown in Figure 20.8. Use of different AEA compounds result in a wide range of SFI but a very narrow range of ABI, indicating that the ABI is the most appropriate method to determine concrete compatibility of a material. As evident from this figure C-PAC™ has ABI values below 10 mg g^{-1} and very low SFI. The data in this graph is used to set specification for concrete-compatibility of PAC/fly ash mixtures (see the next section).

20.3
Production of Concrete-Compatible Products Including C-PAC™

In C-PAC™ production, a one-step method is used. Before detailing this production technique, a review of a number of other techniques is presented. Fly ash that is mixed with carbon can be treated and passivated with ozone. Hurt *et al.* [9] in US Patent 6 136 089 teaches such method. Chen *et al.* [10] also discusses this technique in their paper. Ozone chemically passivates the surface of carbon in fly ash

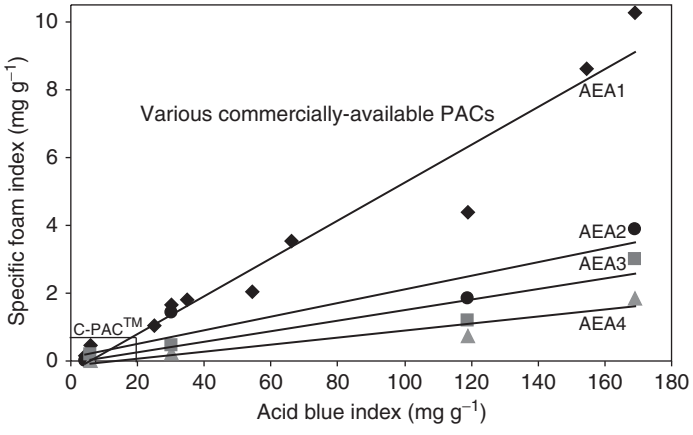

Figure 20.8 Comparison between ABIs and SFI of a number of activated carbons and C-PAC™.

and thus improves the air entrainment characteristic of fly ash. This process leaves the carbon in place, but adds surface oxygen complexes whose presence inhibits adsorption of the surfactant. This procedure requires treating large quantities of fly ash. Nelson [11] teaches a similar method that is only applied to the produced activated carbon before its injection into the flue gas and mixing with the fly ash. This method treats smaller volumes of solid material but still is an additional step in the production of activated carbon.

Jolicoeur *et al.* [12] discuss the use of "sacrificial agents or admixtures" to overcome the negative impact of carbon particles in adsorption of AEAs. The model sacrificial agent used in their study was ethyleneglycolphenylether (EGPE). They showed that addition of EGPE prevents the deleterious carbon effect on air entrainment by altering the surfactant adsorption and the surface energy (wetting behavior) of the carbon particles. They also observed that the addition of excessive dosages of EGPE has no detrimental consequences on air entrainment. However, this method still requires addition of another compound to the cement mixture. Another method to prevent the deleterious effect of carbon in fly ash is by carbon burnout [13]. In this method and before use in concrete mixture, the carbon in fly ash is simply burnt off in a fluidized-bed reactor with temperatures reaching 860 °F. Obviously, this process requires addition of external energy to accomplish carbon burn-off. This is a drawback of this technique.

A low-ABI carbon-based mercury sorbent can be produced by activating carbon using a one-step carbonaceous mercury sorbent precursor consisting of wood, lignite, coconut shell, or coal. The activation temperature and time period should be limited such that the ABI of the activated carbonaceous mercury sorbent does not exceed 15 mg g^{-1} of sorbent (a specification discussed in the next section). This constitutes a one-step production process and no post-treatment processing of the activated carbon is required.

The keys to creating carbonaceous mercury sorbents that can be used together with fly ash in air-entrained concretes are: (i) a minimized PAC mesoporosity and/or (ii) a proper carbon surface chemistry. According to the International Union of Pure and Applied Chemistry's guidance on Reporting Physisorption Data for Gas/Solid Systems, activated carbon pores with widths less than 2 nm are considered micropores. Pores with widths between 2 and 50 nm are considered mesopores and pores with widths exceeding 50 nm are considered macropores. To create a concrete-compatible carbonaceous mercury sorbent, the carbon's mesoporosity must be minimized, while retaining adequate reactive microporosity. AEA compounds are relatively large molecules, on the order of 1 – 3 nm long. By minimizing the number of pores that the AEA molecules can fit into or be transported through, the amount of AEA that can be deleteriously adsorbed from the concrete slurry can also be minimized. The particular surface chemistry of the carbonaceous mercury sorbent is also very important in determining the degree of AEA adsorption on PACs. The presence of particular oxygen functional groups on the surface of the PAC and the net charge of the surface could promote or impede the attachment of AEAs. Oxygen-containing functional groups created during air activation should impart an acidic, hydrophilic character to the carbon surface, which can repel the hydrophilic heads of the AEA molecules. By increasing the hydrophilicity of the PACs the adsorption of AEAs may be retarded, with little deleterious effect on gas-phase mercury adsorption. Additional information regarding production of C-PAC™ can be found elsewhere [14, 15].

20.4 C-PAC™ Specification

Albemarle Corporation has developed a brominated activated-carbon-based mercury sorbent with a very low SFI value, called *C-PAC™*. The ABI of this material is less than 10 mg g^{-1} (see Figure 20.8). ABI is the most important characteristic of this concrete-friendly™ material determining its use in concrete. Based on extensive testing, Albemarle has determined that ABI values of <15 mg g^{-1} are acceptable. There are a number of other specifications that determine the effectiveness of C-PAC™ both for mercury removal and its concrete-friendliness. These values are listed in Table 20.1.

20.4.1 Commercial Application of C-PAC™

In this section, full-scale test results performed with C-PAC™ at a number of utilities and cement plants are presented and discussed. The focus is on the effectiveness of mercury removal using C-PAC™ and the effect of the sorbent on the concrete parameters of the resultant fly ash.

Table 20.1 C-PAC™ specifications.

Property	Value
Acid Blue 80 Index (mg g^{-1})	<15
Bromine (wt%)	7
Moisture (%)	8
Iodine number (mg g^{-1})	>500
Tapped bulk density (g $cm^{-3)}$	0.56
Particle size less than 325 mesh (%)	>95
Ash content (wt%)	<12
Ignition temperature (°C)	>400

20.4.2
Full-Scale C-PAC™ Trials at Midwest Generation's Crawford Station

The goal of the full-scale C-PAC™ injection for mercury control at the Crawford plant was to determine if greater than 70% reduction of mercury could be achieved while maintaining the quality of the fly ash for concrete sales. The Crawford Station Unit 7 fires PRB (Powder River Basin) coal and has an ESP with a specific collection area of 0.4 m^2 per actual cubic meters per minute (120 ft^2 per 1000 actual cubic foot per minute). Much of this plant's fly ash has historically been sold for concrete use. During the month-long continuous test, C-PAC™ was injected at an average rate of 74 mg/m^3 (4.6 pounds of sorbent per million actual cubic feet of flue gas or lb $MMacf^{-1}$). An average total mercury removal rate of over 80% was achieved, as indicated in Figure 20.9.

The sorbent injection rate varied over the course of the trial, as it might in commercial practice, putting varying amounts of the sorbent in the fly ash and

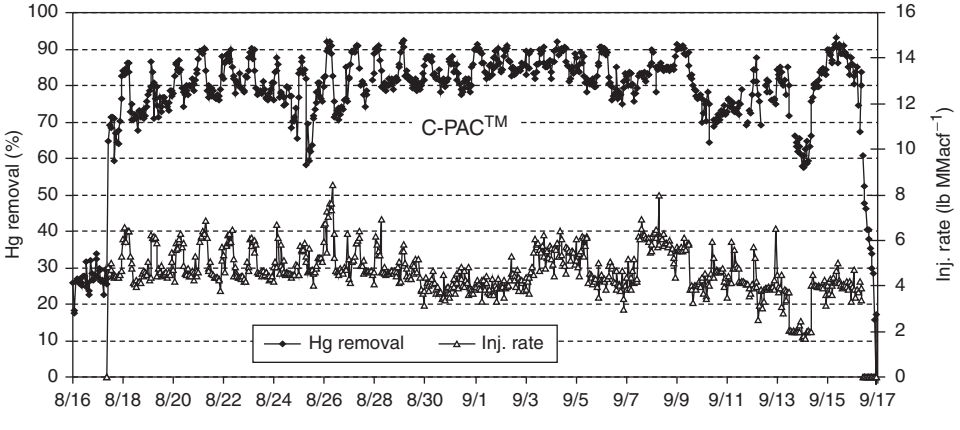

Figure 20.9 Crawford unit 7 mercury removal and injection rates over 30 days (1 lb $MMacf^{-1}$ = 16 mg m^{-3}).

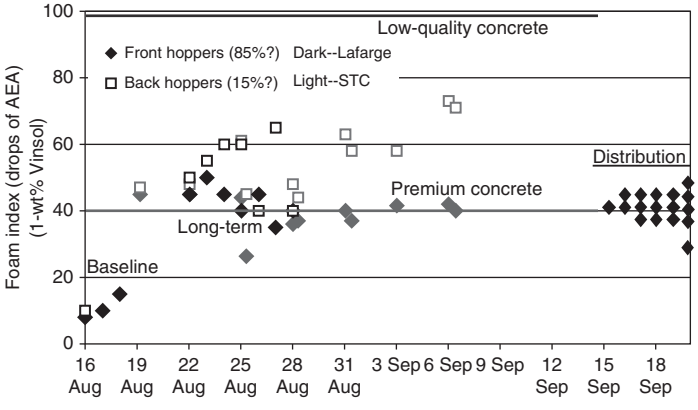

Figure 20.10 Foam index of Crawford fly ash during a 30-days C-PAC injection trial.

challenging the consistency of the fly ash for concrete use. Despite this, the resulting AEA adsorption of the ashes held to a tight band (see Figure 20.10). During the trial, the stack opacity improved, rather than degraded. It was observed that C-PAC™ injection had the co-benefit of improving the particulate collection performance of the ESP.

The resulting fly ash from this unit was usable in concrete. Moreover, fly ash from the front hoppers was usable in premium concrete (Figure 20.10). Using Vinsol® AEA, if the foam index is <40 drops, Crawford's fly ash is considered acceptable for cement replacement in premium concrete. At 99 drops or less, it can be used in standard concrete. The 40-drop cut off for premium concrete is a somewhat arbitrary value, based on the foam index of the unburned carbon and, particularly, on the variation observed in this value. The standard deviation of the C-PAC™-containing ash was only four drops, while that of the baseline control ash was even higher, at five drops.

20.4.3
Full-Scale C-PAC™ Trials the PPL Montana Corette Station

The purpose of the trial conducted at the Corette Steam Generating Station of PPL Montana was to determine whether the injection of C-PAC™ could reduce the mercury emissions by 80% while maintaining the ability to sell the fly ash for use in concrete. Two different continuous mercury monitors (PSA continuous emission monitor (CEM) and Ohio Lumex) and an Appendix K sorbent trap sampler were used for mercury measurements at this site. The injection trial was around the clock beginning at an injection rate of 3 lb MMacf^{-1}, based on an ESP inlet (cold-side) flow basis. In the first phase of the parametric testing, mercury removal rates of >80% were achieved at an injection rate of 3 lb MMacf^{-1} and >90% at an injection rate of 5 lb MMacf^{-1} (see Figure 20.11).

PPL Corette burns a PRB subbituminous coal. The coal samples contained about 30% moisture, <5% ash, and 0.3% sulfur. The coal heat content was slightly

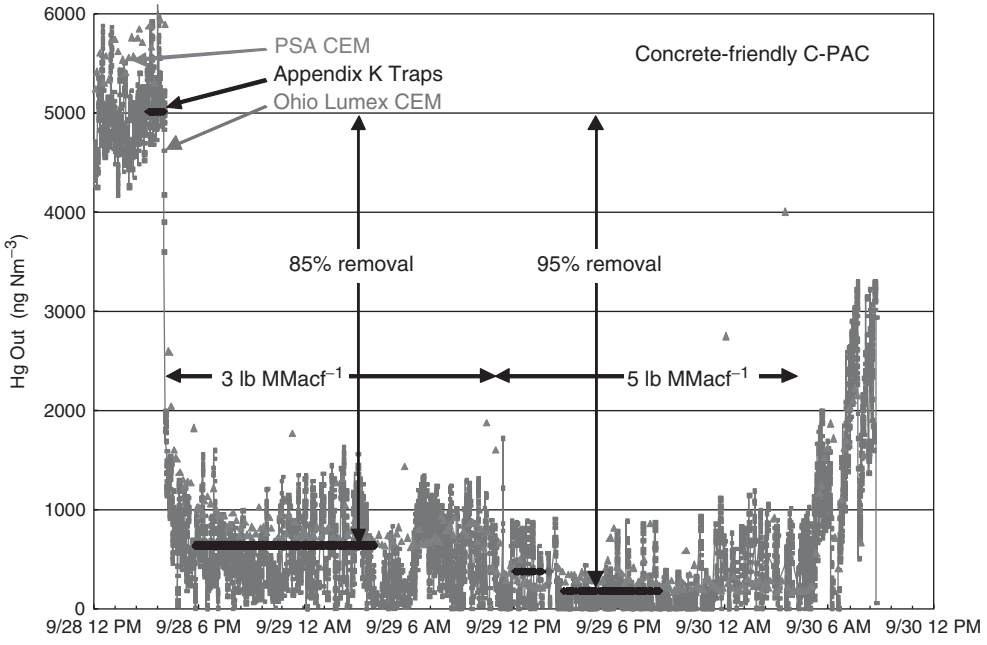

Figure 20.11 Mercury removal and C-PAC™ injection rate at Corette (1 lb MMacf^{-1} = 16 mg m^{-3}).

below 19.8 MJ kg^{-1} (8500 Btu lb^{-1}). The average mercury content of the coal was approximately 0.080 μg g^{-1} on a dry basis. Analysis of the fly ash samples collected during the test confirmed that the proper amount of mercury was being removed from the flue gas and collected in the fly ash. The foam index testing of the resulting fly ash indicated that the fly ash maintained its ability to be used in cement. All of the fly ash generated during the C-PAC™ injection period was transferred into PPL's storage silos and sold for concrete use.

20.4.4 Cement Kiln Mercury Emission Control Using C-PAC™

Portland cement kilns are another major mercury emission source, and the U.S. EPA promulgated in 2010 the final MACT standard for cement plants. One option for the cement plants to meet MACT Hg emission control requirement is to add a polishing baghouse to the kiln at a cost of millions of dollars. An alternative and cost-effective option is the injection of C-PAC™ at the existing baghouse, as illustrated in Figure 20.12.

In this technique, C-PAC™, which is both thermally stable and concrete-compatible, is injected as needed upstream of the primary existing particulate control device to reduce and maintain the mercury emission concentration to an acceptable level. Depending on the site, continuous C-PAC™ injection may

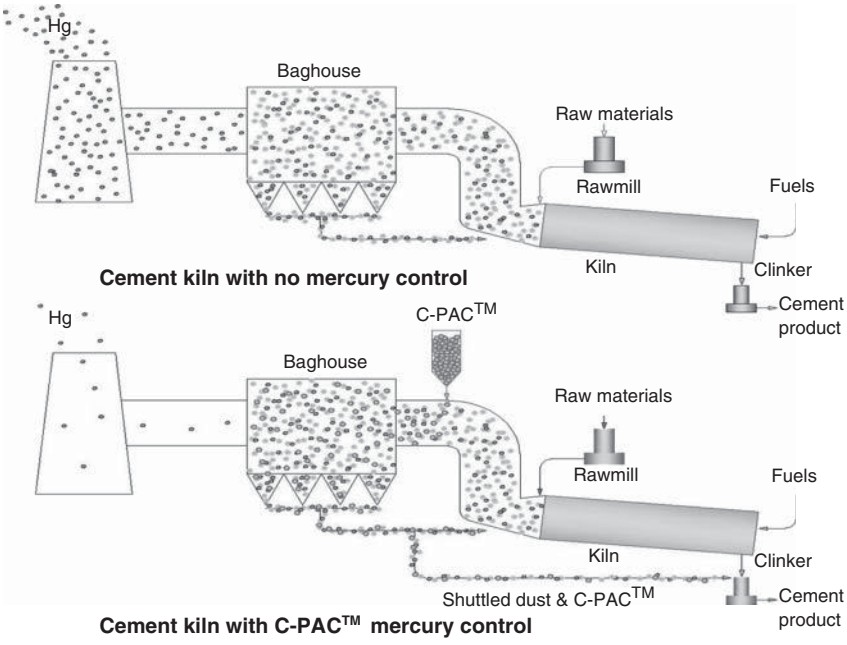

Figure 20.12 Illustration of C-PAC™ injection scheme at a cement plant.

be needed or C-PAC™ injection may only be required when the raw mill is off and Hg is at the highest level. (See Chapter 9 for a detailed discussion of mercury behavior in cement kilns.) Subsequently a percentage of the CKD containing mercury-laden sorbent is shuttled to the finished mill for use in the final cement product. In this way, no waste disposal or loss of the CKD occurs. Very good performance with C-PAC™ has been observed in several demonstrations, as well as commercial applications. The advantages of this in-process Hg control technique for the cement kilns include:

1) Requires only a sorbent injection system (low capital cost).
2) Sorbent is the main additional operating cost.
3) The timeframe for equipment design, procurement, and installation is short.

The sorbent requirements for this technique are that it must be temperature insensitive, concrete-compatible and have a high capability for Hg capture.

20.5 Concrete Compatibility Test – Field Fly Ash/C-PAC™ Mixture

In collaboration with two major fly ash marketers in the United States (Headwater Resources and Lafarge), Albemarle Corporation has examined in more detail the

concrete compatibility of the fly ash generated at Midwest Generation's Crawford Station. The results of these studies are summarized below.

20.5.1 Air Content of Fresh Concrete

The performance of C-PAC™/fly ash was compared with a non-sorbent control (fly ash only) and an alternative commercial PAC/fly ash. To make concrete with 6 vol% voids, about twice the amount of AEA additives was needed for C-PAC™/fly ash, while approximately 10 times the amount of AEA was needed for the alternative PAC/fly ash. Even though somewhat more AEA was required in the C-PAC™ concrete than in the non-sorbent control to achieve the same air content, the dosage still satisfied the contractor specifications. Furthermore, it was found that the properties of fly ash with C-PAC™ were very consistent, even more consistent than the baseline fly ash. The added cost of more AEA is negligible relative to the benefits of utilizing the fly ash in concrete production and eliminating the cost and environmental impact of the landfill.

20.5.2 Unconfined Compressive Strength (UCS)

Compressive strength is the capacity of the concrete to withstand axially directed compressive forces. Concretes produced with fly ash containing C-PAC™ met the target compressive strength of 4000 psi at 14 days (see Figure 20.13). In fact, it appears that the C-PAC™ also improves early strength relative to the control samples (no fly ash or base line fly ash) as shown in Figure 20.13.

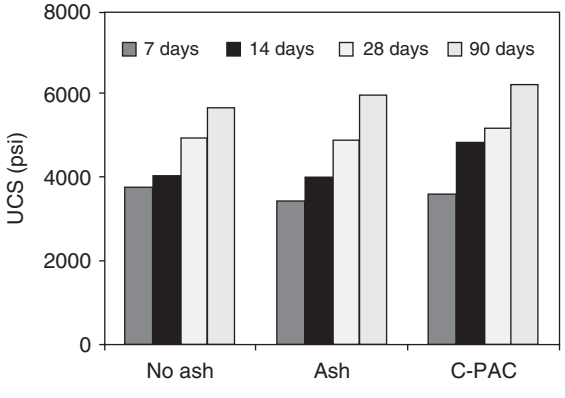

Figure 20.13 UCS of various concretes.

Table 20.2 Mercury leaching of the blank and ACI fly ashes.

Fly ash	Hg content (ng g^{-1})	Hg content in leachate (ng l^{-1})		
		DI water	Acetic acid	Sodium carbonate
Blank extraction solution		11	13	25
Baseline fly ash without mercury sorbent	39	15	9	34
Fly ash with C-PAC™	2004	22	5	14

20.5.3
Stability of Mercury in Fly Ash and Concrete

To assess the effect of C-PAC on the stability of the mercury in fly ash and concrete, the EPA's Toxic Characteristic Leaching Procedure (TCLP) and Synthetic Groundwater Leaching Procedure (SGLP) was applied to a number of samples. The fly ash collected during the Crawford mercury emission control trial was tested and the results are summarized in Table 20.2.

The fly ash samples containing the mercury sorbent generally exhibited a lower rate of mercury release even though it contained as much as two orders of magnitude more mercury. In all cases except for distilled water, the mercury leachate concentration from the long-term fly ash samples was below that of the bland extraction solution. Senior *et al.* [6] also studied leachability of the captured mercury by activated carbon in fly ash and found minimal leaching under various leaching protocols. Liu *et al.* [16] also provides further evidence that the sequestered mercury in concrete is not leachable.

Other properties of concrete with C-PAC™-laden fly ash including air stability, air voids distribution, and setting time were also investigated and it was confirmed that C-PAC™ mercury sorbents at appropriate dosage levels do not deleteriously affect any of the important properties of concrete.

Production of concrete-compatible, carbon-based mercury sorbents according to the procedures outlined in this chapter should result in continuous beneficial use of fly ash in concrete.

Novel Capture Technologies: Non-carbon Sorbents and Photochemical Oxidations

Karen J. Uffalussy and Evan J. Granite

21.1
Introduction

This chapter focuses on removal of mercury by novel techniques. First, we begin with a brief overview of the pitfalls of current mercury removal strategies and materials that motivate the research, design, and demonstration of non-carbon sorbents. Next we review current non-carbon sorbent materials and photochemical technologies being developed for mercury and other trace contaminant removal from flue gas.

One of the current industrially validated technologies is the removal of oxidized mercury in scrubbers, and this is utilized in approximately 25% of US coal-fired power plants [1]. Elemental mercury is highly insoluble in water, and scrubbing systems are not always effective in removing this form of mercury [2]. Furthermore, the option of scrubber removal of mercury is not available or implemented at all coal-fired boilers, as is the case of western low-sulfur coal-derived flue gas, which does not necessitate further SO*x* removal for compliance [3].

Another industrially validated and well-documented method is powdered activated carbon (PAC) injection, which is introduced into the ductwork upstream of either a cold-side electrostatic precipitator (ESP) or a fabric filter baghouse, in order to remove elemental and oxidized mercury by sorption at temperatures below approximately 400 °F (200 °C) [1, 4]. This retrofit technology is potentially applicable to 75% of coal-fired power plants that are not equipped with scrubbers in the United States [1]. The PAC has a short residence time within the ductwork, and the material must be well dispersed within the flue gas, typically at modest temperatures below 400 °F (200 °C), to achieve high mercury removal. Particle size and proper gas distribution and dispersion play important roles in achieving effective in-flight mercury capture for carbon-based sorbents [4, 5], and PAC injection must take place downstream of hot-side ESP because of the possibility that the carbon may ignite [6]. Carbon sorbents also can ignite in filter baghouses or hopper downstream, adding to a long list of challenges in designing and implementing effective carbon sorbent systems. Furthermore, an increase in flue gas SO_3 concentration results in decreased carbon sorbent effectiveness in removal of

Mercury Control: for Coal-Derived Gas Streams, First Edition.

mercury, and variations in coal type can be detrimental in achieving steady high mercury capture for multiple reasons [7]. The presence of activated carbon in fly ash is detrimental to the utilization of fly ash as a cement additive, and even the use of COHPAC and TOXECON systems (which supply the sorbent injection with its own dust capture system and separates the used sorbent from fly ash) does not sufficiently answer the problems with respect to SO_3 susceptibility or what to do with used PAC sorbent. As carbon sorbents can decrease the efficacy of fly ash as a cement additive, a replacement that is cement additive friendly is desired from both environmental and economic perspectives.

Carbon sorbents are typically used over a lower temperature range for mercury capture. The use of carbon sorbent at higher temperatures results in the volatilization of this captured mercury, with halogenated PAC materials extending this range to some extent. Finding a sorbent candidate that is effective at removing elemental mercury at high temperatures is beneficial as elemental mercury is most prevalent at higher process temperatures, and elemental mercury is the most difficult species to control because of its high volatility relative to other trace contaminants, low reactivity with conventionally used sorbents, and its low solubility in water [8–11]. Many inorganic compounds can react with mercury to facilitate its removal, including metal oxides, metal sulfides, and metal halides. Some of these materials can be utilized as sorbents, and may have advantages over activated carbons. These novel materials are discussed in detail in earlier work from the Department of Energy (DOE) [9, 11]. Sorbents that operate under varying conditions and circumstances are desirable, and here we present several such unique sorbents and their proposed processes.

Photochemical removal of mercury by application of ultraviolet (UV) light has several intriguing advantages over sorbent-based processes. The UV methods are potentially applicable in gases that poison carbon-based sorbents, and are also suitable as potential polishing techniques, ensuring near 100% removal of mercury.

21.2 Non-carbon Sorbents

21.2.1 Amended Silicates, Novinda

21.2.1.1 Background and Motivations

Amended Silicates are inexpensive, non-carbon substrates amended with mercury binding sites. The silicate-based substrate is chemically similar to fly ash; sites react with elemental and oxidized mercury species to bind the mercury to the sorbent. ADA (spun off later as Novinda) wanted to create a sorbent that would not affect fly ash quality for resale as a replacement for Portland cement [12], reduce or remove landfill burying costs associated with PAC and brominated PAC, and prevent the contamination of other high-value materials such as gypsum

[13]. Another major concern was that the use of the mineral sorbent should not interrupt or affect the overall process in any way. Their ideal sorbent would be nonleachable, inflammable, acid-gas resistant, and less corrosive than PAC, while also being overall economically and environmentally attractive. The company has developed several generations of sorbent materials made up of varying substrates and metal sulfides, which achieve these goals and are capable of capturing mercury at higher temperatures and pressures [14, 15]. Here, we discuss the sorbent's mercury capture mechanism and several of the material's sorbent demonstrations at various scales.

21.2.1.2 How Does the Amended Silicates Sorbent Work?

The Amended Silicates material is essentially made of an inexpensive phyllosilicate-type mineral substrate (montmorillonite, vermiculite, allophane) that has been "amended" by a metal sulfide functional group that acts as the active site for mercury capture [13, 16]. The flat sheetlike silicate structure is exposed to a solution of one or more polyvalent metal salts (M = Sn(II), Sn(IV), Fe(II), Fe(III), Ti, Mn, Zn, Mo, etc.), and an ion exchange reaction results in the initial form of the material. This material is then washed with water and subsequently exposed to either a gas or liquid sulfide (Thio-Red®, Na_2S, CaS_x, CS_3^{2-}), and the insoluble metal sulfides precipitate to the surface of the silicate substrate lattice. The resulting material is spray dried, yielding the Amended Silicates material which is characterized by molecularly thin films of layered metal sulfide amendments (transition metal chalcogenides and/or polyvalent metal sulfides) [16]. This layered structure renders the sorbents unaffected by acidic flue gases, likely due to the polar acid gas molecules being unable to break through the interlayer sites (decorated with high-density sulfur atoms) where heavy metals are attracted. The exposure of these metals to the acid gas would otherwise degrade sorbent performance, as is the case for PAC- and zeolite-based sorbents. As the sorbent's active sites are concentrated at the surface, the most expensive part of the material (the metal sulfide) is more fully utilized compared to materials that undergo both internal and external capture mechanisms [16]. Therefore, the capture material is less likely to be limited by residence time requirements or internal diffusion limitations found with other materials.

Initial laboratory-scale packed bed tests reported in 2003 showed Amended Silicates to have a mercury capacity several times that of activated carbon [17], and further pilot testing demonstrated that significantly less Amended Silicates sorbent material is needed to keep mercury stack emissions below MATS limits (compared to PAC)[13]. This additional capacity is attributed to the material's chemisorption capture mechanism, and at elevated temperatures and pressures could be relatively high. Laboratory-scale investigations were performed at conditions as high as 770 °F and 200 psig [17]. At higher pressure, the mercury capacity actually increased by a factor of 5 compared to the sorbent capacity at atmospheric pressure (with sorbent mercury capacity in excess of 3% by weight). A large percentage of mercury remained on the sorbent even after the pressure was reduced

down to 20 psig, and it could only be removed by chemical digestion. Thus, it was determined that the Amended Silicates material is not suited for a regenerable sorbent material, but instead is better suited as a disposable sorbent bed material. This disposable material would be a great Portland cement additive candidate owing to the mercury-sorbent bond stability and could also be disposed of safely as a nonhazardous waste. On the basis of the high capacity at high pressures, it was suggested that 3.5 tons of sorbent in a fixed bed could be used to capture all of the mercury from 1 million tons of coal [17]. Several additional Amended Silicates formulations identified over the past 10 years are top-performing sorbents in varying coal flue gas compositions [14, 16–18]. One of the more recent formulations, AS-022, was found to be resistant to SO_3 poisoning, and retained 95% or greater mercury removal rates even over long periods of time (>20 min) and as much as 20 ppm of SO_3 at laboratory-scale testing [13].

21.2.1.3 Demonstrations

One of the earlier pilot tests performed by ADA was at the 275 MW Xcel Energy Comanche Station Unit 2 in Pueblo, Colorado, between November 2002 and March 2003. ADA designed and built the pilot plant for mercury sorbent testing of various particulate control configurations using a slipstream from the Powder River Basin (PRB) coal burning power plant. The low chloride content of PRB coal results in a larger percentage of elemental vapor-phase mercury, which is typically the more challenging species to remove from flue gas. The pilot plant was configured with a reverse gas baghouse particulate control module, and several injection and sampling ports. The injection rate varied (1.6–9 MMacf), along with the residence time, and injection temperature (200–325 F, with a target range between 280 and 300 °F). Mercury concentrations in the slipstream flue gas ranged from 4 to 8 μg Nm^{-3}, with the fraction of particulate-bound mercury well under 20%. Impinger samples were taken and analyzed, and ADA found that their Amended Silicates resulted in 70–96% mercury capture using injection rates of 1.6–9 lb $MMacf^{-1}$, with 40% or more removed in the first 1 s of residence time. Increasing the injection rates resulted in increased mercury removal [17]. These slipstream tests agreed with another early pilot test where Amended Silicates exhibited rapid removal of vapor-phase mercury, suggesting that the material would perform considerably better than PAC in a plant equipped with an ESP [17]. More recent testing suggests that the Amended Silicates material lowers the bulk resistivity of PRB fly ash and thus can improve the performance of CS-ESPs [14].

Another major demonstration using Amended Silicates was performed at Duke Energy's North Bend, Ohio Miami Fort Unit 6 facility over a 6 week period in early 2006 (funded by DOE and EPA (Environmental Protection Agency)). This facility operates a 175 MW boiler with a cold-side ESP, and burns bituminous coal originating from KY, WV, OH, PA, and IL [12, 19]. Over 75 tons of the Amended Silicates material was made by BASF for this specific demonstration. A baseline was established at the beginning of the trial, where 0–10% of mercury was captured by native fly ash and 1/3 to 2/3 of the total mercury was found to be in

the elemental form [20]. After the baseline period, the Amended Silicates material was injected at various ratios in order to find optimum operating parameters, which was then followed by a 30 day trial at a target Amended Silicates injection ratio of 5–6 lb $MMacf^{-1}$. Afterwards, PAC (NORIT's DARCO HG) was injected for 5 days at several different ratios for comparison purposes. The results from the tests showed that Amended Silicates injection resulted in 40% mercury control, but that this was also achieved with the PAC sorbent, both at injection rates between 5 and 6 lb $MMacf^{-1}$. Increasing injection rates did not result in increased mercury capture for either material, which contradicts the findings from PRB coal slipstream studies. The ESP operating parameters and overall process were not affected by Amended Silicates sorbent injection [12]. Furthermore, tests performed by Boral and Separation Technologies found that Amended Silicates fly ash did not affect the sale of the material as a concrete additive, but that PAC fly ash was rendered unsuitable as a concrete additive material [12].

Changes to the Amended Silicates material were made, and new versions of the material were developed after the Miami Fort tests. The next major demonstration took place between February 2011 and November 2011 at the Gillette Energy Complex of Black Hill's Wygen Units 1, 2, and 3. These units burned PRB coal, utilized pulse jet baghouses for particulate and sorbent collection, selective catalytic reduction catalysts (SCR) for NO*x* reduction, and a spray dryer absorber (SDA) for removal of SO_2 [14]. The sorbent trials were again run using varying Amended Silicates injection rates over short periods, constant Amended Silicates injection rates over longer periods, and PAC/Br-PAC injection for comparison purposes. Test results indicated that steady-state mercury removal was obtained after approximately 24 h of Amended Silicates injection, and that the mercury level was reduced by 70% in the first 90 min to 2 h after injection began. For higher injection rates of 3.3 lb $MMacf^{-1}$, the overall mercury removal was 90–95%, and for lower injection rates of 1.7 lb $MMacf^{-1}$, the overall mercury removal was over 85% [14]. After Amended Silicates injection was stopped, the filter bag cake dust continued to capture mercury, evidenced by the slow recovery of initial stack mercury levels up to 24 h, showing the additional mercury sorbent capture capacity. Not only was the Amended Silicates material capable of being used in the existing dry sorbent injection units (for PAC), but its use did not affect the plant's operation or equipment, nor did it affect fly ash viability for disposal or sale. A neighboring unit (Neil Simpson 2) employing a circulating dry scrubber (CDS) and a CS-ESP was used for testing a different particulate/SO_2 control system with Amended Silicates. The low mercury stack levels meant lower Amended Silicates injection rates were needed, and mercury stack levels well below the EPA/MATS (Mercury and Air Toxics Standard) were achieved. Furthermore, the injection of $CaCl_2$ to promote oxidation of volatile mercury compounds was studied, and it was found that for the baghouse/SDA configuration, a synergistic reduction in mercury was observed when using Amended Silicates. For the case of CS-ESP/CDS, there was no noticeable difference in stack emissions. While the Br-PAC and PAC injections did benefit from $CaCl_2$, neither cases outperformed the Amended Silicates material [14].

The most recent demonstration of ADA/Novinda's most recent Amended Silicates material (AS-022) was performed at the 315 MW Santee Cooper Winyah Station Unit 4, burning eastern bituminous coal and equipped with SCR/CS-ESP and a wet flue gas desulfurization unit (WFGD) [13, 18]. The host site uses their WFGD to generate gypsum that is then sold to wallboard manufacturers, so it was important that the use of Amended Silicates did not affect the salability of the gypsum product. While wanting to demonstrate the efficacy of the AS-022 material, they also wanted to observe the effect of varying the injection locations (temperature and air heater location) and simultaneous hydrated lime injection has on mercury stack emissions.

During pretrial characterization, it was found that a large percentage of SO_3 is removed via condensation at the air heater, so it was decided that AS-022 injection would be best after this point to reduce SO_3 interactions with the sorbent. Furthermore, the largest percentage of mercury removal already occurred at the WFGD, approximately ~90% of which was determined to be almost all Hg^{2+}, which is not surprising as eastern bituminous coal is high in chloride content and, along with SCR catalysts, will promote mercury oxidation. While the WFGD is capable of removing oxidized mercury, the challenge is in removing elemental mercury before it reaches the WFGD using sorbent injection. After AS-022 injection began, it took several days to establish mercury stack emission equilibrium, but this was determined to be a function of the WFGD volume and plant load. However, after that 3- to 4-day period, the majority of mercury was captured at the ESP with the Amended Silicates material, and the amount of dissolved mercury in the WFGD decreased substantially. The hydrated lime injection increased the amount of mercury removed at the ESP, but when the hydrated lime was shut off, the WFGD removed the balance to keep stack emissions under the EPA/MATS limits; any effect that SO_3 would have on the Amended Silicates material mercury capture was essentially controlled by the passive removal of mercury at the WFGD. In addition, the injection of AS-022 before the preheater was found to be optimal owing to increased flue gas and/or AS-022 contact time and more uniform distribution. As the hydrated lime injection was located below the SCR outlet and before the air heater, this was reducing the occurrence of SO_3, which might have otherwise affected the AS-022 performance. Overall, the mercury stack emissions were measured at 0.5 lb $TBtu^{-1}$ (below EPA/MATS 1.2 lb $TBtu^{-1}$ limit), with the majority of mercury capture occurring at the ESP, which decreased the amount of mercury dissolved in WFGD fluid. Not only did the injection of Amended Silicates not affect the gypsum quality but a decrease in AS-022 flow rate kept the stack emissions below the EPA/MATS limit [13, 18].

21.2.1.4 **Conclusions**

The Amended Silicates material is reported to be a cost-competitive alternative to other sorbent materials, such as PAC and Br-PAC. This is a function of the inexpensive, large-scale manufacture of the material and the salability of the fly

ash as a Portland cement additive [13]. In addition, there is little impact to ongoing operation, as the injection of the material uses readily available and demonstrated injection equipment and Amended Silicates have continually been proved to not affect/damage any equipment nor affect any downstream processes [14, 17, 18]. The material's reliable mercury control performance was not affected by low-chlorine coals, moisture, or acid gas constituents. From an environmental perspective, disposal of used Amended Silicates material is much more attractive, as the mercury is tightly bound to the sorbent because of the chemical reaction converting bound mercury to a very stable and insoluble mercuric sulfide that occurs naturally in the Earth's crust, and TLCP fly ash leaching tests consistently report below detection for mercury [13].

21.2.2 MinPlus CDEM Group BV

21.2.2.1 Background and Motivations

MinPlus has been researching cost-effective and widely usable sorbent materials since 1995 for the capture of trace contaminants, as indicated by their wide range of patents for such materials [21–24]. The basis behind the MinPlus sorbent coupled with Mobotec's integrated process is the use of a highly reactive mineral sorbent combined with a highly effective delivery and dispersion system to achieve high-temperature removal of mercury from flue gas. Both MinPlus and Mobotec are interested in high-temperature removal of mercury directly from flue gas in the open radiant furnace itself. The MinPlus sorbent altogether eliminates the need for additional process equipment for mercury removal as it is directly injected into the boiler furnace.

MinPlus can be used upstream of hot-side ESPs because of its high-temperature operating range of 1650–2010 °F (900–1100 °C), removing mercury earlier in the process footprint, and the MinPlus sorbent will not ignite in hoppers or ESPs. MinPlus claims that their sorbent can easily handle variations in mercury concentration. The MinPlus material adds strength to cement as a fly ash additive, and is thus a unique candidate to use in place of carbon-based sorbents where increasing fly ash utilization is vital for cement manufacture. The conservation of the fly ash quality is due to the strong chemical binding of mercury to the MinPlus material and the unique mineral properties of the sorbent. More importantly, though, with respect to mercury capture, is that it takes an extended period of heating time at temperatures above 1700 °F (927 °C) for mercury to begin to be re-released, again supporting the material's stable nature and the chemisorption model [25].

21.2.2.2 How Does the MinPlus Sorbent Work?

The white fly ash like sorbent material is thermally produced from mixing $Ca(OH)_2$, $CaCO_3$, and Al_2O_3-$2SiO_2$-$2H_2O$, (kaolinite/calcite/lime) and is manufactured on the level of metric tons as a by-product from paper recycling residues [6, 26]. The material has a mean particle size of 10 μm based on Malvern particle size distribution analysis [26]. MinPlus is reactive over a wide range

of temperatures, undergoes rapid calcination and chemical transformations when injected into hot flue gas, and these transformations are what control its high-temperature mercury sorption behavior [6]. However, in order for mercury capture to occur in flue gas for this material, the gas mixture needs to contain at least 4000 ppm of oxygen, but the sorbent was reported to still effectively capture mercury in the presence of water [27].

Experimental work using a quartz tube reactor (47 mm I.D × 190 cm) through which varying feed rates of sorbent ($1-6.9\ g\ h^{-1}$) and preheated flue gas mixture ($2.2-4.7\ L\ min^{-1}$) were mixed with a steady supply of elemental mercury ($\sim 25\ \mu g\ m^{-3}$) have shown that MinPlus mercury removal efficiency is sensitive to both sorbent feed rates and to furnace temperature, where increasing either sorbent feed rates or temperature increases mercury capture. This correlation suggests that the mechanism of mercury capture is chemisorption rather than physisorption based. Mercury is predominantly in its elemental form at higher temperatures, and it is this elemental mercury which MinPlus excels at capturing. In fact, between 83% and 90% removal efficiency was observed at temperatures between 1650 and 2010 °F (900–1100 °C) for laboratory-scale tests, yet negligible sorption below 1100 °F (600 °C) [6, 26].

Two types of capture mechanisms were observed, one of which is an "in-flight" capture mechanism with an average residence time of 8 s and optimal mercury capture temperature at approximately 1650 °F (900 °C). The in-flight mechanism involves sorbent initial activation by internal reactions, mercury sorption, and subsequent deactivation if temperatures are too high for too long a period because of a "catastrophic melt" that results in pore closure. Interestingly, analysis of the in-flight deactivated sorbent particles showed that spent solids contained calcium alumino-silicate (Gehlenite) and calcium silicate products, which are specifically formed during activation/calcination at higher temperatures and is likely part of the in-flight mercury capture mechanism and subsequent deactivation [6, 26]. The second type of capture mechanism is characterized by sorbent that formed "scales" on reactor walls and did not appear to undergo deactivation through some sort of wall-stabilization effect. In fact, over a period of time at 2010 °F (1100 °C), the wall-bound sorbent managed to continue capturing mercury without reaching a maximum even after sorbent flow was ceased.

Wendt *et al.* noted that there is an interesting effect that the sorbent interaction with the quartz wall reactor has on mercury capture and uptake, and that it is quite possible that the quartz wall reactor affected capture based on data inconsistencies [27]. Further tests showed that when compared to Inconel reactors, the quartz reactor improved mercury capture, and that adding some form of SiO_2 to the sorbent mixture also stimulates mercury capture [25]. This is postulated to be through the formation of some type of active species that is triggered through the presence of silica but limited by the type of silica content as well as contact time. Additional tests with different types of fly ash with differing types of silica content greatly affected the mercury uptake. This was most evident in full-scale tests that were performed with PRB fly ash, where low to no reactivity with the MinPlus sorbent was detected whatsoever [25].

21.2.2.3 Demonstrations of Sorbent

Successful fixed-bed tests at the University of Arizona and dispersed-phase testing in a 1.75 MW coal-fired pilot plant at the Southern Research Institute in Birmingham, Alabama, led MinPlus to full-scale tests to test the capabilities of their sorbent material. A collaboration with Mobotec's injection and mixing systems were part of this demonstration. These tests were performed at the Richmond Power and Light Whitewater Valley 65 MW Power Plant Unit 2 in Richmond, Indiana, and at a 154 MW power plant in North Carolina. Both plants were equipped with a rotating opposed fired air system (ROFA, supplied by Mobotec), which can generate a highly turbulent mixture of flue gas via asymmetric air nozzle flow. The Mobotec Rotamix system, designed for selective noncatalytic NO*x* reduction (SNCR), coupled with ROFA results in effective direct in-furnace injection mixing and distribution of the MinPlus material that leads to greater utilization of the total furnace volume, optimal sorbent-flue gas contact time, and desirable sorbent temperature profiles [25].

The Richmond Power and Light Whitewater Valley power plant utilized in this demonstration burns bituminous high S Illinois coal, and is a tangentially fired Combustion Engineering pulverized coal-fired 12-boiler with a full load capacity of 65 MW at a steam pressure of 1450 psi and superheat temperature of 1005 °F (541 °C)[2, 7]. This system is equipped with an FSI system that was designed for the delivery of limestone for SO*x* control, but the SNCR and SO*x* control systems were not in service during the MinPlus demonstration. The mixing methodology is important with respect to the contact time and temperature at which the sorbent contacts the flue gas. Eight Rotomix/FSI injection ports, divided into two banks of four ports, were available, and typically either two or four of these ports were used. The MinPlus sorbent was injected pneumatically and fed through the injection ports at over 450 ft s^{-1} directly into the furnace and flue gas (temperature at the injection ports between 2000 and 2200 °F (1093 and 1204 °C)). The demonstration lasted about a week (second week of November 2005), and the results show that the MinPlus sorbent yielded over 95% mercury capture, up to 98%, with mercury stack emission measurements decreasing from 4 μg Nm^{-3} (background; no mercury removal sorbent added) to 0.2 μg Nm^{-3} at 3% O_2 [2]. It is assumed that as elemental mercury is the predominant species at elevated temperatures, the MinPlus sorbent captures mercury in its elemental form. Therefore, any negative effect that plant load, equipment, and coal type have on a sorbent's ability to capture mercury is essentially eliminated with this sorbent material. In addition, mercury was found to be predominantly bound to mineral sorbent, and the wall-bound mercury sorbent capture mechanism appeared to be effective for a period of time after the injection was stopped [2]. There is also an enhanced capture observed over previous testing that occurred at the Southern Research Institute (1.75 MW) coal-fired pilot plant, which resulted in mercury capture rates of approximately 65% [28]. The authors attributed the higher Whitewater Valley mercury capture to a higher injection temperature and better injection/mixing system, where mixing

and distribution of the sorbent in the flue gas is critical [2]. The MinPlus injection did not affect any other aspect of the plant, including fly ash quality and ESP performance.

The next MinPlus sorbent demonstration was at the North Carolina 154 MW Power Plant, a 154 MW, 1956 Combustion Engineering corner-fired design with four levels of pulverized coal burners [7]. This plant also burns eastern bituminous coal, and the demonstration lasted 2 weeks in March 2006. In this plant, the MinPlus sorbent was fed through precalibrated feeding screws from a transportable silo and it was then pneumatically sent to the Rotamix air boxes, mixed into the Rotamix air, and then entered the boiler contacting flue gas at over 450 ft s^{-1}. Similar to the Whitewater test, eight ports were available, and variations of these eight were tested to find the optimal dispersion when using side ports while also using no more than four ports. The temperature of the flue gas it contacted was estimated to be between 1600 and 2670 °F (871 and 1466 °C) [7]. The results showed a 70–80% removal of mercury, where initial mercury measurements of 5 μg Nm^{-3} was reduced to 1 μg Nm^{-3}, measured after ESP. This demonstration also found that use of the MinPlus sorbent did not affect any aspect of the plant, and leaching tests showed that there was complete binding of the mercury on the sorbent material [7].

MinPlus currently operates a full-scale demonstration plant located in Duiven, the Netherlands. This plant is operated as a joint venture between MinPlus-CDEM and a municipal and industrial waste incineration company with a focus on green pollution abatement technology in the paper recycling field.

21.2.2.4 Conclusions

The MinPlus sorbent is an inexpensive recycled material, and the used nonregenerable sorbent material is meant to be combined directly with fly ash. Ash quality measurements of the spent sorbent material mixtures found that the fly ash quality was not affected and could be used for resale as a Portland cement additive [2, 7]. The captured mercury and other trace contaminants do not revolatilize until approximately 1600 °F (871 °C), thus making this another stable mercury capture material that is a possible candidate for safe disposal [25]. The economic advantage of injecting directly into the boiler is that the majority of mercury is bound to sorbent and removed from the process before possible contamination of aluminum equipment downstream from the boiler. Furthermore, tax incentives might also be available for utilizing a process that recycles/reuses paper industry waste [29].

21.2.3 Pahlman Process – Enviroscrub

21.2.3.1 Background and Motivations

The Pahlman process is a closed-loop dry scrubbing process utilizing Pahlmanite™ sorbent, which is made up of low-density oxides of manganese (MnO, Mn_2O_3, and MnO_2) black powder that can adsorb a large percentage of flue gas SO*x* and NO*x* (reported to be >97%) [30]. Upon regeneration, its

sorbent yields raw sulfates and nitrates that are used to manufacture marketable commercial byproducts such as sodium sulfate, ammonium nitrate, and potassium sulfate. The process can remove multiple pollutants by a single-, dual-, or multistage dry process, eliminates undesired waste streams, and ultimately is intended for the replacement of FGD (flue gas desulfurization), SCR, and activated carbon injection technology [31].

21.2.3.2 How Does the Process and Sorbent Work?

The dry sorbent is sprayed into contact with flue gas, mercury vapor is oxidized, and this oxidized via a proprietary mechanism. This oxidized mercury vapor is then adsorbed along with chlorides, SO*x*, and NO*x*. The sorbent has a high affinity for sulfur compounds and this reaction happens relatively quicker compared to mercury and NO*x* adsorption. The temperature at which sulfates and nitrates of manganese decompose dictates the inlet process gas temperature range, and patent literature suggests that a typical temperature range would be 60 - 250 °F (16 - 121 °C), and the temperature should not exceed 350 °F (177 °C) [32–34]. A baghouse collects the sorbent and provides further residence time to contact the sorbent material with the flue gas [30]. Once the sorbent is removed from the baghouse, it is mixed with water and next regenerated via a persulfate oxidant and a base in a separate reactor. The insoluble manganese oxides are insoluble in water and separate out of solution with pollutant salts. A proprietary filter is used to separate trace contaminant metals such as mercury from the solution, which is reported to be a proprietary reaction forming a Mn–Hg complex. It is known that lattice oxygen from manganese oxides can react with elemental mercury to form mercury manganates. The pollutant salts can then be processed with potassium or ammonium to produce sulfate and nitrate salts of high value [30, 32–34].

21.2.3.3 Demonstrations

The first major demonstration of the Pahlman process was performed at the DTE Energy River Rouge Power Station Unit 3 located in Michigan in June 2003. The 290 MW pulverized coal wall-fired boiler plant was burning a PRB/eastern bituminous blend (40 : 60 to 60 : 40), and a 500–1000 SCFM slipstream was diverted to the mobile Enviroscrub pilot unit for processing [30]. The pilot unit used the slipstream to achieve its operating temperature, and subsequently the sorbent was loaded into the baghouse reaction chamber for testing. Inlet and outlet mercury measurements were conducted using the Ontario Hydro method and mercury semicontinuous emission monitors (SCEMs). Concentrations of O_2, NO*x*, SO*x*, CO_2, and CO were also measured during the test. Continuous emission monitoring system (CEMS) data gave an average steady state removal of SO_2 to be ~99.8%, NO*x* removal of ~98.2%, and the Energy and Environmental Research Center from the University of North Dakota reported a mercury removal of ~97% (oxidized, 1.02–0.03 $\mu g\, m^{-3}$) [31].

The second major demonstration of the Pahlman process was performed on a slipstream at the 550 MW Unit 4 at Minnesota Power's Boswell Energy Center in Cohasset, Minnesota, between December 2003 and January 2004. A 500–1000

SCFM slipstream of flue gas was diverted from the coal-fired Combustion Engineering tangentially fired boiler utilizing PRB subbituminous coal to the same mobile Enviroscrub pilot unit that underwent identical processing procedures. CEMS data reported an average steady-state removal of SO_2 to be ~99%, NO*x* removal of ~95.8%, and the Energy and Environmental Research Center from the University of ND reported a mercury removal of ~94.3% (84.4% oxidized, 99.2% elemental) [31].

21.2.3.4 Conclusions

Manganese oxide is inexpensive and abundant, and occurs in over 30 different forms, so acquiring this material easily is quite feasible. On the basis of Enviroscrub's design criteria, the plant runs at approximately 34.1% efficiency, requires about 3.3% of the power it generates in order to operate, and operating expense and capital costs both decrease as a function of plant capacity [31]. The capital cost savings for the Enviroscrub Pahlman process system is between 20% and 50% compared to conventional WFGD/SCR scrubbing technologies because of a decrease in operational equipment and space requirements. Furthermore, operating and maintenance costs decrease by 25–40% when considering the production of marketable byproducts and the removal of waste streams [30, 31]. However, progress still remains to be made on the front of optimization, simulations, and construction of a full-scale pilot plant for further testing and proof of concept at a larger scale than the current mobile unit set-up [35].

21.3 Photochemical Removal of Mercury from Flue Gas

The oxidation of mercury facilitates its capture. Although possessing numerous compounds, mercury is a semi-noble metal, and is exceeding insoluble in water. Ultraviolet light can supply the needed activation energy to induce the reaction of mercury to more amenable compounds for removal. Compounds of mercury tend to condense upon surfaces such as fly ash, and can be captured in a wet scrubber. Photochemical reactions of mercury with various constituents of flue gas can be an attractive alternative or polishing step for sorbent- or scrubber-based processes for mercury capture. There are several potential routes for the photochemical removal of mercury. One method employs short-wave ultraviolet radiation to facilitate the oxidation and removal of mercury. A second technique uses long-wave ultraviolet light in combination with a photocatalyst to oxidize and capture mercury. These techniques are discussed here.

21.3.1 Sensitized Oxidation of Mercury: GP-254 Process

Elemental mercury will absorb or reemit (fluoresce) 253.7 nm ultraviolet light. This ability to absorb or reemit 254 nm light is the basis for detection through

atomic absorption, atomic emission, or atomic fluorescence detectors. In atomic absorption spectroscopy (AAS) detectors, elemental mercury absorbs a photon of 254 nm light and goes to the 6 ($^3P_1$) excited state, denoted as Hg* or Hg 6 ($^3P_1$), and shown here:

$$\text{Hg} + 253.7 \text{ nm radiation} \rightarrow \text{Hg}^* \text{ or Hg } 6\ (^3P_1) \tag{21.1}$$

In atomic emission spectroscopy (AES) detectors for mercury, the atom of excited mercury emits a photon of 254 nm light, and goes back to the ground state.

$$\text{Hg}^* \rightarrow \text{Hg} + 253.7 \text{ nm radiation} \tag{21.2}$$

In atomic fluorescence spectrometry (AFS) detection of mercury, steps (21.1) and (21.2) occur within an infinitesimal fraction of a second, and the intensity of the emitted light (fluorescence) is measured. These processes are the basis for continuous emissions monitors (CEMs) of mercury, and are discussed in Chapter 5.

Dickinson and Sherrill [36] discovered the photochemical formation of mercuric oxide in 1926 described by the reaction:

$$\text{Hg} + 2\ \text{O}_2 + 253.7 - \text{nm light} \rightarrow \text{HgO} + \text{O}_3 \tag{21.3}$$

In the reaction mechanism, elemental mercury serves as a sensitizer for the formation of ozone, and ozone oxidizes mercury to form mercuric oxide. The term *sensitizer* means that elemental mercury in the 6 ($^3P_1$) excited state induces chemical reactions to occur. When the mercury collides with another atom or molecule, it can transfer its energy from the excited state to this species, setting the stage for chemical reactions. Activation energy for chemical reactions are typically supplied by heat, but can also be supplied by light.

The eminent Canadian photochemist Harry Gunning discovered many reactions for which elemental mercury can serve as a sensitizer over five decades spanning the 1940s through 1980s. Some of these sensitized oxidation reactions discovered by Gunning and others [37–43] involve reactants such as moisture, nitrogen oxide, sulfur trioxide, hydrogen chloride, and carbon dioxide that are abundant in coal-derived flue gas, and are present at concentrations that are many orders of magnitude greater than the concentration of mercury (around 1 ppb). Some of these reactions include

$$\text{Hg} + \text{H}_2\text{O} + 253.7\text{-nm light} \rightarrow \text{HgO} + \text{H}_2 \tag{21.4}$$

$$\text{Hg} + \text{HCl} + 253.7\text{-nm light} \rightarrow \text{HgCl} + 1/2\ \text{H}_2 \tag{21.5}$$

$$\text{Hg} + \text{NO}_2 + 253.7\text{-nm light} \rightarrow \text{HgO} + \text{NO} \tag{21.6}$$

$$\text{Hg} + \text{SO}_3 + 253.7\text{-nm light} \rightarrow \text{HgO} + \text{SO}_2 \tag{21.7}$$

$$\text{Hg} + \text{CO}_2 + 253.7\text{-nm light} \rightarrow \text{HgO} + \text{CO} \tag{21.8}$$

Granite and Pennline [44–47] employed reactions (21.3) through (21.8) to facilitate the removal of mercury from flue gases in the laboratory through pilot-scales.

The technology, dubbed GP-254 Process, is available for license through the DOE. The technology could serve as a small and inexpensive polishing step to guarantee near 100% removal of mercury from flue gas. It is noted that even 1 or 2 ppm of SO_3, commonly present within coal-derived flue gases, can severely poison the activated carbons used to capture mercury [48, 49]. Thus, the GP-254 UV Process could serve as a polishing step in these cases by reaction (21.7). It has also been recently suggested that NO_2 can hinder the performance of activated carbons for the capture of mercury [50], and this UV Process could again remove mercury in this case through reaction (21.6).

21.3.2 Photocatalytic Oxidation of Mercury

It is known that certain band-gap semiconductor oxides such as titanium oxide can serve as oxidation catalysts in the presence of long-wave ultraviolet light. Kaluza15 [51] discovered that titanium oxide and other oxides could photo-oxidize mercury to mercuric oxide in 1971. Biswas and coworkers [52–55] studied the capture of mercury in flue gas using titanium oxide particles and ultraviolet light. The ultraviolet light often emanated from the glowing discharge fields of the ESPs, present within many coal-fired power plants. The US DOE [56] studied the photo-catalytic oxidation of mercury to mercuric oxide using 365-nm long-wave ultraviolet light and both titanium oxide powders, as well as titanium oxide coated self-cleaning glasses. The reactions occurring on the titanium oxide surface can be crudely represented through (21.9) and (21.10) as [56]:

$$Hg_{(gas)} + \text{band-gap particle} + \text{light} + O_{2(gas)} \rightarrow HgO_{(ad)} + \text{radicals}_{(surf)} \quad (21.9)$$

$$Hg_{(gas)} + \text{band-gap particle} + \text{light} + H_2O_{(gas)} \rightarrow HgO_{(ad)} + \text{radicals}_{(surf)} \quad (21.10)$$

There are several band-gap semiconductor oxides such as titanium and zinc oxides present in air that can oxidize mercury under the influence of sunlight, potentially impacting the fate of mercury in the environment [56]. Additional research is merited on the use of photocatalysts for the oxidation and capture of mercury from flue gases.

22
Sorbents for Gasification Processes

Henry W. Pennline and Evan J. Granite

22.1
Introduction

Gasification is a process whereby coal can be decomposed into simpler compounds by reacting it with steam and oxygen at elevated temperatures and pressures. The major product compounds include hydrogen (H_2) and carbon monoxide (CO), which can both be used as a fuel or as building blocks for chemicals (see Chapter 8 also). In chemical production, the $H_2 + CO$ mixture, called *synthesis gas* or *syngas*, can be sent to a catalyst assembly to fabricate various chemicals. Gasoline, diesel fuel, substitute natural gas, and other organic chemicals can be produced in such an operation. In power generation, the $H_2 + CO$ mixture, sometimes referred to as *fuel gas*, can be combusted and expanded in a gas turbine before recovering the heat of combustion in what is called an *integrated gasification combined cycle* (*IGCC*) operation. In either of the above-mentioned cases, the product gas from the gasification process is in a reducing atmosphere and the mercury that was in the coal is typically in the elemental form. With respect to sorbents, mercury removal in the gasification process can occur at either elevated temperatures (149–371 °C; 300–700 °F) or at lower temperatures (ambient to 100 °C). The temperature range is dependent on the final use of the gasification products. In IGCC, elevated temperature removal is desired so that a higher thermal efficiency of the power generation scheme can be maintained. This requirement may not apply to synfuels production. In addition, global warming and the impact that carbon capture and sequestration may have on mitigation of the greenhouse gas carbon dioxide could have a role in determining the process conditions for the removal of mercury. Sorbents for mercury removal can be characterized by the material type, such as activated carbons, stable metal oxides, and noble metals. The mercury removal capabilities with limitations for different families of materials are discussed.

Mercury Control: for Coal-Derived Gas Streams, First Edition.

22.2 Background

A major concern for power systems that use coal as an energy source is the air emissions from the plant. Although certain air emissions are currently regulated in the United States, the emergence of new regulations for other pollutants is on the near horizon. On the basis of a 1998 Report to Congress, the Environmental Protection Agency (EPA) in 2000 had announced its finding that regulation of mercury emissions from utility steam generating units was necessary and appropriate [1]. In addition, the Clear Skies Initiative was proposed in 2002 to dramatically limit the emissions of mercury from coal-utilizing facilities [2]. Emission standards were proposed in 2003 but promulgation did not occur until late 2011. The development of mercury emission regulations will have a direct impact on coal-using power-generation facilities, both conventional steam generating systems as well as IGCC systems.

Gasification is an important strategy for increasing the utilization of abundant domestic coal reserves. Owing to the increase in thermal efficiency for IGCC systems and the potential ability to effectively capture and sequester carbon dioxide emissions, the U.S. Department of Energy envisions increased use of gasification in the United States over the next 20 years [3]. A near-zero emissions goal will be strived for with respect to pollutants, including mercury.

For the gasification process and, in particular, for IGCC, the characterization of the location of mercury within the plant is critical with respect to the eventual capture of the mercury. A total characterization of an advanced gasification technology was conducted in 1995 with Dow Chemical's Louisiana Gasification Technology Inc. [4]. Gas, liquid, and solid streams around the plant were measured for mercury. Although the mercury material closure was poor for the comprehensive study and significant advances in mercury sampling techniques have been made since the study, several important findings were established. The mercury material closure around the plant was poor, possibly suggesting that some of the measurements were in error or that an accumulation of mercury within the plant occurred. Of the gas-phase mercury, over 70% left the plant in the turbine exhaust flue gas.

Later, as part of EPA's Information Collection Request, Tampa Electric's Polk Power Station and PSI Energy's Wabash River Generating Station – both IGCC units – were characterized with respect to mercury air emissions (a full characterization of all streams was not conducted) [4, 5]. In this exercise, the Ontario-Hydro sampling technique was used to speciate the mercury in the flue gas after the turbine combustor. The important conclusions from this data-gathering effort were that near 60% of the mercury in the coal exited in the turbine combustion flue gas and the vast majority of the mercury in this flue gas was in the elemental form. From the information on these units and pertaining to the final disposition of the mercury in the present IGCC systems, it is speculated that a majority of mercury migrates through the system as elemental mercury and that the remainder of the mercury is probably accumulated within one of the scrubbing systems needed to

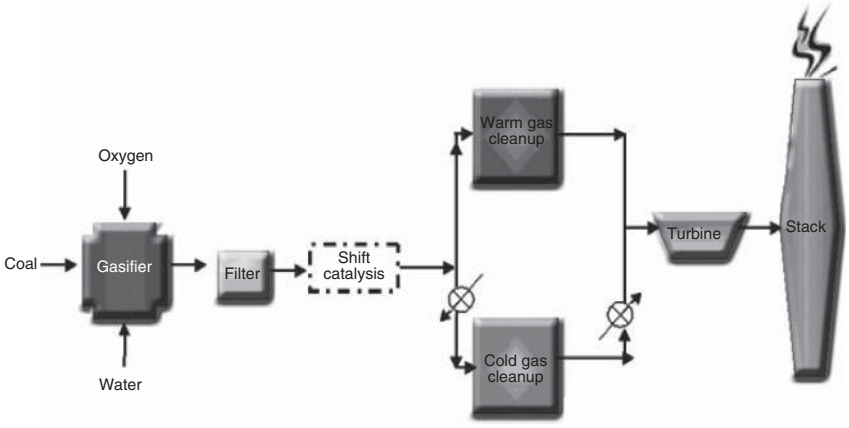

Figure 22.1 Simplistic flow schematic of an IGCC process.

clean the fuel gas before further processing it. In both these facilities, the fuel gas was cooled and then hydrogen sulfide was removed by a liquid solvent scrubbing technique before the gas was sent to the turbine combustor. Further evidence that the mercury in the fuel gas is mostly elemental can be found in gasification thermodynamic modeling or experimental studies [6–9].

Figure 22.1 is a rudimentary flow diagram of an IGCC installation with two options for gas cleanup. The lower path is similar to the one used at the Polk and Wabash Stations where a low temperature (>38 °C; 100 °F) wet scrubbing technique, such as Selexol, is used to remove the hydrogen sulfide. The upper flow path in Figure 22.1 indicates the option where acid gas cleaning occurs within a warm gas cleanup (sometimes called *humid gas cleanup*) system rather than at the previously described cold (lower) temperatures. There are various reasons for opting for the warm gas mercury cleanup as compared to the cold gas cleanup. The main advantage in cleaning the gas in an IGCC application at higher temperature is that the thermal plant efficiency can be as much as 2–3% greater as compared to the lower temperature acid gas cleaning scenario. Provided the temperature is sufficient so that the dew point of the fuel gas is not approached, the moisture content in this warm/humid gas stream remains in the gas phase, as compared to the cold gas cleanup case, and can be used in the turbine expansion. Additional areas of efficiency improvements are that the transfer of heat and latent heat to the more efficient gas turbine cycle are maximized; the capital and operating costs are lowered by reducing the duty on any heat exchangers; and the need for waste water treatment facilities is eliminated [10, 11]. Note that a third option for mercury cleanup could be after the fuel is combusted in the gas turbine. However, the gas is expanded and thus a significantly greater volume of gas would need to be processed.

In addition to the improved IGCC plant thermal efficiency for warm gas cleanup, another reason is that the capability exists for removing a vast majority of the coal-inlet mercury at one location. As seen in the cold gas cleanup systems

at the Polk and Wabash Stations, a substantial amount of the inlet mercury within the feed coal was not accounted for. Although liquid streams were not monitored for mercury in the analysis, it is speculated that the lost mercury is probably within these streams. If mercury removal techniques could be implemented at the elevated warm gas temperature within the process at elevated pressure, then the potential issue of mercury appearing in condensate, wet scrubbing streams, and so on, is eliminated. The partial pressure and thereby the driving force of the gaseous mercury is also higher at the elevated pressure of the system. However, similar issues with potential mercury appearance in wet scrubbing streams occur if the mercury is collected after the combustion of the fuel gas in the turbine combustor exhaust stream. In addition, if Hg removal is left to after the fuel gas is combusted, a much higher volume of gas needs to be processed as compared to the precombustion pressurized case. Cost and equipment size considerations become important.

As in mercury mitigation from flue gas produced by the combustion of coal, the use of a sorbent is a feasible technique to remove mercury within a gasification process. The challenges are many. As mentioned, the temperature options may limit the type of sorbent. Activated carbons generally perform via adsorption of mercury and this is enhanced at a lower temperature as compared to the elevated warm gas temperature case. Conditions can be harsh depending on the location of the removal, as the sorbent could be exposed to various compounds at different concentrations, for example, hydrogen sulfide, moisture, hydrogen chloride, ammonia, and other trace components. Potential deactivation due to poisoning and sintering must be addressed. Although the challenges can be stringent, research in the sorbent area has progressed and thus the sorbents and operating information are addressed in the following sections.

22.3
Warm/Humid Gas Temperature Mercury Sorbent Capture Techniques

There is limited information available on the removal of mercury from high-temperature syngas streams, although there have been some contributions to the general knowledge since 2000. Results from a pilot-scale gasifier suggest that all of the mercury in the coal ends up in the fuel gas [7, 12]. The data from this pilot-scale gasifier suggest that activated carbon and other carbon sorbents will be unsuited for mercury capture from syngas at temperatures greater than 204 °C (400 °F) [7, 12]. Robust high-temperature sorbents, as well as other techniques, are needed for mercury capture from syngas for continued development and proliferation of gasification technology.

In the studies with the various warm gas sorbents, there are some commonalities with respect to the testing. Most of the sorbents tested are in the form of pellets or granular sized materials, although one group has used a monolith design. Sorbents are typically tested in a fixed bed. Elemental mercury permeation tubes are generally used to spike a known gas composition. In many cases, the

sorbent is envisioned as being a multipollutant absorber and besides the removal of mercury, other trace components within the synthesis/fuel gas are desired to be captured, that is, arsine, hydrogen selinide, and so on. Although there are online analyzers for mercury detection in flue gases produced by the combustion of coal, some modification needs to occur so that they can be used in fuel gas applications. Certain analytical techniques have been developed for some of the other trace compounds [13], but reliable continuous, standard, online analysis for mercury in reducing conditions needs to be established. In certain cases, analysis of solids for mercury after the sorbent testing has been used in the determination of the amount of mercury captured on the sorbent. Most studies would be considered laboratory- or bench-scale and have not progressed out of the laboratory setting. However, in certain investigations, the research was actually conducted with real synthesis gas produced from gasification facilities, such as the Power Systems Development Facility (PSDF) in Wilsonville, AL.

As to more mature development of a technology, TDA [14–16] has used their geode sorbent development for multicomponent control. In this novel sorbent design, pockets of active sorbent material are surrounded with a porous but hard, strong shell that provides a wear resistant pellet. This design is similar to a geode as it has a cavity with the desired crystals surrounded by a protective exterior. This structure is very strong because there is a continuous support phase; it effectively contains the sorbent inside small holes in the interior of the pellet, allows the sorbent to expand and contract freely without disrupting the pellet structure, and allows gases to diffuse quickly in and out of the pellet. Copper-based sorbent formulations have been used to remove trace contaminants from fuel gas streams, that is, arsenic [16]. Substrate materials included alumina, titania, or silica. The active material precursors and inert substrates were combined using the geode technology, enabling the incorporation of large quantities of active material into the final sorbent pellet, without plugging the pores of the substrate material and reducing its porosity.

Initial testing in a packed bed of pellets was conducted with simulated gas streams that were spiked with the trace contaminants. The mercury, arsenic, and selenium concentrations at the outlet of the reactor bed were continuously monitored with online analyzers. Breakthrough and saturation capacities of the sorbents were determined for temperatures between 160 and 260 °C and near 450 psig. Mercury capacities were high at the elevated temperatures, and the sorbent has a high capacity for arsenic even in the presence of high concentrations of sulfur. Experiments with multiple trace metals showed that the sorbent could simultaneously remove all these contaminants (mercury, arsenic, and selenium) from syngas in one step [14].

Demonstration tests using actual fuel gas from a gasifier were conducted at two locations: at the PSDF in Wilsonville, AL and at the University of North Dakota Energy and Environmental Research Center (EERC) where lignite and bituminous coals were the feed materials (see Figure 22.2). Overall, the test results indicated that the TDA sorbent was capable of removing multicontaminants in the coal-derived synthesis gas at high temperature. Mercury was successfully removed

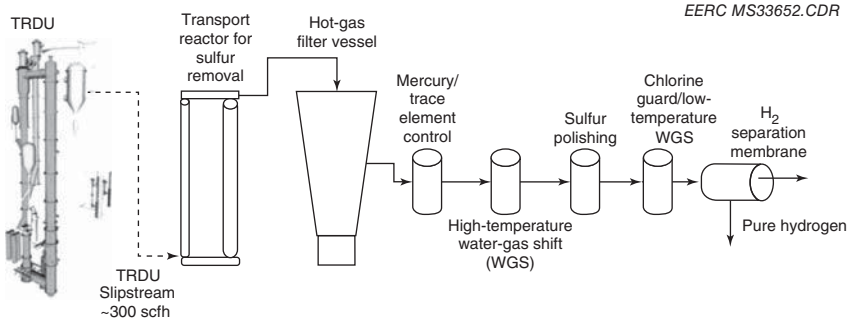

Figure 22.2 Schematic of demonstration unit at UNDEERC [15].

from the synthesis gas streams generated by different gasifiers using different coals at different sites and achieved greater than 95% Hg removal efficiency at 260 °C. This sorbent can be operated in a regenerable manner to remove Hg from the bed, while irreversibly removing all other trace metals including As, Se, and Cd with high capacity. From leaching tests, the fate of the mercury on the sorbent will remain on the sorbent once it is disposed [15].

The Gas Technology Institute (GTI) had developed the Ultra-Clean Process to control various pollutants from syngas, including mercury. The process injects fine sulfur and halide sorbent particles into two stages of barrier filter–reactors integrated in series, coupling efficient particle capture with an effective entrained and filter cake reaction environment. As can be seen in Figure 22.3, sulfur and halides are removed to extremely low levels by injection of various sorbents in the two stages, with the second stage temperature near 288 °C (550 °F). It is projected that for IGCC applications, the mercury removal could be a separate step or incorporated into the second stage of the process, and the mercury could be removed in the temperature range of 149–399 °C (300–750 °F), depending on the moisture content in the fuel gas [17].

Testing for mercury capture occurred in a packed bed reactor system using various simulated fuel gas mixtures and with a PSA Sir Galahad II analyzer. Materials that were tested were based on the oxides of copper, manganese, molybdenum, and zinc as well as mixed oxides and activated carbons. Some sorbents were purchased and others were made by GTI using a modified sol–gel technique or a wet impregnation method. The results with activated carbons were similar to other researchers in that elevated temperature hinders the adsorption of the mercury onto the carbon. With respect to the oxides, copper- and molybdenum-based sorbents, sulfidation of the sorbent is important in the mercury removal performance, possibly by altering the physical/chemical properties of the sorbent with a benefit for the higher loading of sulfur. In either case, the trend was that the effectiveness of the capture decreased as the temperature increased. In more recent work, nanocrystalline metal oxides/sulfides sorbents were evaluated in the temperature range of 150–260 °C, and again a temperature increase appears to have a negative impact on the mercury capacity of the sorbent [18].

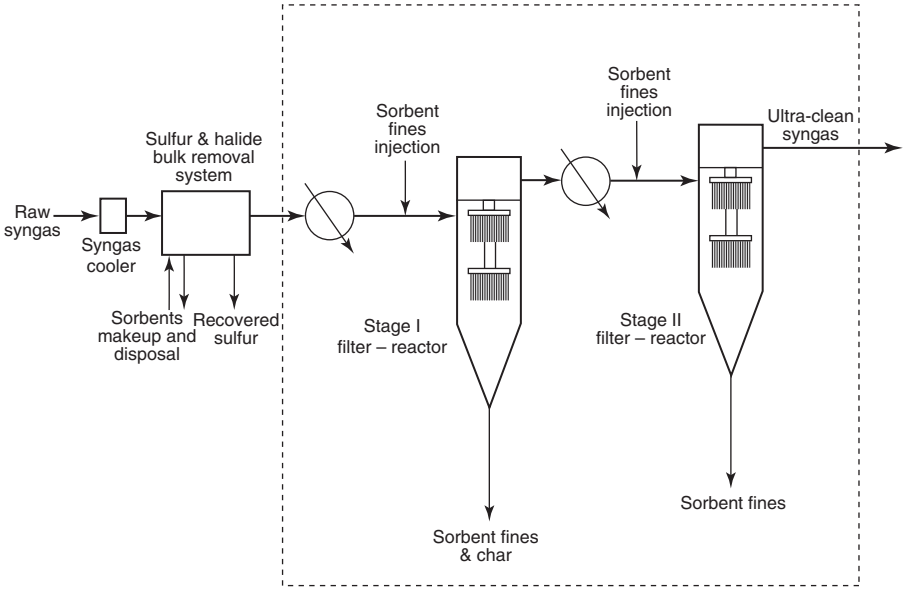

Figure 22.3 Ultra-Clean process flow diagram [17].

In a study conducted at the U.S. Department of Energy's National Energy Technology Laboratory (NETL), thermodynamic considerations followed by actual experimentation were used to screen candidates for mercury removal [19]. Interest was not only in mercury removal but also in the removal of selenium and arsenic. Samples were tested in a laboratory-scale reactor operating at ambient pressure, and capacities for mercury were calculated by flowing a known amount of mercury over the sorbent for a period of time (350 min) and having the spent sorbent solid chemically analyzed for mercury. Platinum and palladium were two candidates that had excellent capacities, even in the presence of simulated fuel gas with other components (hydrogen, carbon monoxide, carbon dioxide, hydrogen sulfide, and moisture). It was noted that the presence of these species impacts the adsorption of mercury as compared to testing under a spiked nitrogen flow. Mercury capacities remained appreciable in the 204–288 °C temperature range. As a noble metal is used, regeneration of the sorbent may be necessary and potential heat or chemical treatments are proposed to rejuvenate the spent sorbent [20].

In a collaboration between NETL and Johnson Matthey, further mercury capture studies with the palladium-alumina-supported sorbent were conducted with different metal loadings ranging from 2 to 9 wt% and over the temperature range of 204–388 °C [21]. The palladium-based sorbent performed better than the platinum-based one, and X-ray diffraction studies indicated a formation of solid solution of mercury within the palladium. Interestingly, a computational study that used *ab initio* methods based on density functional theory predicted material properties in which elemental mercury in the gaseous state would

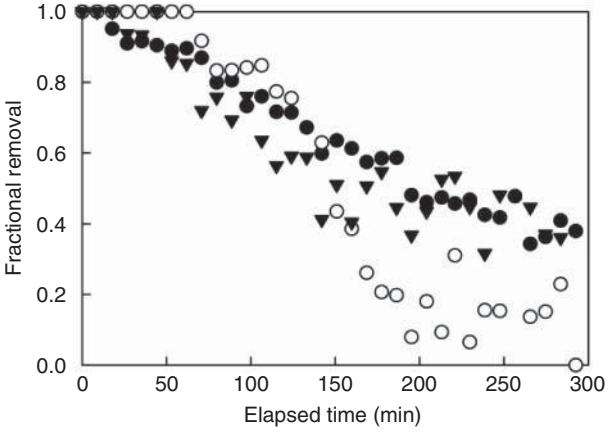

Figure 22.4 Fractional removal with time for 0.7 ppmv PH_3, 2.5 ppmv AsH_3, and 16.7 ppmv H_2Se removal on a 10 mg 5 wt% Pd/Al_2O_3 packed bed at 204 °C in the standard simulated fuel gas. Dark circle – AsH_3; open circle – H_2Se; and triangle – PH_3 [23].

bind to a pure metal to form a binary amalgam [22]. The candidate materials for the highest amalgam formations were the noble metals, of which palladium was highlighted in the computational exercise. In later experimental studies, interest broadened for other contaminant materials to be removed in the fuel gas, including not only mercury but also arsenic, selenium, and phosphorus, which, in the reducing atmosphere, are in the forms of arsine, hydrogen selinide, and phosphine, respectively [23] see Figure 22.4). Tests were conducted using the same reactor system as before, but a gas chromatograph/ion trap mass spectrometer was used for detection of these other compounds [13]. Arsine, phosphine, and hydrogen selenide could be removed from the simulated fuel gas at warm gas cleanup temperatures with the palladium gamma-alumina sorbent.

For these laboratory-scale tests, exposure to the materials of removal interest is usually much larger than what the sorbent would see in an actual situation. This fact would make these sorbents even more amenable to removing trace pollutants as their capacities would most likely increase. Successful testing of the palladium sorbent at real conditions has occurred at the PSDF in Wilsonville, AL [24]. In the slipstream tests, a fixed packed bed of near 10 pounds of sorbent held at 260 °C removed nearly all of the selenium, arsenic, and mercury present within the fuel gas over several weeks. Additional tests with this sorbent in the PSDF have verified the removal capacities.

The University of North Dakota EERC has been investigating promoted monoliths in collaboration with Corning. The monolith is a honeycomb-shaped (parallel-channel) polymeric body with the major ingredient being phenolic resin, fabricated through extrusion, carbonization, and activation processes [25]. The polymer body is carbonized at an elevated temperature in an inert atmosphere, which converts the phenolic resin to graphitic carbon mixed with amorphous carbon domains. It is activated by the removal of the amorphous

carbon by reacting it with carbon dioxide at elevated temperature. Surface areas are typically around 500-$m^2\ g^{-1}$, and additives, such as sulfur, can be introduced before the extrusion step. In the testing rig, simulated fuel gas mixtures spiked with elemental mercury were flowed over the monolith at temperatures between 177 and 260 °C and at elevated pressure. A modified PSA Sir Galahad was used to continuously monitor the mercury. Initial results with these monoliths and incorporating an undisclosed additive were successful in controlling mercury emissions, although with time online, some devolatilization of the mercury occurs but possibly due to the devolatilization of the additive.

Recent testing has also confirmed the ability of the monolith coated with an improved additive to remove mercury at a high level for an extended period of time (see Figure 22.2) [26]. Although the baseline testing occurs at 180 °C, a test at 260 °C (500 °F) did show some decrease in the capacity of the sorbent for mercury removal. One Corning-treated monolith showed effective capture of mercury for over 150 h of testing at 180 °C and was found to be very effective even at pressures up to 600 psig and temperatures up to 370 °C. Additional testing of monoliths and sorbents with various additives revealed that these materials were able to remove other trace components in the fuel gas, that is, arsine and hydrogen selenide, at 204 °C (400 °F) [27].

RTI International is pursuing an approach to mercury removal that is analogous to the one used in their hot gas desulfurization from syngas, which is utilizing a chemically reactive sorbent. They realize that the thermodynamic efficiency of the IGCC cycle is improved if the thermal energy of the fuel gas can be preserved, and thus their sorbent-based desulfurization can be accomplished reliably at 260–316 °C (500–600 °F). Therefore, this temperature range is also targeted for their mercury removal [28].

The experimental approach taken was similar to that of King *et al*. [19]. Performance of the sorbent materials was based on the amount of mercury uptake as measured by offline analysis of the sorbent at the end of an exposure period. Initially, results with sorbents were reported by spiking a stream of nitrogen with elemental mercury. After a test protocol was established, candidate sorbents were typically exposed to the carrier gas/mercury vapor stream for 30-min at 572 °F (300 °C). Mixed metal oxide sorbents, both in sulfide and oxidized forms, were investigated along with commercially available materials. Some of the candidates performed quite well in removing the Hg from the gas stream, although a mechanism for capture was not discussed as the sorbents typically contained multiple components.

In a continuation of these studies [29], composite metal oxides were investigated along with proprietary sorbents and an impregnated activated carbon. The sorbents were selected on the basis of various factors, including surface area, predicted stability in the syngas matrix, expected material costs, and identification of materials that irreversibly bind with elemental mercury at the targeted temperature (typically near 300 °C). The parameters of temperature and gas matrix were of interest with respect to mercury capacity. In general, screening results clearly favored lower temperatures as compared to the 300 °C

baseline. At this temperature and exposed to Hg in nitrogen, the mixed metal oxide sorbents performed adequately. However, in a syngas with or without moisture and without hydrogen sulfide, these sorbents performed poorly. One potential explanation given was that the major syngas components chemically reduced the metal oxide components of the sorbents, thus decreasing the active oxide species responsible for the mercury retention. In addition, the presence of H_2S typically had a deleterious impact on the mercury capacity of the sorbents investigated.

The main thrust for the sorbents discussed was to remove mercury in the warm/humid gas range in an IGCC application. However, certain sorbents can be used in a more elevated temperature range beyond the warm/humid range. The University of Utah has worked with CDEM to demonstrate the MinPlus sorbent, which is an inorganic, mineral-based substance derived from a unique thermal process in which sludge from paper recycling is converted into the desired material [30]. The material serves as a special mineral additive to cement, and the primary constituents are limestone, meta-kaolinite, lime, inerts, and various trace components.

The sorbent was injected into a simulated gas flow in a dispersed-phase entrained bed reactor system. Overall mercury removal efficiency increased with increasing sorbent feed rate and with reaction temperature, suggesting an overall chemisorption mechanism. For the reactor configuration, an overall maximum Hg removal of about 83–90% was achievable at a temperature range of 900–1100 °C. The mercury removal was attributed to an in-flight mechanism as well as to one related to the deposition of the MinPlus sorbent on the reactor walls. It was shown that at 1100 °C, the sorbent ability to capture Hg was greatly diminished, possibly due to a change in composition and/or morphology of the initial material. The impact of the other components in fuel gas, especially hydrogen sulfide, was not discussed in the communication.

22.4 Cold Gas Cleanup of Mercury

From the previous discussion, mercury is most likely in the elemental form after the coal has been gasified. If not removed at elevated temperature in one location, the mercury can be impacted by various processes along the gas cleanup path as related to the final use of the fuel gas or syngas. It should be remembered that although there is a paucity of mercury information in actual commercial gasification systems, past information on actual IGCC units that use gas cleanup at cold temperatures indicate that not all the mercury is accounted for and leads to the speculation that some of the mercury may end up in some of the gas cleanup process streams. However, a substantial amount of mercury still remains in the fuel gas and would need to be removed. At low temperatures (<100 °C), it has been shown that activated carbon can remove the mercury. Other mercury sorbent

materials have also been investigated at these low temperatures. In addition, a wet scrubbing process has also been proposed.

22.4.1 Carbon-Based Materials

Eastman Chemical Company was the first company to operate a commercial coal gasification facility in the United States and has maintained greater that 98% availability for more than two decades [31]. Mercury removal has been commercially demonstrated in this gasification facility. Eastman has developed and successfully applied activated carbon-based mercury control technology at their facility located in Kingsport, TN. Eastman has been operating Chevron Texaco gasifiers at this facility since 1983 to provide syngas for the production of acetyl chemicals [4, 28]. Calgon's HGR-P sulfur-impregnated, pellet-activated carbon beds are utilized with the following performance characteristics:

- Operating conditions: Approximately 30 °C and 900 psi;
- Gas contact time in bed: Near 20 s based on total packed volume;
- Removal efficiency: 90 – 95%;
- Carbon lifetime: 12 – 18 months.

At the lower temperature of operation, this activated carbon technique can be considered proved and is the baseline technology for mercury removal. Various designs for gasification plants, more specifically IGCC, propose to use sulfur-promoted activated carbon beds for mercury control [32 – 34]. Once the efficiency price has been paid by cooling syngas to near 38 °C (100 °F), the incremental cost to remove other components is reduced because the gas cleaning occurs at essentially ambient temperature. Again, the challenge for fuel gas cleanup is to develop gas purification methods that do not require gas cooling that, in turn, lowers overall thermal plant efficiency.

Testing using activated carbons with actual fuel gas did occur at Tampa Electric's Polk Power Station [35]. A packed bed of sulfur impregnated activated carbon (Calgon HGR-P) was fed with a slip stream of syngas containing hydrogen sulfide. Mercury analyses of the gas and the solid followed. Although about half of the feed to the plant was petroleum coke rather than coal, over 90% of the mercury in the feed to the carbon bed was removed.

Various experimental studies with carbon-based materials have also been conducted and have resulted in similar findings. Reed *et al*. [7] obtained samples of fines that were collected in a hot gas filter following a gasifier. The composition of the material was primarily carbon with some sulfur, and the material was collected by a hot gas filer at 580 °C from a 2-MWt gasifier operated on a mixture of coal and sewage sludge. Although further work was needed, the sorbent was able to capture elemental mercury at temperatures below 200 °C, and significant mercury removal was observed at a temperature of 110 °C.

Spanish researchers [36] investigated the importance of sulfur promotion of an activated carbon. A Norit carbon (a peat-based, steam-activated carbon) was

the baseline, and this was impregnated with sulfur compounds to form a second sorbent candidate. Simulated syngas streams with a spike of elemental mercury were passed over beds of the materials. For the gasification case, a better retention of the mercury occurred with the sulfur-containing sorbent as compared to the baseline carbon sorbent, because it was speculated that chemisorptions and/or reaction between sulfur compounds and mercury may occur as compared to just physical adsorption. Surface chemistry was thought to be more important than porous texture in controlling mercury retention in activated carbons.

The impact of gaseous components within syngas was studied [37]. In this experimental study, an activated carbon made from coconut shell was investigated. A simulated syngas flowed over a packed bed of the material at atmospheric pressure and in the temperature range of 80–300 °C. The amount of HCl and H_2S in the gas stream could be varied along with the elemental mercury. It was found that the presence of HCl accelerated the mercury removal rate by the activated carbon. However, the presence of H_2S suppressed the mercury removal in the presence of HCl. The stabilities of the mercury species captured on the activated carbon depended on the presence of the acid gases HCl and H_2S. The effect of temperature was similar to the findings of others where, typically, an increase in temperature has a negative impact on the Hg adsorption capacity of the sorbent. In one of those studies, British researchers [38] investigated a commercial Norit Darco "Hg" activated carbon. Mercury spiked in nitrogen flowed over the packed bed of sorbent in the temperature range of 100–200 °C. As found previously, the capture efficiency is seen to decrease as the temperature is increased. It should be noted that this activated carbon had a high capacity for arsenic removal in the temperature range of 200–400 °C.

22.4.2 Other Materials

Various transition metal sulfides have been proposed as mercury sorbents for fuel gas. In one case, Japanese researchers [39] investigated iron-based sorbents where they envisioned the mercury removal unit to be located just before the wet desulfurization unit in the gas cleanup system. Experimentation was conducted in a thermogravimetric analyzer and packed bed where a simulated fuel gas was spiked with elemental mercury. Unsupported and supported iron oxides that were calcined to different temperatures were tested within the temperature range of 60–100 °C under atmospheric pressure. The effects of temperature and gas composition on the sulfidation of the iron oxides, mercury removal activity, and carbonyl sulfide (COS) formation were investigated. Results indicate that the fabrication of the sorbent, that is, calcination and support, plays an important role in its behavior. Sulfidation of the iron oxide decreased and COS formation decreased with increasing calcination temperature. With decreasing operating temperature, the mercury removal performance increased. For comparison, reagent grade FeS and FeS_2 were active for elemental mercury removal in the simulated fuel gas without forming any COS.

Copper-based mercury sorbents have also been proposed in a fuel gas application at 160 °C [40]. In addition, an effort to clean mercury using copper sulfide from a natural gas stream could have implications for synthesis/fuel gas cleanup. In this study [41], the concern was related to mercury in natural gas and its potential to cause corrosion of downstream aluminum heat exchangers as a result of amalgamation. The sorbent is a mixture of copper sulfide and other materials and was assumed to operate at ambient temperature. On the basis of experience with the material, various precautions were needed to get the sorbent bed up to standard operation, such as removal of oxygen from the inert purge gas during loading of the sorbent. Results indicate that the mercury reduction exceeded the expectations for this copper sulfide sorbent. These results are similar to a previous study [42] with CuS and its ability to remove elemental mercury below 90 °C, although that research effort was not conducted using an atmosphere of reducing gas that would be found in a fuel gas system.

A series of unpromoted and iodine-, bromide-, and/or sulfuric acid-modified chitosan/chitin sorbents were tested in a laboratory-scale fixed-bed reactor system [43]. Elemental mercury was spiked in nitrogen that contained moisture, and temperature of operation was varied from 40 to 135 °C. Although this mixture was to simulate a combustion flue gas, it could also be extrapolated as a simulated fuel gas. Promotion of the chitosan was deemed important with respect to mercury removal, and the presence of moisture can increase the modified chitosan sorbent capacity for mercury uptake. A better mercury uptake capacity and higher mercury removal efficiency occurred at 135 °C as compared to 40 °C and was thought to be associated with a chemisorption mechanism between mercury and the promoters within the sorbent.

Finally, the use of fly ash in mercury removal was investigated by Spanish researchers [44, 45]. In this particular case, fly ashes from different combustion sites were tested in a packed bed reactor by flowing a simulated fuel gas that contained elemental mercury at 120 °C. The mercury retention capacities on the fly ashes in the gasification atmosphere were similar to that found when just nitrogen was spiked with mercury. The nature of the fly ash is determinant in the control of mercury capture. In later studies [45], a temperature programmed decomposition was used to identify the species of mercury that were present on the spent sorbent. Mercury sulfides were determined to be present, and it would be expected in a gasification atmosphere that contained H_2S.

22.4.3
Wet Scrubbing Technique

Typical wet scrubbing processes for the removal of contaminants from fuel gas or syngas do not intentionally remove mercury, although there may be evidence that they unintentionally capture the mercury [28, 35]. One wet scrubbing process that was developed for multicontaminant removal in fuel gas was the University of California Sulfur Recovery Process at High Pressure or (UCSRP-HP) [46, 47]. Research at the University of California coupled with experimental work at

GTI led to the development of an integrated multicontaminant removal process, whereby syngas is sent to a reactor column at a temperature above the melting point and below the polymerization temperature of elemental sulfur at elevated pressure. Desulfurization occurs in the range of 285–300 °F and the process integrates the removal of trace contaminants and heavy metals. The countercurrent-flow reactor column is divided into two sections: a scrub section and the reactor section. In the reactor section, a stream of glycol ether, such as diethylene glycol methyl ether, is used to catalyze a reaction and form a liquid sulfur that can be separated from solvent. In the preceding scrub section, an aqueous glycol ether solvent, such as diethylene glycol, is used to remove hydrogen chloride and the heavy metals mercury, arsenic, and cadmium that will be absorbed to form their respective, very insoluble sulfides. Selenium will be absorbed to form highly soluble ammonium selenide under the conditions of operation. It was proposed that a small slipstream of the diethylene glycol stream be withdrawn for filtration and other treatment to remove the accumulated impurities, especially the mercury-containing one. Laboratory-scale tests indicated that 95% of the mercury could be removed with diethylene glycol as the solvent. Bench scale testing with coal-derived syngas has been proposed [47].

22.5 Summary

Gasification of coal for power generation and chemical production is projected to increase in the future. Many factors could impact this future market, such as the decreased consumption of domestic and foreign oil for chemical fabrication and the potential regulation of the greenhouse gas carbon dioxide. In any event, mercury emissions from gasification-based technologies in the United States will need to be controlled as mandated by law. Similar to post-combustion control of mercury, the use of sorbents is a necessity in the control of mercury. Along the gas cleanup pathway for gasification processes, it is beneficial to remove the mercury at one location and at elevated temperature. Various sorbent results have been discussed where this is applicable. In addition, sorbent investigations have been reported at lower temperatures. Because of the novelty of gasification-based processes and the more recent interest in mercury control, one sorbent-based process for mercury capture is not outstanding. Granted that activated carbon has been shown to be a valid technique at lower temperatures, one clear-cut sorbent technology does not stand out at the beneficial higher temperature of operation. More research and development in this fledgling area is needed.

Mercury-Carbon Surface Chemistry

Edwin S. Olson

23.1
Nature of the Bonding of Mercury to the Carbon Surface

At low temperatures, elemental mercury is adsorbed to high-surface-area carbons by physisorption mechanisms. The term *physical adsorption* or *physisorption* implies a weak bond involving van der Waals or induced dipole forces between the mercury atom and the carbon surface. This means that the outer 6s electrons in the mercury atom, which are shielded from the nucleus by a lot of inner electrons, become polarized by dipole charges on the carbon surface so that they set up their own dipole moment, resulting in a dipole attraction to the carbon surface.

Although some early reports attributed mercury sorption at higher temperatures in air and flue gas to the physisorption mechanism [1], it is now understood that chemisorption is the primary mechanism in these conditions for mercury capture on carbon; elemental mercury becomes oxidized on the carbon and binds as a Hg(II) compound. Both spectroscopic and reactivity data provide compelling evidence for a chemisorption mechanism for mercury capture on carbons in flue gas at moderate temperatures. An early paper on mercury sorption on a nonimpregnated Saran carbon [2] showed an immediate and complete breakthrough of mercury at 150 °C in an air stream corresponding to a velocity/sorbent ratio of $2.5\,l\,s\,g^{-1}$, indicating that physical adsorption cannot occur at this temperature. Later, using a stopped-flow reactor with activated carbons at temperatures in the range of 100–300 °C, Hall showed that the apparent reaction order for Hg^0 sorption is half order in molecular oxygen [3]. Thus, the carbons are catalyzing the oxidation of mercury with oxygen as the primary oxidant. In a flow-through experiment with a nonimpregnated bituminous carbon at 140 °C in air at a slow flow rate ($0.19\,l\,s^{-1}$), Krishnan *et al.* [4] observed an early breakthrough, but a gradual decrease in capacity. As there did not appear to be any effect of Hg^0 concentration on the capture of Hg, the reaction was zero order with respect to Hg^0 concentration. Thus, the limiting factor was the low number of active sites in the activated carbon. But why did Singha [2] not see any sorption? In more recent flow-through experiments at the EERC with granular carbon (Calgon

F400 or NORIT GAC1240) beds at 150 °C, we showed that at slow flow rates, the breakthrough time in nitrogen was instantaneous, but was significantly longer in air [5]. With F400 at fast flow rates, breakthrough was instantaneous for both gases; thus, there was clearly a space velocity factor in these experiments. Therefore, only at very slow flow rates can one see sorption occurring in air.

Further evidence for the formation of oxidized mercury on the carbon was obtained from desorption experiments. Heating the spent sorbent beds from a variety of experiments to temperatures over 200 °C resulted in release of mercury. Sometimes temperatures of 750 °C were needed to eliminate the mercury from the sorbent. Although the released mercury in these thermal experiments was mostly elemental, it is unlikely that any Hg^0 existed on the carbon, as Hg^0 volatilized easily at ambient temperatures in an air stream. When heated in a 10% hydrogen stream, the spent sorbents released mercury at 125 °C as Hg^0. This is the reported temperature for reduction of Hg (II) compounds.

Some of the most conclusive evidence for chemisorption comes from an examination of the chemical form of mercury on the spent carbons using X-ray adsorption fine structure (XAFS) spectroscopy. XAFS is a powerful spectroscopic technique that can distinguish elemental and some of the oxidized mercury forms in a solid sample on the basis of the inflection point differences (IPDs) in the energy absorbance curve. Huggins *et al.* [6] showed that the mercury IPD of sorbents exposed to flue gas was not consistent with that of elemental mercury or with mercury bonded to oxygen. Rather, the IPD varied with gas composition and was consistent with a Hg(II) species bonded to a polarizable (soft) element such as chlorine, carbon, or reduced sulfur. This observation also rules out mercury compounds, such as HgO, $HgSO_4$, or $Hg(NO_3)_2$, as well as bonds between Hg and surface oxygen groups, including phenoxide, lactone, or ketone groups that had been previously suggested as binding sites for mercury, and also most mineral surfaces, such as iron or other metal oxides, silicates, and carbonates. Organic and inorganic sulfides are rapidly oxidized to sulfonates and sulfates, respectively [7, 8] and these are also ruled out by the spectroscopic data [6], as they bind via the oxygen rather than the sulfur(VI). When a sorption experiment was carried out with moisture present, but no flue gas, the IPD data for the mercury line indicated that the mercury was bonded to at least one oxygen [9], so there is more than one possible structure resulting from chemisorption, depending on the oxidant, type of sorbent, or conditions, and this structure might include bonds to some combination of carbon, sulfur, oxygen, or halogen.

23.2
Effects of Acid Gases on Mercury Capacities on Carbon

As discussed, activated carbons have little affinity for elemental mercury in air, but the sorption properties of the same carbons change drastically in flue gas. The interactions of the acid gases with the carbon surface determine the reactivity of the carbon to the mercury, as well as the capacity of the carbon for mercury.

The description of this interaction has provided valuable clues to the detailed mechanism of Hg chemisorption and binding on carbon.

An early study on acid gas effects with mercury on a carbon surface was that conducted by Young and Musich, with carbons exposed to gas-phase Hg also containing HCl and SO_2 [10].

Enhanced Hg sorption was observed in gas containing HCl. Because HCl is the major form of halogen in flue gas (see Chapter 7), at least at temperatures at which Hg capture occurs, we need to understand its role in the capture mechanism. Because HCl is not an oxidant, and Hg is oxidized on carbon in the absence of HCl [5], it is clear that neither HCl nor Cl_2 derived from HCl are necessary or independently responsible for oxidation of Hg on the surface.

Two studies published in 1998 [1, 11] pointed out some important effects of flue gas components on mercury sorption; however, many of these effects were not understood until the interactions were later investigated. A large factorial series of tests [12] using powdered activated carbon (Norit Americas flue gas desulfurization (FGD) carbon) was conducted at the EERC in a bench-scale system consisting of a thin fixed-bed reactor in gas streams (100–150 °C) containing 11–15 μg m^{-3} of Hg^0 in various simulated flue gas compositions consisting of acidic (SO_2, NO_2, and HCl) gases plus a base mixture of N_2, O_2, NO, CO_2, and H_2O. The results of these experiments (breakthrough curves) showed that NO_2 or the combination of HCl plus O_2 is required for effective Hg^0 capture, so these represent the primary oxidants or electron acceptors for mercury oxidation. Some acid gases had negative effects on mercury sorption, especially in combination. In one series of tests conducted with constant NO_2 concentration [13], increasing the SO_2 concentration gave shorter mercury breakthrough times (Figure 23.1). When SO_2 was omitted, no breakthrough occurred. In another series of tests at a constant SO_2 concentration, increasing the NO_2 concentration gave shorter mercury breakthrough times (Figure 23.2). Not only was SO_2 retarding the mercury capture, the retarding effect became more important as the NO_2 concentration increased. Thus, understanding of a very important interaction between NO_2, SO_2, and the Hg sorption began to develop. This strong interaction indicated that the NO_2 was oxidizing the SO_2 as well as the mercury on the carbon surface, and the resulting sulfur(VI) was inhibiting the mercury capture and causing the breakthrough. This effect was consistent with previous studies on the carbon-catalyzed oxidation of SO_2 [14]. The water in the flue gas was also needed for breakthrough to occur, which could be attributed to a requirement for the formation of sulfur(VI) [12].

The EERC work [12] also established that the Hg emitted after breakthrough (i.e., when there is no more net Hg sorption on the carbon) was mostly oxidized and can exceed inlet Hg concentration immediately following breakthrough. Olson showed that Hg emitted after breakthrough in the absence of HCl was $Hg(NO_3)_2$ [15], although in the presence of high HCl (50 ppm) concentrations, the emitted oxidized form is undoubtedly $HgCl_2$. This does not mean, however, that either of these two compounds has collected in the carbon before breakthrough. In fact, both forms easily desorb from an inert solid surface at 150 °C [16, 17], and so are not likely to be present on the carbon before breakthrough.

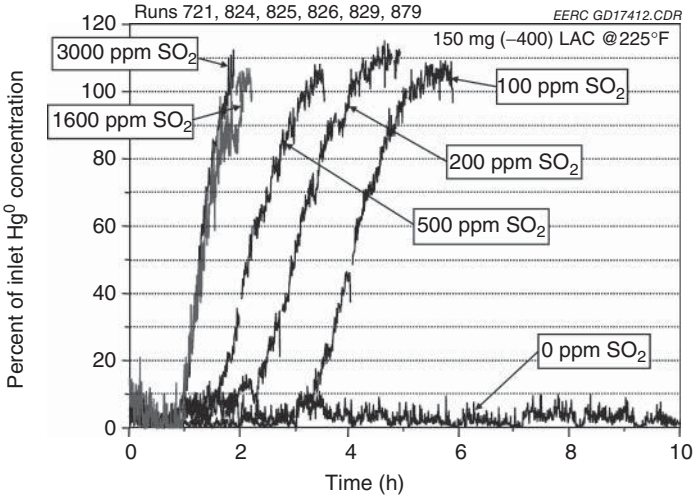

Figure 23.1 Mercury breakthrough curves for set of SO_2 concentrations with 15 μg m^{-3} Hg^0, 50 ppm HCl, 300 ppm NO, 20 ppm NO_2, and other baseline gases [13]. (Used with permission of the Energy and Environmental Center.)

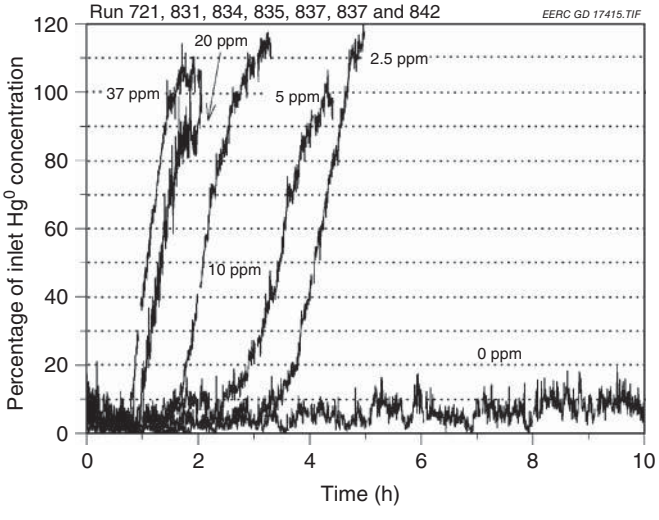

Figure 23.2 Mercury breakthrough curves for set of NO_2 concentrations with 15 μg m^{-3} Hg^0, 50 ppm HCl, 300 ppm NO, 1600 ppm SO_2, and other baseline gases [13]. (Used with permission of the Energy and Environmental Center.)

On the basis of these parametric studies and recognition that mercury is still converted to Hg(II) after breakthrough, an initial mechanism for chemisorption [18] that described the chemisorption mechanism as oxidation and competitive binding of the oxidized mercury with a catalytic carbon site or sites was presented. Oxidation of Hg^0 to form a bound Hg(II) species occurs with the electrons donated

to an electron-accepting (i.e., Lewis acid) site on the carbon. The electrons may be lost to NO_2 or O_2 the primary oxidants. Thus, the carbon plays a catalytic role, but the resulting oxidized mercury is bonded to the carbon structure. A donated electron pair results in formation of a carbon–mercury covalent bond, but this structure is labile, as the parametric tests revealed. An explanation for the SO_2, NO_2, H_2O inhibition of mercury capture is that the breakthrough behavior in the parametric tests was dominated by the competition for binding sites between the Hg(II) and acid components, mainly H_2SO_4 generated from the oxidation of SO_2 on the carbon, which continue to build up on the carbon surface during exposure to flue gas. When the binding sites are completely occupied by acidic species derived from the flue gas, Hg(II) salts are displaced from the binding sites. The equilibrium is shifted toward Hg salt release because of the high concentration and lower volatility of H_2SO_4.

But mercury oxidation still occurs even after complete breakthrough. That is, oxidation occurs in the presence of the bound sulfuric acid, although not always at the same rate as the initial rate. The loss of capacity must not be the result of pore plugging by species resulting from acid gases, as this would stop both oxidation and binding. But pore plugging could slow the oxidation rate.

The competitive inhibition of Hg binding by S(VI) was further demonstrated by Presto and Granite [19]. Halogenated and nonhalogenated carbon samples exposed to SO_3 or impregnated with H_2SO_4 (10 wt%) showed significantly decreased mercury capacity. The effect of water and NO_2 in converting SO_2 on the carbon to sulfuric acid was also confirmed.

Carey *et al.* [1] showed that increasing the inlet Hg concentration resulted in increasing the capacity of the carbon. What is now understood is that the capacity is determined largely by the sulfur(VI) formation and this occurs at the same rate no matter what the mercury concentration is. As the number of active sites for oxidation is very large, the more inlet mercury there is, the more is captured until the binding sites are filled with sulfur VI. Fundamentally, the breakthrough sorption curves that were being drawn did not provide the equilibrium capacity of the sorbent for mercury; instead, they gave an indication of how fast the sorbent was being poisoned by sulfuric acid.

The extensive mineral matter (35%) of the Norit Americas FGD sorbent could contribute basic sites for Hg binding, but a sequential removal of the inorganic matter from the FGD sorbent did not significantly affect the breakthrough behavior [20]. Basic mineral groups, such as CaO present in the FGD sorbent, therefore played no role in the mercury–flue gas interactions that determine the breakthrough capacity. Actually, several activated carbons prepared from pure carbon precursors were perfectly good sorbents. This suggests that the bound Hg is actually an organometallic complex. However, sorption of $HgCl_2$ from a flue gas may not exhibit this exclusivity, because an oxidation site is not needed and any basic site on the sorbent may bind Hg(II).

Further evidence for a competitive binding mechanism for Hg(II) and flue-gas-derived components at a carbon site was provided in a series of studies carried out at the EERC, in which carbons were exposed to various combinations of flue

gases representative of high Cl coals for different times and the spent carbons were analyzed by X-ray photoelectron spectroscopy (XPS) [7, 8]. These studies verified that sulfur(VI) (sulfate, bisulfate, sulfonate, or sulfuric acid) was the major sulfur species on all the exposed sorbent samples, and the longer the exposure to SO_2, the more sulfate was found in the sample. When NO_2 or H_2O was omitted from the flue gas, less sulfate accumulated. Thus, adsorbed SO_2 was clearly oxidized on the sorbent surface to sulfur(VI) species in a process facilitated by NO_2 and H_2O. Additional XPS work [8] with flue gas streams containing low concentrations of HCl typical of western coals, showed that organochlorine intermediates build up on the carbon surface and then disappear along with the bound mercury as the concentration of sulfuric acid increases. The XPS data also indicate that two types of chlorine are present: ionic and covalent, and that both chlorine forms disappeared from the sample at breakthrough. That chlorine is present as both chloride ion and covalent (organic) chlorine indicates that the HCl in the flue gas can donate a hydrogen ion to a basic site, as well as add both hydrogen and chlorine to a basic site to form the organochlorine product. The accumulation of chlorine in the absence of SO_2 as well as the disappearance of chlorine after continued exposure in SO_2 is explained by competition of HCl with bisulfate or sulfuric acid. As more H_2SO_4 is generated from SO_2 at the carbon surface, it displaces the more volatile HCl. Because disappearance of chlorine is coincident with mercury breakthrough, it is clear that Hg(II) is also in competition at the same site. Because of the interference caused by silicon, XPS data could not be obtained for the mercury species present in the exposed sorbents.

23.3 Kinetic HCl Effect

Although the early experiments revealed the nature of the competitive effects of flue gas components on mercury capacity, determining their role in the oxidative portion of the capture mechanism required further analysis. This information would be essential to designing sorbents with faster oxidation. The key to understanding the role of HCl in the oxidation mechanism was provided by testing of carbon sorbents in atmospheres containing low amounts of HCl. In parametric bench-scale tests conducted in very low HCl concentrations, such as those obtained when low-Cl coals (1 ppmv in the flue gas) are burned, the capture efficiency at the start of the run was low (about 50% of inlet concentration), followed by an increase in capture efficiency to the 90–95% capture rate [12]. This effect was also seen in breakthrough curves for a number of sorbents prepared from low-rank coals [21]. This behavior contrasts with the capture of mercury in relatively high HCl concentrations (50 ppm), where capture at the start was always very high (more than 95% of inlet concentration). The higher HCl concentration thus eliminated this induction period during which poor capture is obtained, and, therefore,

a promotional effect of the accumulating HCl on the activity of the carbon in catalyzing the oxidation of mercury was indicated. Ghorishi *et al.* [22] reported an increase in sorbent capacity as a result of pretreating the sorbent with aqueous HCl. Thus, consideration of the effects of HCl on Hg sorption curves led to a concept for understanding how the HCl promotes the mercury oxidation. This promotion was not because the HCl was directly involved in the oxidation, as it is in fact a highly reduced form of chlorine, and it is therefore not thermodynamically feasible to oxidize Hg with HCl.

The possible role of atomic chlorine in surface reactions was briefly examined. For HCl-promoted activated carbon (AC), Hg oxidation was not impeded by the presence of free radical scavengers, indicating that an alternative mechanism involving Cl atoms was not likely [23]. Furthermore, the addition of olefins (cyclohexene and styrene) to an HCl-treated carbon gave no substitution products, which would have resulted from abstraction of hydrogen by any Cl atoms present [24]. In contrast, the addition of HCl to the styrene occurred exclusively via the Markownikoff regioselectivity, indicating a cation mechanism. Thus, all four experiments indicated the absence of a radical or halogen atom pathway.

Several features of the oxidation site were inferred from the HCl promotion and bonding effects that led to development of a detailed chemical mechanism of mercury capture on the carbon surface [23–26]. This mechanism assumes a single carbon site for oxidation and binding but in two different forms and thus offers more detail on the nature of the bonding site and its interaction with flue gases and Hg. The mechanism, shown in Figure 23.3, used the concept proposed by Radovic and Bockrath [27] that zigzag carbene edge structures represent active sites for carbon reactivity. The mechanism for the catalytic role of acids, such as HCl, in the mercury oxidation step proposed addition of HCl and other acids to the carbene edge carbons to form carbenium chloride ion pairs (Lewis acid) that represent an oxidation site [26]. Reactions of the edge carbon with molecular halogens generate similar highly reactive carbenium structures. The

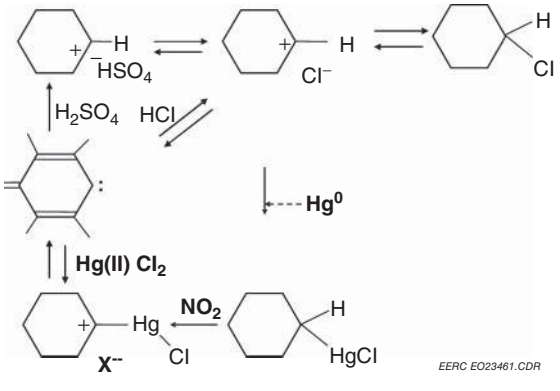

Figure 23.3 Oxidation mechanism – carbenium ion oxidant.

mechanism proceeds with Hg^0 oxidation by the carbenium halide ion pair to form an organomercury intermediate. This intermediate can be subsequently oxidized by NO_2 to a bound Hg^{2+} species. After breakthrough, $HgCl_2$ is continuously released as sulfuric acid competes for the site.

The oxidation of activated carbon is promoted not only by the addition of HCl, but any other acid, including small amounts of sulfuric acid [5, 24]. Comparative testing of a large number of acid-promoted ACs showed that they exhibit a specific acid catalysis, not a general acid catalysis. That is, those acids with polarizable counterions (HI > HBr > HCl) show faster initial rates compared with strong and weak oxyacids and fluoroacids [24]. This finding is consistent with a mechanism where the halide ion proximate to the cation actually can assist in the oxidation mechanism by stabilizing the incipient mercurinium ion forming in the transition state.

Later, the mechanism was somewhat modified to include the role of NO_2 in helping to promote the oxidation site [28]. The combination of HCl and NO_2 in the gas was a very effective promoter of mercury oxidation. The current thought is that multiple charges in the aromatic system may concentrate more of the positive charge and, thus, the oxidation potential at the protonated edge site [29, 30].

The number of active sites on a carbon-based sorbent can be estimated by determining the amount of accumulated sulfate at the time of Hg breakthrough, when essentially all of the binding sites are occupied by sulfate and unavailable for binding Hg. The amount of bound sulfate was calculated from the measured rate of SO_2 oxidation on Norit Americas Darco FGD [31] and the breakthrough time in a fixed-bed bench-scale test. This calculation gave 3.4 mol of potential sites per kilogram of carbon. The question in actual use of the carbon is how fast these sites are promoted to active status.

Early research [1] determined that mercury capacity was inversely related to temperature, and was incorrectly attributed to physisorption. A better explanation for the lower capacity in flue gas at higher temperature is that the rate of oxidation of SO_2 to sulfuric acid increases with temperature, so that the buildup of poisoning H_2SO_4 on the sorbent occurs at a faster rate. It may also be true in general that the rate of loss of $HgCl_2$ from the active sites is faster at high temperature than the rate of oxidation. This is not a true equilibrium as elemental mercury is going on the carbon and oxidized mercury is coming off. The question of temperature dependence of the oxidation was only recently answered. Comparisons of the initial capture efficiency (where kinetic rather than capacity effects predominate) in low-Cl gas at high and low temperature showed that Hg^0 was captured more effectively at the higher temperature. As the rate increases with temperature, the oxidation step is rate controlling and the physisorption reverse reaction is not of importance in controlling the rate. The implications of this finding for control technology are that when contact time is very short and reactivity is important, then higher temperatures will give faster oxidation rates for both mercury and SO_2, but the effect of faster SO_2 reaction to sulfate is not important because binding sites are still abundant in the short time period. For sorbents

collected on a filter bag and in contact with the flue gas for a long time, the capacity will be greater at a lower temperature, because sulfate builds up more slowly at the lower temperature.

Halogenated carbons typically exhibit very high initial rates of mercury oxidation, with no induction period. So they are very effective in mercury capture in utilities where the contact time of the sorbent carbon and the gas phase in the duct is short. However, the capacity of the halogenated carbons may actually be less than that of the nonhalogenated carbons. Presto and Granite demonstrated that in a packed bed reactor with good gas–solid contact, bromination of the carbon does not increase the capacity [19].

Current work involves decoupling the oxidation from the binding steps so that effects of gas components on the oxidation step can be determined, and rate constants derived. These experiments utilize a sorbent bed that has broken through so that most of the inlet Hg^0 is oxidized by the bed in the flue gas, but no mercury is captured [31]. Then, by measuring the Hg^0 and total Hg in the effluent gas simultaneously for a matrix of experiments in which one, two, three, and four components are deleted or reduced, rates of oxidation, and changes in binding chemistry can be determined for each condition. Thus, removal of NO_2 resulted in a significant decrease in oxidation rate, but oxidation was still able to occur (pseudo first order $k = 1.4\,\mathrm{l\,s\,g^{-1}}$ sorbent) with O_2 and NO present. Removal of HCl from the gas composition decreased the oxidation rate, consistent with the specific acid catalysis mechanism, but, because oxidation still occurred, the oxidation can evidently occur via the sulfate-bound carbenium ion.

23.4 Summary

Several factors that determine the amount and rate of Hg capture on carbons have been described. Most important are (i) the competitive interactions of the flue gas components with each other and oxidized mercury on the carbon surface sites in determining mercury capacity on carbon and (ii) the interactions of the acid gases with the carbon surface in determining the reactivity of the carbon for oxidation of mercury. The description and understanding of these interactions has provided valuable clues to the mechanism of Hg chemisorption and binding on carbon. The key to understanding the role of HCl was the finding that sorption experiments conducted in low amounts of or no HCl experienced an induction effect, an initial period of time where the reactivity to Hg oxidation develops [5]. This finding led to the concept of acid promotion of a carbon site to form a carbenium ion that is highly reactive for oxidation, resulting in formation of an organomercury intermediate. The direction in sorbent research recently has been guided by the insight that more reactive or more selective oxidation sites can be generated by varying the carbenium ion structures that are formed.

Atomistic-Level Models

Jennifer Wilcox

24.1
Introduction

Understanding the speciation of mercury throughout the coal-combustion process is crucial to the design of efficient and effective mercury removal technologies. Mercury oxidation takes place through combined homogeneous (i.e., strictly in the gas phase) and heterogeneous (i.e., gas–surface interactions) pathways. Both bench-scale combustion experiments [1] and quantum-chemistry-based theoretical model efforts [2, 3] indicate that homogeneous mercury oxidation is responsible for, at most, 10% of the overall oxidation in a typical coal-fired flue gas with chlorine levels at 500 ppmv (e.g., HCl equivalent). These studies have been additionally confirmed by recent work that compares model predictions to bench-scale experiments, with the simulation predictions dependent on previous kinetic submodels developed specifically for Hg oxidation [4, 5]. Mercury speciation in coal-fired flue gases are extremely complex and depend on many factors, some of which include the mineralogy and chemistry of the coal, combustion conditions, power plant configuration, flue-gas composition, and temperature-time history from the boiler to the stack.

The extent to which particulate-bound mercury (Hg_p), gaseous oxidized mercury (Hg^{2+}), and gaseous elemental mercury (Hg^0) are emitted from the stack is also dependent on the existing pollution controls in a given power plant. The effective removal of Hg through existing flue-gas control technologies acts as a co-benefit (as discussed elsewhere in this book). For instance, electrostatic precipitators (ESPs), in particular cold-side ESPs and hot-side ESPs, capture, on average, 27% and 4% of Hg, while fabric filters (FFs) are more effective with approximately 58% Hg removal [6]. In general, Hg_p or Hg^{2+} is easier to capture using one of these control technologies. In addition, oxidized Hg may also be captured in existing flue-gas desulfurization (FGD) units as the oxidized form is water-soluble. Activated carbon injection (ACI) is a direct method used for Hg capture, in which powdered activated carbon (PAC) is injected into the plant's flue-gas stream where it adsorbs gaseous Hg and is collected in downstream particulate control devices, such as FFs or ESPs. Heterogeneous investigations include both adsorption and

oxidation mechanisms associated with natural surfaces present in the flue gas such as fly ash, but also include surfaces associated with existing control technologies, such as selective catalytic reduction (SCR) catalysts or specific Hg-control technologies such as activated carbon (AC) or precious-metal sorbents and catalysts. The fundamental model investigations carried out to date may be classified into three major categories: homogeneous Hg oxidation kinetics, chemisorption on AC, and adsorption and amalgamation of Hg with precious metals.

24.2 Homogeneous Mercury Oxidation Kinetics

24.2.1 Mercury–Chlorine Chemistry

Gas-phase oxidation occurs primarily via chlorine species originally present in the coal as the gases cool down through the air preheater and air pollution control devices. Thermodynamic calculations predict that Hg oxidation occurs at temperatures below approximately 700 °C and that Hg will be completely oxidized at or below 450 °C [7]. Regardless of the thermodynamic equilibrium model predictions, experimental evidence has found that not all of the Hg is oxidized in the flue gas, regardless of the chlorine content of the coal. These experimental findings have led the Hg control community to determine that Hg oxidation is kinetically, rather than thermodynamically, limited [7]. For this reason, there has been significant investigation of determining accurate Hg oxidation kinetics from quantum-mechanical-based estimates because of the difficulty of the flue-gas measurements.

Some of the first studies to include quantum chemistry into the examination of the oxidation kinetics of Hg for flue-gas applications are those of Sliger *et al*. [8, 9], in which a homogeneous kinetic model for Hg oxidation via chlorine was determined and coupled with bench-scale combustion experiments. On the basis of these experiments, it was found that oxidation increases with increasing HCl concentration, which is consistent with previous experiments carried out by Hall *et al*. [10, 11] Adding to these initial investigations, the work of Wilcox *et al*. [12–14] and Krishnakumar and Helble [15] provide a fairly complete set of Hg oxidation kinetics via Cl-containing compounds for the following set of reactions:

$$Hg + Cl \leftrightarrow HgCl \tag{R1}$$

$$Hg + O \leftrightarrow HgO \tag{R2}$$

$$Hg + Cl_2 \leftrightarrow HgCl + Cl \tag{R3}$$

$$Hg + Cl_2 \leftrightarrow HgCl_2 \tag{R4}$$

$$Hg + HCl \leftrightarrow HgCl + H \quad \text{(R5)}$$

$$Hg + HOCl \leftrightarrow HgCl + OH \quad \text{(R6)}$$

$$HgCl + Cl \leftrightarrow HgCl_2 \quad \text{(R7)}$$

$$HgCl + Cl_2 \leftrightarrow HgCl_2 + Cl \quad \text{(R8)}$$

$$HgCl + HCl \leftrightarrow HgCl_2 + H \quad \text{(R9)}$$

$$HgCl + HOCl \leftrightarrow HgCl_2 + OH \quad \text{(R10)}$$

Reactions 1, 2, 4, and 7 are all unimolecular decomposition reactions in the reverse direction and are often writing in terms of a collision partner "M" on either side of the reaction. The collision partner is omitted here and as such the rate constants reported herein are in units of $cm^3\,mol\,s^{-1}$ for the forward directions and s^{-1} for the reverse directions. If the concentration of the collision partner is taken into account, the forward direction of the recombination reactions would have units of $cm^6\,mol^2\,s^{-1}$. The remaining reactions are classified as bimolecular with reported units of $cm^3\,mol\,s^{-1}$. A variety of quantum-mechanical-based approaches have been carried out to accurately predict the rate constants of R1–R10. As there are limited experimental data available for these reactions, especially at high temperature, the levels of theory employed have been benchmarked against available experimental structural and thermochemical data. A comparison of predicted to measured vibrational frequency and bond distance data is presented in Tables 24.1 and 24.2, respectively. The levels of theory considered in Tables 24.1 and 24.2 are based on previous high-level kinetics predictions that have relied on these combined methods and basis set choices. The methods that have resulted in the most accurate predictions include B3LYP, MP2, MP4, QCISD, QCISD(T), and CCSD(T), and have been used alongside a variety of basis sets. Owing to the large number of electrons in Hg [16], basis sets incorporating relativistic effects for the inner-core electrons are required. The work of Wilcox *et al*. on Hg oxidation via Cl-containing compounds has relied primarily upon two basis sets, that is, the "60VDZ" basis set of the Stevens *et al*. [17] group and the "60MDF" basis set of the Stuttgart [18] group. Both of these basis sets replace 60 of Hg's atomic core electrons with a relativistic effective core potential. The work of Krishnakumar and Helble [15] has relied upon the "SDD" basis set for Hg, which uses Stuttgart [18] pseodopotentials, in addition to the "CEP-121G" basis set, which uses pseodopotentials developed from the Stevens [17] group. For the non-Hg species, either the D95++(3df,3pd) or the Pople 6-311++G(3pd,3df) basis set was used. Both of these basis sets include diffused and polarization functions on the O, Cl, Br, and H atoms. For the prediction of Hg oxidation via Br-containing compounds, Wilcox and Okano [19] used the augmented correlation-consistent basis set developed by Peterson *et al*. [20, 21], termed *AVTZ*.

a) All predictions from Wilcox *et al.* [12–14, 19] with the exception of SDD and CEP-121G basis sets, which were sourced from Krishnakumar and Helble [15].

The predicted vibrational frequencies of the ground states of HgCl, HgBr, HgO, $HgCl_2$, and $HgBr_2$, have all been compared to experimental data, except in the case of HgO, in which experimental data was unavailable. There have been two experimental reports of the single vibrational mode of HgCl reported in the literature, that is, 292.61 [22] and 298.97 cm^{-1} [23] and a number of experimental investigations [25–28] on the vibrational modes of $HgCl_2$. From Table 24.1 it can be seen that the QCISD (CEP-121G, 60VDZ) and MP2/CEP-121G levels of theory agree best with experiment. In addition, the QCISD/60VDZ level of theory was also able to accurately predict the vibrational frequencies of $HgCl_2$. A number of experimental measurements [24, 27, 29–31, 33] have also been made on HgBr and $HgBr_2$, and a comparison of experiment to prediction shown in Table 24.1 indicates that the CCSD(T)/AVTZ level of theory is the most accurate.

Table 24.1 also includes a comparison of the predicted equilibrium bond distances to available measured data. Experimental measurements [34–36] of HgCl bond distances range from 2.23 to 2.50 Å. All of the levels of theory investigated predict bond distances within this range. The experimental bond distances [34, 38, 39] for $HgCl_2$ range from 2.25 to 2.44, and again, both levels of theory considered

Table 24.2 Comparison between experimental and theoretical bond lengths (Å) for various mercury-containing compounds.

Molecular species	Bond length (Å)		Level of theory[a)]
	Experiment	Prediction	
HgCl	2.23–2.50 [34–36]	2.40	MP4/SDD
		2.41	QCISD (CEP-121G; 60VDZ) QCISD(T)/SDD
		2.48	B3LYP/60VDZ
		2.49	MP2/CEP-121G
HgBr	2.62 [24]	2.62	B3LYP/60VDZ
		2.64	B3LYP/60MDF
		2.70	CCSD(T)/AVTZ
HgO	2.03 [37]	2.07	QCISD(T)/60VDZ
$HgCl_2$	2.25–2.44 [34, 38, 39]	2.30	QCISD/60VDZ
		2.32	B3LYP/60VDZ
$HgBr_2$	2.378 [40]	2.40	CCSD(T)/AVTZ
		2.46	B3LYP (60MDF; 60VDZ)

a) All predictions from Wilcox *et al.* [12–14, 19] with the exception of SDD and CEP-121G basis sets, which were sourced from Krishnakumar and Helble [15].

provide accurate predictions. The QCISD(T)/60VDZ level of theory predicts a bond distance of 2.07 Å for HgO, which agrees reasonably well with the experimental value [37] of 2.03 Å from X-ray diffraction measurements. The HgBr bond distance was measured by Tellinghuisen and Ashmore [24] using emissions spectra photography, with an estimated bond distance of 2.62 Å, which matches exactly with the predicted value from B3LYP/60VDZ. Experimental results of Deyanov *et al.* [40] yield an Hg–Br bond distance within the $HgBr_2$ molecule of 2.378 Å. In general, the CCSD(T)/AVTZ level of theory predicts both the HgBr and $HgBr_2$ geometries reasonably accurately, deviating from experiment by 0.08 and 0.03 Å, respectively.

In addition to the spectroscopic and structure comparison, the enthalpy changes of the reactions of interest have also been predicted and directly compared to available experimental data. Table 24.3 shows both thermochemical and kinetic parameter predictions along with available experimental estimates for reaction enthalpies. In particular, Reaction 1 has received a lot of attention because of the discrepancies reported in the literature and it has been established as the rate-determining step for homogeneous Hg oxidation. The rate constant has been measured experimentally by Donohoue *et al.* [41] using laser-induced fluorescence and by Horne *et al.* [42] using flash photolysis. An effective second-order rate constant of $4.57 \times 10^{11}\,cm^3\,mol\,s^{-1}$ was calculated by Donohoue *et al.* from their reported Arrhenius expression at 260 K and 1 atm. Similarly, the second-order rate constant reported by Horne *et al.* at 393 K and 1 atm is $1.95 \times 10^{13}\,cm^3\,mol\,s^{-1}$. There has been one quantum-based theoretic prediction for the rate constant of the forward recombination pathway of Reaction 1 by

Table 24.3 Comparison between thermochemical (reaction enthalpy) and kinetic (rate constant) parameters of mercury oxidation via chlorine-containing compounds over various levels of theory.

Reaction	*Thermochemistry*		*Kinetics*		Level of theory

a) Temperature-dependent rate expression is $k = AT e^{-E_a/RT}$.
b) Units of A are in per second.
c) Temperature-dependent rate expression is $k = A\left(\frac{T}{298}\right)^{-n}$, with n listed in the E_a column.
d) Temperature-dependent rate expression is $k = AT e^{-E_a/RT}$.
e) Temperature-dependent rate expression is $k = AT^{2.4} e^{-E_a/RT}$.
Numbers in parentheses represent powers of 10.

Krishnakumar and Helble [15] at the MP2/CEP-121G level of theory, which is 3.77×10^9 and 1.52×10^{10} cm^3 mol s^{-1} at 260 and 939 K, respectively. The reverse rate constant of Reaction 1 may be estimated on the basis of available experimental equilibrium constant as the equilibrium constant is equal to the ratio of the forward and reverse rate constants. The reverse unimolecular decomposition of HgCl was investigated by Wilcox *et al*. [14] at the QCISD/60DVZ level of theory with a prediction of 1.45×10^4 s^{-1}, compared to the experimentally calculated estimate of 4.31×10^3 s^{-1}, derived from the measurement of Horne *et al*. at 393 K and 1 atm. Both MP2/CEP-121G and QCISD/60VDZ levels of theory predict the heat of reaction for HgCl decomposition accurately to within 1 kcal mol^{-1}, as shown in Table 24.3.

For the HgO formation reaction (R2), both the forward and reverse rate constants have been predicted by Wilcox [13] at 1 atm and over a temperature range of 298–2000 K, with the kinetic parameters of the forward recombination reaction presented in Table 24.3. It is noted that the thermal decomposition temperature of mercuric oxide is 773 K. There are no experimental rate constant data to compare to, but the heat of reaction has been compared against previously reported theoretical and experimental estimates. Estimating the enthalpy of formation of HgO has received a great deal of attention in the literature, and this formation enthalpy is required for accurate estimation of the reaction enthalpy. Theoretical calculations [39, 43, 44] have reported enthalpies of formation ranging between 60.2 and 81.2 kcal mol^{-1}, with an experimental estimate [38] of 10 kcal mol^{-1}. The reaction enthalpy estimates are listed in Table 24.3 and range from −4.00 to −13.97 kcal mol^{-1} based on theory to −64.22 kcal mol^{-1} based on experiment. The QCISD(T)/60VDZ level of theory predicts an enthalpy of reaction of −10.58, which agrees well with previous estimates and was used to determine the temperature-dependent rate constant parameters at 1 atm. Both thermochemical and kinetic parameters are available in Table 24.3 for Reactions 3–10, with the details of comparison and calculation available in the original work of these previous studies. The goal of these fundamental gas-phase submodels is to provide kinetic data to global reaction models that would otherwise be deficient owing to the limited experimental data available over the flue-gas temperature range of interest.

Bench-scale simulated flue-gas experiments have been carried out by Fry *et al*. [45] and Cauch *et al*. [1] to accurately measure Hg oxidation as a function of quench rate. Fry *et al*. [45] carried out experiments to evaluate the effects of quench rate and quartz surface area on Hg oxidation and performed a detailed kinetic modeling analysis of homogeneous Hg oxidation reactions. In their system, Hg and Cl_2 are injected into a natural gas-fired premixed burner to produce a radical pool representative of real combustion systems and passed through a quenching section following the hot temperature region in the furnace as the quench rate of the flue gas can influence the extent of Hg oxidation. Two different temperature profiles were employed, producing quench rates of −210 and −440 K s^{-1}. The Hg concentration in the reactor was 25 μg m^{-3}, while Cl_2 concentrations ranged from 100 to 600 ppmv (equivalent HCl concentration).

At Cl_2 concentrations of 200 ppmv, the larger quench rate resulted in a 52% increase in Hg oxidation compared to the lower quench rate. On the basis of kinetic modeling of the post-flame chlorine species, it was assumed that the Cl_2 molecules are converted to Cl radical species as they pass through the flame and then are subsequently converted predominantly to HCl. When investigating the effect of surface area of the quartz reactor, a threefold increase in surface area resulted in a 19% decrease in Hg oxidation, which is explained by the chlorine radical termination at the surface. It was concluded that quartz surfaces do not catalyze Hg oxidation reactions, but inhibit them, and that these surface interactions are negligible.

Recent experimental results of Cauch *et al*. [1] have shown that previously reported homogeneous Hg oxidation in the presence of chlorine may be exaggerated because of bias when using wet-chemistry measurement techniques. Linak *et al*. [46] have shown that Cl_2, in a simulated flue gas in the absence of SO_2, creates a bias in the Ontario Hydro method and overpredicts the concentrations of oxidized Hg. It has been shown that as little as 1 ppmv Cl_2 is enough to create a bias of 10–20% in the amount of oxidized Hg captured in the KCl solution. Within this study, the bias was eliminated by adding SO_2 to the flue gas or adding sodium thiosulfate ($Na_2S_2O_3$) to the KCl impinger. Similarly, Ryan and Keeney [47], in an actual flue-gas environment, have demonstrated that 10 ppmv Cl_2 added to the flue gas without SO_2 results in 91.5% oxidized Hg, with a decrease to 39% when the KCl impingers are spiked with sodium thiosulfate. A simulation study has been carried out by Gharebaghi *et al*. [4, 5] using the results from the experiments of Cauch *et al*. [1] with the corrected conditioning system to test the performance of the fundamental homogeneous Hg oxidation kinetics. Simulation of Hg speciation was carried out using the PREMIX module of the CHEMKIN II software package [48]. The Arrhenius parameters for the model predictions were taken from a combination of sources, with Reactions 1, 3, 5–10 included in the model in particular. The experimental rate constant determined by Donohoue *et al*. [41] was used for Reaction 1, model predictions from Niksa *et al*. [49] were used for Reactions 3 and 7, and quantum-level theoretical predictions were provided from Wilcox *et al*. [12, 14] for Reactions 5, 6, 8–10. Additional supporting mechanisms include chlorine chemistry from Roesler *et al*. [50], C/H/O mechanism by Dreyer *et al*. [51], and the Leeds SO_x and NO_x mechanism [52], resulting in a global combustion model of 80 species and 361 reactions. Figure 24.1 shows the results of the simulation predictions and their comparison to the bench-scale experiments of Cauch *et al*. [1] The model provides reasonable agreement with the experimental data at the 440 K s^{-1} quench rate, but underpredicts the data at 210 K s^{-1}.

The experimentally derived activation energies and rate constants can have significant errors due to wall effects as well as uncertainties in the determination of mercury and its compounds down to parts per billion and lower levels in flue gas. Noting these potentially large experimental uncertainties introduced by heterogeneous chemistry occurring on the reactor walls, and the measurement uncertainties, the models appear to reasonably reflect the experimental data.

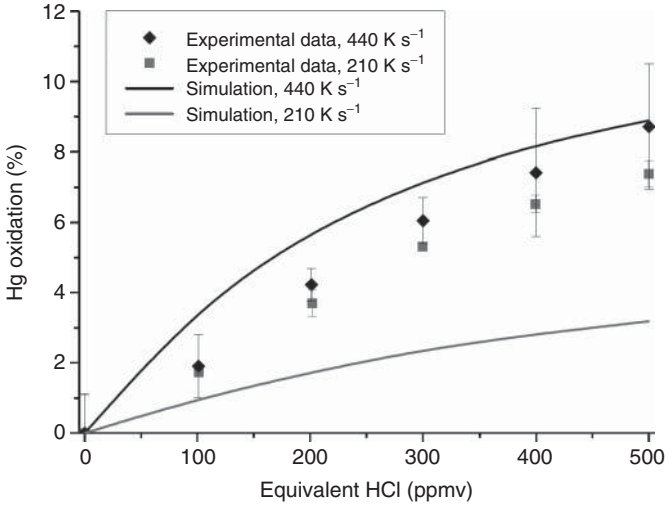

Figure 24.1 Error bars represent the standard deviation from analysis of multiple experiments.

24.2.2 Mercury–Bromine Chemistry

Significant attention has been paid to Hg oxidation via bromine, in addition to chlorine, because of the enhanced Hg oxidation kinetics of Br-containing compounds. Previous investigations report that bromine reacts faster than chlorine toward the production of $HgBr_2$. Similar to the Hg oxidation reactions involving Cl-containing species, Gharebaghi *et al.* [4] have also simulated Hg oxidation based on the following reactions:

$$Hg + Br \leftrightarrow HgBr \quad \text{(R11)}$$

$$Hg + Br_2 \leftrightarrow HgBr + Br \quad \text{(R12)}$$

$$Hg + HBr \leftrightarrow HgBr + H \quad \text{(R13)}$$

$$Hg + HOBr \leftrightarrow HgBr + OH \quad \text{(R14)}$$

$$HgBr + Br \leftrightarrow HgBr_2 \quad \text{(R15)}$$

$$HgBr + Br_2 \leftrightarrow HgBr_2 + Br \quad \text{(R16)}$$

$$HgBr + HBr \leftrightarrow HgBr_2 + H \quad \text{(R17)}$$

$$HgBr + HOBr \leftrightarrow HgBr_2 + OH \quad \text{(R18)}$$

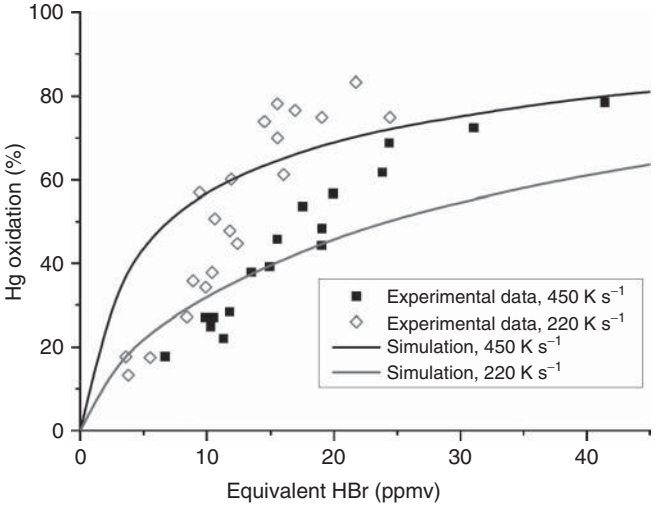

Figure 24.2 Comparison of measured and predicted Hg oxidation with HBr addition at two different reactor temperature quench rates [4].

Similar to the methodology previously discussed, Gharebaghi *et al*. [4] have used a variety of fundamentally derived rate parameters to simulate the global oxidation behavior of these reactions and have directly compared to experimental predictions of Cauch *et al*. [1], as shown in Figure 24.2. The rate parameters of Reaction 11 were taken from the experiments of Donohoue *et al*. [53] using laser-induced fluorescence, while the rate parameters of Reactions 14, 16, and 18 were taken from work carried out by Niksa *et al*. [54] The rate parameters for Reaction 15 was calculated from first principles by Goodsite *et al*. [55], while the parameters for Reactions 12, 13, and 17 were provided by Wilcox and Okano [19] and are based on first-principle quantum mechanical calculations. Table 24.4 provides a fairly complete list of thermochemical and kinetic parameters associated with 8 of the 10 Hg–Br reactions of interest. In previous work, Wilcox and Okano [19] compared their predicted rate data of Reactions 11, 12, and 15 to available experimental [53, 56] and theoretical [55–60] data in the literature. In particular, the theoretical rate constant prediction of 3.84×10^{11} cm^3 mol s^{-1} at the CCSD(T)/AVTZ level of theory for the forward direction of Reaction 11 agrees well with other theoretical [56–59] (ranging between 1.80×10^{11} and 1.92×10^{12} cm^3 mol s^{-1}) and experimental [53] (ranging between 1.08×10^{11} and 3.25×10^{11} cm^3 mol s^{-1}) estimates at 298 K and 1 atm. In addition, for Reaction 12, the theoretical rate constant prediction of 9.9×10^{-8} cm^3 mol s^{-1} at the B3LYP/60VDZ level of theory for the forward direction agrees well with a slight underprediction compared to other theoretical calculations [60], which range between 1.96×10^{-7} and 3.25×10^{-7} cm^3 mol s^{-1} at 298 K and 1 atm. Additional details are available in the manuscript of Wilcox and Okano [19].

Table 24.4 Comparison between thermochemical (reaction enthalpy) and kinetic (rate constant) parameters of mercury oxidation via bromine-containing compounds over various levels of theory.

Reaction	*Thermochemistry*		*Kinetics*		Level of theory [19]
	ΔH_{rxn} (kcal mol^{-1})		A (cm^3 mol s^{-1})	E_a (kcal mol^{-1})	
	Experiment [38]	Prediction	Prediction

a) Temperature-dependent rate expression is $k = A\left(\frac{T}{298}\right)^{-n}$ with n listed in the E_a column.
Numbers in parentheses represent powers of 10.

The concentration of equivalent HBr was varied between 0 and 45 ppmv compared to a range of 0–500 ppmv of equivalent HCl as HBr dissociates more readily than HCl, resulting in a greater quantity of Br radicals for Hg oxidation. The homogeneous Hg oxidation model via bromine predicts that oxidation begins at a higher temperature than in the case of chlorine, at approximately 1100 K compared to 800 K (chlorine). The simulated results are in reasonable agreement with experiment for the 450 K s^{-1} quench rate above 25 ppmv equivalent HBr, but overestimate oxidation at lower concentrations. On the other hand, for the 220 K s^{-1} quench rate, the simulations underpredict oxidation at high temperature and show reasonable agreement at concentrations less than 10 ppmv equivalent HBr. Owing to the disagreement between the simulation predictions and experiments, it is clear that additional work is still required in this area. It is also noted that there is substantial uncertainty in the experimentally derived kinetic parameters.

From these previous combined modeling-experimental studies it is clear that homogeneous Hg oxidation is only one aspect of the complete mechanism in the complex flue-gas environment. In reality, surfaces are present in the form of unburned carbon, which may serve to both adsorb and oxidize Hg. Oxidized Hg may be captured in existing downstream wet FGD units and Hg^p may be captured via ESPs or FFs. Therefore, understanding the mechanism of Hg reactivity across carbon surfaces is imperative to its effective control.

24.3
Heterogeneous Chemistry

24.3.1
Mercury Adsorption on Activated Carbon

AC has been extensively tested in laboratory- and full-scale systems and has shown the capacity to capture both elemental and oxidized Hg in coal combustion flue gas. A relatively large amount of AC injection is required for the control of Hg from subbituminous-coal- or lignite-combustion flue gas. Depending on the system conditions, an AC-to-mercury mass ratio of at least 3000–20 000 (C/Hg) may be necessary to achieve 90% Hg removal [61–63]. Currently, the design of more effective Hg capture technology is limited by incomplete understanding of the mechanism(s) of Hg oxidation and adsorption on carbon surfaces [64].

The development of accurate fundamental models for Hg–AC reactivity requires careful characterization experiments on materials exposed to well-controlled reaction conditions. Therefore, an overview of such experiments will be discussed before the theoretical model efforts. It is generally accepted that acidic sites on the surface are responsible for elemental Hg capture on AC [65, 66]. In its atomic state, Hg acts as a base in that it has the propensity to oxidize (i.e., donates electrons to a surface or another gas-phase molecule); therefore, Hg will readily interact with acidic sites on the carbon surface. However, once oxidized, and thus acidic in nature, Hg species are thought to compete with acidic gases for the basic sites available on the carbon surface.

The presence of halogens (i.e., bromine, chlorine, and iodine) promotes Hg oxidation on carbon surfaces [66, 67]. Subsequently, AC demonstrates higher Hg removal performance in the flue gas of coals with greater chlorine content, as the combustion of such coal results in a higher concentration of HCl in the flue gas. Hutson *et al*. [68] exposed brominated and chlorinated AC to Hg-laden simulated flue gas and characterized the sorbents using X-ray absorption spectroscopy (XAS) and X-ray photoelectron spectroscopy (XPS). Within this work no evidence was found for homogeneous oxidation of Hg, and no Hg was found present on the AC surface; however, oxidized Hg was found on the surface, present as a chlorinated or brominated species. It is important to note that owing to the low coverage of Hg on the carbon, the speciation of Hg was not determined. Given the results, the authors proposed Hg capture on chlorinated and brominated carbons occurs via surface oxidation of Hg with subsequent adsorption on the carbon surface. Similar to its role in homogeneous Hg oxidation, bromine is thought to have a stronger promotional effect on Hg oxidation/adsorption, but the reason for the difference between bromine and chlorine is not well understood. Recently, the Hg oxidation was demonstrated on a wood-derived Cl-promoted AC in both N_2 and flue gas [69]. The adsorption of Hg on AC was shown to be a chemisorption process, where all Hg was oxidized to Hg^{2+} on the surface as a result of chlorine promotion. While chlorine was consumed, Hg^{2+} was still noted as being present in the outlet gas, indicating that the AC was also capable of catalyzing Hg oxidation.

Huggins *et al*. [70] characterized AC samples after testing in Hg-laden simulated flue-gas conditions using X-ray absorption fine structure (XAFS) spectroscopy. The XAFS results revealed that chlorine and sulfur are adsorbed on the AC surface after exposure to HCl and SO_2, and Hg-anion chemical bonds are formed in the sorbent materials. They suggest that the acidic flue-gas species (e.g., HCl, HNO_3, H_2SO_4) promote the creation of active sites for Hg chemisorption on the carbon surface, and that an oxidation process, either in the gas phase or simultaneously as the Hg atom interacts with the sorbents, is involved in the capture of Hg. Olson *et al*. [66] performed fixed-bed tests with various gas conditions for Hg and $HgCl_2$ adsorption on AC and found that the presence of both HCl and NO_2 reduced the induction period of Hg oxidation, and that in general acid flue-gas components significantly impacted the adsorption of oxidized Hg species. The formation and presence of the oxidized form, $Hg(NO_3)_2$, was observed in the effluent gas in the presence of NO_2, but in the absence of HCl. Laumb *et al*. [71] carried out surface analyses using XPS on ACs exposed to Hg-laden simulated flue gas (e.g., SO_2, NO_2, HCl, H_2O), but were unable to determine the oxidative state of surface-bound Hg due to interference with silicon (Si), which is present at comparable levels to Hg within the carbon matrix. Wilcox *et al*. [72] investigated the binding mechanism of Hg on brominated AC sorbents with a combination of XPS and theoretical modeling. It was found that Hg exists in the oxidized forms on brominated carbon surfaces, as shown in Figure 24.3.

Ab initio electronic structure investigations based on density functional theory (DFT) have been conducted to elucidate the interaction of Hg with AC, using simplified carbon models to represent AC. There have been a limited number of theoretical investigations, and, to the authors' knowledge, the effect of acid flue-gas species on Hg-AC interactions has not been investigated. AC is very difficult to model given its highly inhomogeneous structure. Several initial theoretical investigations have been conducted using cluster models to represent graphene, ranging from single benzene rings [73] to multiple fused rings [74] with embedded halogens as shown in Figure 24.4.

Carbon with Cl-containing functional groups exhibits enhanced Hg adsorption capacity. Furthermore, the most stable Hg surface species was HgCl, while Hg and $HgCl_2$ were found to be thermodynamically unstable on these simplified surfaces of AC [74]. Theoretical calculations by Olson *et al*. [76] supported the role of acidic sites on the AC in Hg capture. They hypothesized that HCl is energetically stable at the cationic zigzag edge sites of AC and proposed three possible models of Hg oxidation:

1) Hg charge transfer complex forms on the cationic center of HCl on AC and is subsequently attacked by Cl^-,
2) elemental Hg interacts simultaneously with the cationic HCl-AC site and Cl^-, or
3) oxidation by the dictation site formed by HCl and NO_2 on AC.

Olsen *et al*. [76] suggested that Hg has the propensity to be oxidized by donating its electrons to a surface or another gas-phase molecule; therefore, in its elemental

state, Hg acts as a Lewis base with the desire to interact with an acidic site, thereby forming a strong C–Hg covalent bond on the carbon surface.

More recent investigations have used plane-wave DFT to model AC, which allows for the use of periodic systems such as a graphene. Graphene ribbons with exposed edge sites have been used for investigations of the reactivity of carbonaceous surfaces to various gas species [77]. Several investigations support the zigzag carbene structure model, where the zigzag edge site acts as a Lewis base and reacts with acid gas components thereby serving as a potential adsorption site for oxidized Hg [77, 78]. A recent DFT study [79] on the effect of chemical functional groups on Hg adsorption on carbon surfaces supports this suggestion. The study indicates that an embedded halogen atom promotes chemisorption on the neighboring site, which is consistent with experimental results, and indicative of Hg oxidation. Results also indicate a varying effect of organic groups on Hg adsorption, with lactone, carbonyl, and semiquinone groups promoting Hg chemisorption while phenol and carboxyl functional groups promote physisorption and reduce overall Hg capture. A mechanistic study of Hg oxidation due to halides on carbon materials proposes that the interactions of microcrystalline graphitic structures with halide ions result in the withdrawal of electrons from the graphitic structure, producing a strong Lewis

acid site [80], with Hg adsorption combined with the electron-transfer results in Hg oxidation.

To date, little work has been conducted on the effect of Br on Hg-AC interactions. Wilcox *et al*. [72] investigated the binding mechanism of Hg on brominated AC sorbents with a combination of experimental work, as discussed previously, and quantum-mechanical modeling using a nine-benzene-rings-wide graphene ribbon. Consistent with Padak and Wilcox's [75] results for Hg adsorption in the presence of chlorine, it was found that HgBr species are more stable on the carbon surface than $HgBr_2$ species. Furthermore, DFT and density of states (DOSs) calculations indicate that Hg is more stable when it is bound to the edge C atom interacting with a single Br atom bound atop of Hg. However, while the form of Hg adsorbed on the AC surface may be oxidized, the exact speciation of the adsorbed Hg is remains in question. Furthermore, the Hg adsorption mechanism on the carbon surface and the effects of the flue-gas components are not well understood. Additional work, including closely coupled experimental and theoretical investigations, is required to determine the binding mechanism of Hg on AC sorbents in various flue-gas environments and to further elucidate the adsorption mechanism of Hg on AC.

24.3.2 Mercury Adsorption on Precious Metals

In general, precious metal adsorption of Hg has been applied to Hg capture from fuel gases of coal gasification processes as these metals, in contrast to carbon-based sorbents, may withstand the high temperatures of gasification processes. For gasification applications, the product is termed a *fuel gas*, and consists primarily of H_2, CO_2, and CO, while in the case of traditional coal combustion, the exhaust gas is termed a *flue gas* and is comprised primarily of N_2 and CO_2.

Precious metals, including palladium (Pd), platinum (Pt), gold (Au), iridium (Ir), and rhodium (Rh), have traditionally been used as modifiers for graphite-tube atomic absorption or emission analysis of solid and liquid samples. Among them, Pd has been identified as the best modifier for the adsorption of Hg [16]. In a study carried out by Steckel [81], DFT is used to carry out electronic structure calculations on slab models representing the (001) and (111) surfaces of silver (Ag), Au, copper (Cu), nickel (Ni), Pd, and Pt. Relatively strong binding for all of the metals was noted, with binding energies of ~1 eV for Pt and Pd. However, the DFT method used appears to underestimate the adsorption energy when compared directly to experimental results. Mercury has been predicted to have a stronger bond with the (001) surface, where fourfold hollow sites exist, in contrast to the threefold hollow sites on (111) surfaces. Aboud *et al*. [82] performed a DFT study of Pd alloyed with small amounts Au, Ag, and Cu and found that doping of the Pd surface increased the overall binding energy of Hg, which is beneficial for a sorption process. Furthermore, the binding energy increased the most when the dopants remained subsurface. In a continuation of the work, Sasmaz *et al*. [83] showed that Pd is primarily responsible for interacting with Hg in both alloys and

overlays and that the interaction is a result of overlap between the s- and p-states of Pd and the d-state of Hg. Figure 24.5 shows various adsorption sites of Hg on binary alloys and overlays of Pd with other metals, M, such that M represents either gold, silver, or copper.

Jain *et al*. [84] theoretically screened potential high-temperature metal sorbents for Hg capture in syngas streams. Using DFT predictions, the enthalpy of amalgamation and oxidation for metals was evaluated to predict the capability of Hg sorption and oxidation in the gas stream, demonstrating that Pd has the highest amalgamation enthalpy of all metals. Figure 24.6 shows the Hg amalgam formation enthalpy versus the binary oxide formation enthalpy to clarify the tendency of various metals for amalgamation and oxidation. Metals above the O_2 gas chemical potential line (i.e., dashed horizontal line) are estimated to form oxides and metals to the right of the Hg gas chemical potential (i.e., dashed vertical line) are estimated to form amalgams in the syngas stream. Metals satisfying both criteria (i.e., Section (II) in Figure 24.6) were found to form oxides rather than amalgams according to the grand canonical potential predictions. An ideal metal, which amalgamates without oxidizing, is located in Section (IV) of Figure 24.6. No metals are available in the most desirable area, but Pd is the closest to the area, indicating that Pd is the most promising metal for Hg capture.

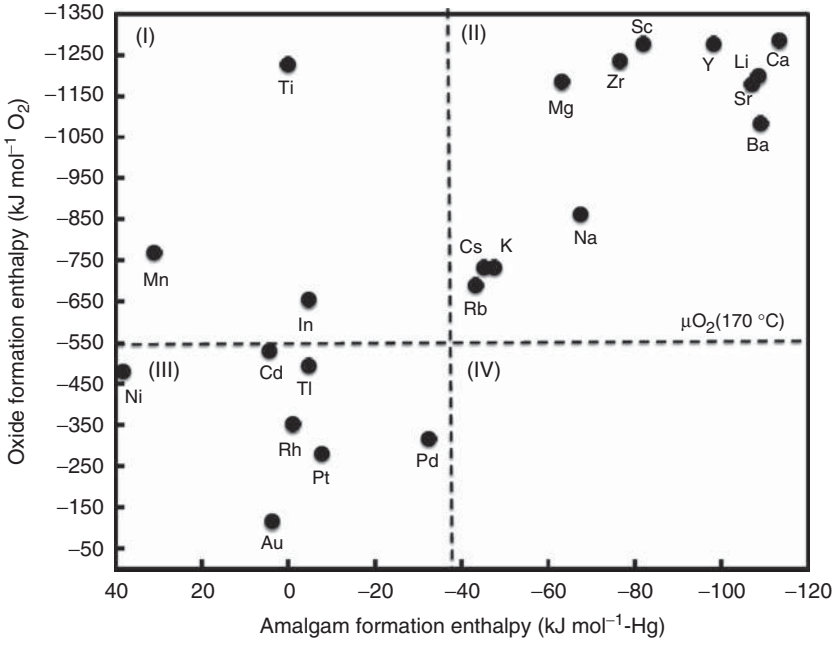

Figure 24.6 Estimated amalgam formation enthalpies of binary Hg amalgam versus binary oxide, normalized per mol of Hg and per mol of O_2, respectively. Dashed horizontal and vertical lines represent the O_2 gas and Hg gas chemical potentials, respectively [84]. (Reprinted with permission from (Jain et al., Chem. Eng. Sci., 65, 3025,2010). Copyright (2010) Elsevier.)

Earlier experiments have validated the mechanisms of reactivity proposed by theory. For example, Baltrus *et al*. [85, 86] showed some evidence of Hg amalgamation on Pd/Al_2O_3. Maximum Hg adsorption on Pd/Al_2O_3 occurs at 204 °C and at low loadings of Pd (<8.5 wt% Pd). An interesting finding is that Hg adsorption is suppressed by an excess of As; however, H_2S in fuel gas can improve this imbalance by moderately inhibiting the As adsorption while enhancing the Hg adsorption [86]. Poulston *et al*. [87] compared the Hg removal capacities of Pd and Pt sorbents supported on alumina and found that Pd is superior to Pt sorbents for Hg removal. This trend is supported by Figure 24.5, which indicates that Pt is located farther from the Section (IV) than Pd. The Hg removal capacity of both Pd and Pt sorbents increase with metal loading but decreases with sorbent temperature. Although most metal sorbent candidates exhibit poor capacities for Hg at temperatures greater than 204 °C, Pd proves to be an attractive sorbent for the Hg removal at elevated temperatures [16]. Fuel-gas substances that may affect the Hg adsorption on metal sorbents may include moisture, H_2S, CO, and H_2 [16]. Baldeck *et al*. [88] presented data on the use of Au traps for the quantitative fuel-gas separation of Hg in the form of an amalgam of Au_2Hg_3. It was suggested that Hg removal on Au is not affected by corrosive substances such as SO_2, H_2S, and organic compounds that may be present in flue gas.

24.4
Conclusions and Future Work

Atomistic modeling efforts have resulted in important insight into the homogeneous and heterogeneous mercury chemistry in power plant flue gases. Future work may focus upon the heterogeneous chemistry of mercury on common fly ash metal oxides, the ductwork walls within the power plants, and the SCR catalysts employed for reduction of NO*x*. Recent and past works [62, 89, 90] hint at a possible important role for iodine and its compounds for promoting the oxidation of mercury in flue gas. It is suggested that further work is merited on the halogens, including both the heterogeneous chemistry on carbon, as well as the gas phase chemistry involving chlorine, bromine, and iodine species.

Predicting Hg Emissions Rates with Device-Level Models and Reaction Mechanisms

Stephen Niksa and Balaji Krishnakumar

25.1
Introduction and Scope

At the turn of the past century, the American utility industry needed to demonstrate which Hg control technologies could be immediately deployed to comply with impending regulations on Hg emissions from coal-fired power plants. This imperative was confounded by the large number of factors that affected Hg emissions, because even Environmental Protection Agency's (EPAs) first Information Collection Request (ICR) testing program had shown that fuel quality, the configuration of units in the gas cleaning system, and numerous gas cleaning conditions affected Hg speciation; hence, the prospects for controlling Hg emissions.

While the bulk of the R&D community was compiling a database of field test measurements that covered the most common fuels, unit configurations, cleaning conditions, and external Hg controls, a small group set out to develop reaction mechanisms and models that could, first, quantitatively interpret the field test database and, ultimately, predict Hg emissions for a particular gas cleaning system as accurately as the Hg speciation could be monitored. Statistical approaches based on regressions of various types of test data never achieved the accuracy needed for strategic compliance planning [1–4]. But some of the approaches based on reaction mechanisms did, and are now being used by both utility companies and original equipment manufacturers to forecast Hg emissions at individual plants and across regional fleets of power stations.

Our collection of reaction mechanisms, called *MercuRator*™ in its commercial implementation, is the basis for this survey of reaction mechanisms that can accurately predict Hg emissions across the entire domain of commercial gas cleaning conditions. Over two dozen previously published articles [5] have evaluated the quantitative accuracy of the model predictions for an assortment of gas cleaning situations, to demonstrate the predictive capabilities. In total, more than 200 field test datasets have been quantitatively interpreted, usually within measurement uncertainties. Here we simply acknowledge that

Mercury Control: for Coal-Derived Gas Streams, First Edition.

MercuRator™ predicts Hg emissions within the measurement uncertainties for any coal in any cleaning configuration across the commercial domain of gas cleaning conditions and, on the basis of that performance, use the mechanisms to assess the most important factors in the practice of Hg emissions control.

25.2 The Reaction System

Our scope covers the properties, compositions, quantities, and operating conditions needed to predict Hg speciation and removals along full-scale flue gas cleaning systems. Pilot-scale gas cleaning systems are also relevant, although the primary reaction systems of interest are commercial. The most important consideration is the distribution of Hg species at all points along the cleaning system; the so-called Hg speciation. Hg vapors are grouped into two forms, elemental (Hg^0) and oxidized (Hg^{2+}), while a single species, particulate Hg (Hg_p), is bound to the unburned carbon (UBC) in fly ash or to injected carbon sorbents. Speciation is crucial to Hg emissions control because Hg^{2+} is completely soluble in flue gas desulfurization (FGD) scrubber solutions (neglecting any reemission of Hg^0 from the FGD solution), whereas Hg^0 is completely insoluble, and Hg_p is removed in any particle collection device (PCD) in proportion to the collection efficiency for UBC, which usually approaches 100%. Consequently, in cleaning systems that effectively capture Hg^{2+} in wet flue gas desulfurization (WFGD) and Hg_p in an electrostatic precipitator (ESP) or fabric (or baghouse) filter (FF), nearly all the Hg leaving the stack will be Hg^0. But in systems without an FGD, the Hg stack emissions will be a mixture of Hg^0 and Hg^{2+} species. Contributions to the stack emissions from Hg_p are almost always negligible for plants with PCDs.

The power plant is first subdivided into a furnace and a gas cleaning system, which are connected at the furnace exit plane upstream of the economizer (ECN). The gas cleaning system is a continuous series of heat exchangers and air pollution control devices (APCDs). Most systems move the flue gas through an ECN into a selective catalytic reduction (SCR) unit, if present; through an air preheater (APH) into a PCD, which is usually a cold-side electrostatic precipitator (ESPc) or FF or mechanical or venturi particle scrubber; and on through a WFGD, if present, and into the stack. One popular variation uses lime injected into a spray drier absorber (SDA) to remove SO_X followed by a FF to recover particulates. Another variation locates the ESP immediately downstream of the ECN (hot-side electrostatic precipitator (ESPh)), and may or may not have a FF downstream of the APH. The gas cleaning configuration is the sequence of units in the cleaning system. Ductwork that connects these units is apportioned to the adjacent units.

The two forms of Hg control are inherent and external. Inherent controls rely on the Hg transformations (and capture) within APCDs primarily devoted to controlling other pollutants, such as an SCR for $deNO_X$ and WFGD and SDA for $deSO_X$. External Hg controls are technologies added to a power plant

specifically to control Hg emissions. The most popular examples are (i) activated carbon injection (ACI) with conventional or brominated carbon sorbents; (ii) addition of halogenation agents to supplement the concentrations of either Cl or Br species in the flue gas; and (iii) additives to WFGDs to ensure that dissolved Hg(II) species are not reemitted into the flue gas as Hg^0. Numerous other control strategies are being developed, including dedicated Hg oxidation units upstream of WFGDs when no SCR is present and various non-carbon sorbents. These are beyond the scope of this article because they are not yet commercially important. Fuel preprocessing to reduce the Hg content, either with froth flotation or density classification schemes or with thermal treatments, are also beyond our scope on the assumption that the Hg content and composition of the fuel fed into a furnace must always be known in advance to forecast the Hg stack emissions.

We assume that flow through the ductwork and heat exchangers in a cleaning system is fully developed and turbulent, so that the concentrations of all flue gas species may be analyzed in a single spatial dimension or in the transit time. Mixing is more important wherever sorbents or halogenation agents are injected into the flow, although the applications community generally appreciates the importance of uniform dispersion of Hg control agents over the flow duct area (notwithstanding several early injector design issues). In contrast, the flows through the channels in an SCR monolith are laminar, by design, as are the flows through the plate spacings within ESPs.

Early analytical work established that the Hg speciation at equilibrium should become dominated by sulfates in the condensed phase at PCD operating temperatures, but these species have never been detected. Instead, measured Hg speciation spans the full gamut from negligible to predominant Hg_p at the PCD, along with negligible to predominant levels of Hg^0 or Hg^{2+}, depending on numerous parametric factors. So equilibrium compositions are irrelevant to Hg emissions prediction. Consequently, our analytical framework will be a time-dependent analysis governed by the chemical reaction kinetics. Such an analysis can only be implemented if supported by an assortment of operating conditions, each specified as a function of the transit time. The most important is the thermal history, which is the mean flue gas temperature as a function of transit time. As seen subsequently, it consists of a series of quench stages for each heat exchanger interrupted by isothermal stages for the SCR, PCD, and WFGD. To incorporate realistic chemical reaction mechanisms, the flue gas composition based on all major species (O_2, H_2O, CO_2, N_2) must be specified, along with several key minor species concentrations (NO, SO_2, SO_3, HCl, total Br, and total Hg). The fly ash loading and its variation in transit time (due to the variable gas density along the quench cycle) must be specified. The UBC level in fly ash is estimated from a measured loss-on-ignition (LOI) level. The UBC specific surface area, in square meters per gram, is also required. Note that the total surface area (and activation) of UBC varies in transit time because the fly ash loading changes, even while LOI and the specific surface area stay the same as the fly ash moves through the cleaning system. Despite many claims to the

contrary in older literature, the participation of any of the mineral phases in fly ash in Hg transformations has never been demonstrated, so we regard UBC as the only reaction substrate in the fly ash. Many other pertinent APCD-specific operating conditions are introduced later, when the Hg transformations through each unit are described.

25.3 Hg Transformations

The following four distinct stages of Hg transformations must be characterized: in-furnace, in-flight, along SCR catalysts, and within WFGDs and SDAs. The in-furnace transformations are rudimentary for Hg, but also cover several much more subtle connections among the ways that pulverized fuels (p.f.s) are injected into furnaces and subsequent Hg conversion throughout gas cleaning systems. In-flight Hg transformations are determined by chemistry in the flue gas stream as it moves through the heat exchangers, ductwork, and PCDs in a cleaning system. The governing chemistry comes in two forms: heterogeneous Hg chemistry occurs via the interaction of select flue gas species and reaction sites on the suspended UBC and sorbent particles in the flow, and on UBC and sorbent deposits on the walls of heat exchangers and, perhaps, ESPs. Homogeneous Hg chemistry involves only gaseous species in the flue gas, with no participation whatsoever by UBC, minerals, or deposits. Transformations along SCR catalysts are restricted to the oxidation of Hg^0 into Hg^{2+} on sites on the promoted V_2O_5 catalysts. However, this Hg^0 oxidation can only be described as an element of a more comprehensive analysis that also describes simultaneous NO reduction, due to essential aspects of a competitive adsorption among NH_3 and the species associated with Hg^0 oxidation. The transformations within WFGDs determine whether any of the aqueous Hg(II) species can be reemitted as Hg^0 into the flue gas and thereby diminish the Hg removal across these units. Each form of the Hg transformations is characterized in turn in succeeding sections.

25.3.1 In-Furnace Transformations

Here we restrict our attention to large utility furnaces fed with whole coals or coal blends in the p.f. size grade. Stoker furnaces, fluidized bed combustors (FBCs), and circulating fluidized bed combustors (CFBCs) are beyond our scope. No chemistry needs to be described in detail within the furnace, because essentially all the Hg and halogens in the fuel are released into the flue gas as vapors, and none of the vapors are scavenged by molten minerals upstream of the furnace exit. Even when pyrite – the densest mineral, by far, which is usually present as extraneous particles – is recovered as bottom ash, it is first heated sufficiently to release its Hg into the flue gas. Similarly, all the Cl and Br in the fuel are released into the flue gas at hundreds of degrees below the

maximum flame temperatures. Chlorine may be incorporated into $CaCl_2$ within molten mineral mixtures with certain low-rank coals and with certain subbituminous/bituminous blends. But, even so, this is always a relatively minor phase that usually sequesters only a small portion of the available Cl, except with some low-rank fuels that have very little inherent Cl to begin with as well as favorable mineral compositions.

On the basis of these observations, the initial condition for the kinetic analysis is the equilibrium flue gas composition at the furnace exit gas temperature (of approximately 1050 °C). To evaluate the equilibrium composition, a furnace stoichiometry is first assigned to match a specified O_2 level in the flue gas at the ECN or, more directly, from specified flow rates for fuel and all the air streams. Such an equilibrium composition cannot accurately estimate the levels of NO, CO, or SO_3 in the flue gas, because the NO and CO concentrations are determined by extremely complex chemistry in the furnace. To circumvent an ambiguous analysis, we stipulate the NO concentration at the ECN as an input parameter. The SO_3 concentration could also be specified as an input parameter but, because it is usually unknown, we use a detailed reaction mechanism in 134 steps that also accounts for heterogeneous production on the Fe-oxides in fly ash and across SCR catalysts [6]. At the furnace exit, all coal-Hg will be present as Hg^0. This equivalence determines the total Hg inventory, which is the Hg concentration that all measured speciation components must sum to, accounting for any Hg removed in downstream APCDs. In practice, there are often very large discrepancies among the estimates based on coal-Hg and summed measured speciation components, because it is always difficult to recover fuel samples that actually represent the fuel properties being converted while the Hg speciation data were recorded. The Cl-species at the furnace exit are completely dominated by HCl, as the concentration of Cl-atoms is on the order of tens of parts per billion and that of Cl_2 is even smaller. But when Br is added to the fuel as an aqueous spray, the concentration of Br-atoms often exceeds that of HBr at the furnace exit, and a detailed homogeneous reaction mechanism is used to describe the Br speciation and its evolution in transit time, as explained subsequently.

Despite the complete vaporization of Hg and halogens in the furnace, it is a mistake to suppose that furnace firing configuration is irrelevant to Hg emissions control, because firing configuration strongly affects the amounts and properties of UBC suspended in the fly ash. Cyclone firing gives the greatest LOI but this LOI is based on the minimum fly ash loadings, owing to the rejection of most coal ash as bottom ash, and its UBC has the minimum specific surface areas [7]. Low-NO_X burners in wall-fired units and low-NO_X controls in T-fired furnaces give more LOI than high-efficiency firing practices [8]. Coal quality is another independent influence on both LOI levels and the specific surface areas of UBC. LOI with low-rank fuels is usually well below 1 wt% of the fly ash, but becomes markedly greater with bituminous coals and, especially, with low-volatility coals. The specific surface area of the LOI from low-rank fuels is several times greater than that with bituminous coals [9], because only bituminous coals melt during

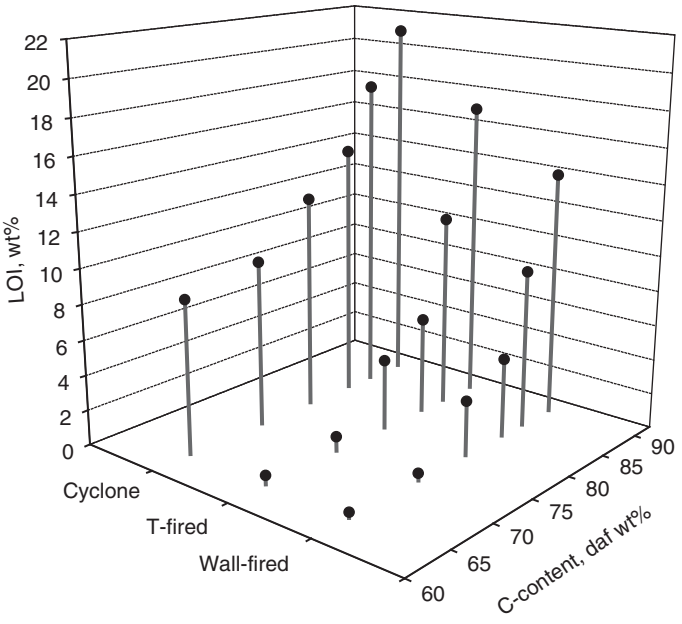

Figure 25.1 Visualization of LOI as a function of the fuel C-content and firing configuration.

the initial stages of combustion and thereby lose most of their internal surface areas.

This rather complicated situation is visualized in 3D in Figure 25.1, which plots LOI for high-efficiency firing practices versus both the C-content of the fuel and the firing configuration. For T- and wall-fired furnaces, the coal quality impact dominates and LOI levels are markedly greater with low-volatility coals than bituminous, and with bituminous than with low-rank coals. The coal quality impact weakens for cyclone firing, although the absolute LOI levels are much greater with this firing configuration than with the other two across the entire range of coal quality. An analogous surface for low-NO_X firing practices would have much greater LOI levels with bituminous and low-volatility coals for T- and wall firing, but similar levels with low-rank coals in all firing configurations and with cyclone firing throughout the range of coal quality. Therefore, the entire surface would be similar except that the LOI with high-rank coals for T- and wall firing would be greater. However, to gauge the impact of these variations on Hg transformations, we must also account for the variations in the specific surface areas. The adjustment between LOI and total UBC surface area for coal quality is about a factor of 7, so that 1 wt% LOI from a subbituminous has a comparable activity to about 7 wt% LOI from a bituminous coal. Of course, LOI is referenced to the total fly ash loading and low-rank coals generally have less mineral matter than high-rank fuels and, therefore, generate less fly ash. But on the basis of equal levels of UBC suspended in flue gas, the UBC from low-rank coals is several times more

active than that from high-rank coals due, in part, to its much greater specific surface area. These observations have great relevance for combustion-modification techniques for enhancing the capture of mercury. We also suspect that the finely dispersed alkali and alkaline earth cations on the UBC from low-rank coals also enhance its chemical activity toward Hg, but this aspect has not yet been characterized in the laboratory.

The impact of coal quality on halogen levels is much simpler. Chlorine is the only significant halogen in the fuel, except in infrequent instances where the Cl-contents in a handful of lignites were so small that the normally negligible levels of coal-Br became relatively significant. In general, low-rank coals generate HCl concentrations in flue gas from single-digit parts per million levels to 20 ppm; high-rank coals generate 25 – 150 ppm; while bituminous coals from the Illinois Basin and from the United Kingdom generate substantially greater concentrations. Aqueous solutions of calcium chlorides and bromides are sometimes sprayed on the fuel to compensate for any natural halogen deficiencies. Perhaps the most important aspect of coal-Cl is its inordinate variability. The testing literature contains instances where coal-Cl varied by as much as a factor of 5 while all other coal properties remained the same during a month-long testing campaign. These variations are completely independent of the primary fuel properties, and can only be accounted for by monitoring coal-Cl on every day of testing, and by running test-specific simulations.

The impact of coal quality and the inherent variability of coal-Hg are much weaker. But the overriding consideration with coal-Hg is that total Hg concentrations in flue gas, at 1 – 10 ppb, are always much too low to affect the concentrations of any other species; in other words, even complete conversion of total Hg leaves the concentrations of all other species unchanged. Of course, coal-Hg and the total Hg concentration in flue gas are scales for the emissions rates and stack Hg concentrations, which are obviously important. But Hg's impact on the process chemistry is severely restricted by its very low absolute concentration. The important implication is that all surface coverages associated with Hg species must be miniscule in the steady state; otherwise, the relaxation times to reach steady states will be incompatible with the reported rapid response times to step changes in the gas cleaning conditions, such as Cl concentrations.

25.3.2 In-Flight Transformations

At the furnace exit, the whole flue gas composition has been specified, including the levels of Hg^0, HCl, HBr, and Br-atoms. The loading and total surface area of UBC in suspension have also been specified. Nearly all the most reactive sites on the UBC have been oxidized but are otherwise accessible. We are now ready to progress forward into the cleaning system, first, to complete the specification of the cleaning conditions and, second, to describe the in-flight Hg transformations.

Regardless of the APCDs in any gas cleaning system, one primary imperative is to extract as much heat as possible from the flue gas before it reaches the stack.

From the furnace exit to the ECN inlet, superheaters reduce the temperature from 1050 to 750 °C in about 1 s, and the ECN cools it to 375 °C in 0.5 s. SCRs operate near-isothermally at 340 – 390 °C with residence times from 1 to 3 s. The APH then quenches the stream to PCD operating temperatures which, for ESPs, vary from 140 to 180 °C with residence times to 15 s and, for FFs, from 120 to 140 °C with times to several seconds. SDAs operate at ESP temperatures, whereas WFGDs operate from 40 to 60 °C. Stack temperatures are usually around 80 °C. A typical thermal history for a cleaning system with only ESPc appears in Figure 25.2. This history is consistent with measured temperatures along several full-scale cleaning systems, although thermal histories for many systems often exhibit large and usually uncharacterized deviations from any baseline thermal history because of differences in the lengths of ductwork and unit sizes. One way to account for these variations is to include detailed specifications on the ductwork in the input requirements. A much less cumbersome way is to adjust the thermal history to match predicted Hg speciation to measured values recorded for baseline operating

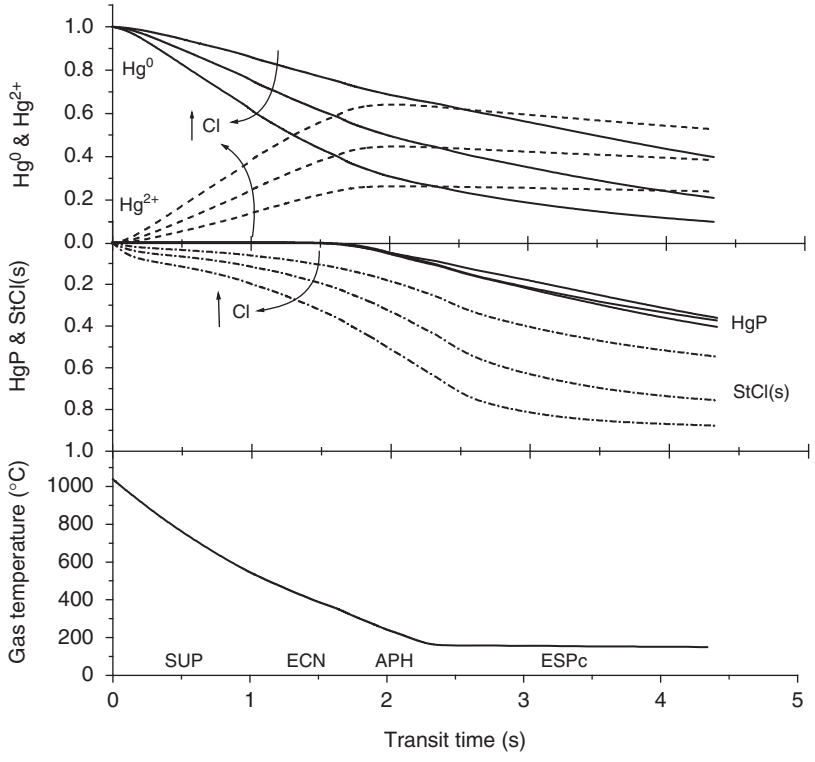

Figure 25.2 MercuRator™ predictions for Hg speciation and (middle panel) the fractional coverage of chlorinated sites on UBC (labeled as StCl(s)) for 7% LOI from a bituminous coal that released 17, 34, and 64 ppm HCl in an ESPc-only cleaning system. The lower panel shows a typical thermal history for commercial gas cleaning systems.

conditions; that is, use the intermediate temperatures in the thermal history to calibrate the analysis to a subject cleaning system. Thermal histories also need to be adjusted as the furnace load is regulated, to account for the longer transit times and cooler operating temperatures under reduced load operation.

These aspects of the thermal history along a cleaning system are important, but the paramount implication from the thermal history in Figure 25.2 reflects the extents of the changes in both temperature and transit time. No process in nature could possibly sustain the same rate-limiting step over such a broad range of temperature; therefore, any proposed reaction mechanism for in-flight Hg transformations must depict several dramatic shifts among the main conversion channels, and these shifts must occur on time scales of only a few seconds. Failure to recognize this essential characteristic of all gas cleaning systems is the main reason that the bulk of testing at laboratory scale is irrelevant to the Hg transformations in commercial cleaning systems. Isothermal laboratory-scale tests can only, at best, be relevant for an instant in the time-temperature pathway of a coal-fired power plant.

Our mechanism for in-flight transformations with only Cl-species has three broad stages, two of which are illustrated in Figure 25.2, and several shifts in the rate-limiting process. In the first stage, the reaction sites on UBC are chlorinated, thereby generating the sites for subsequent Hg chemistry. Such chlorination has never been monitored on coal-derived UBC, but carbon from other sources is known to readily absorb Cl from the gas phase, especially at superheater and ECN operating temperatures [10]. As seen in Table 25.1, we represent this stage as an adsorption equilibrium that balances HCl adsorption, heterogeneous Cl atom recombination, and a hydration reaction. Such a simple adsorption scheme omits the competitive adsorption by S- and N-species, not because they are truly negligible. Rather, these competitions are omitted because the UBC in cleaning systems will always be heavily sulfated and nitrated, so explicitly resolving this competition would add adjustable parameters without improving the fidelity of the surface coverage of the chlorinated sites, which is crucial.

Table 25.1 Heterogeneous Hg conversion mechanism for Cl species on carbon.

Chlorination[a)]	
$StSA(s) + HCl \rightarrow StCl(s) + H$	Chlorination
$StCl(s) + Cl \rightarrow Cl_2 + StSA(s)$	Heterogeneous Cl-atom recombination
$StCl(s) + H_2O \rightarrow HCl + OH + StSA(s)$	Hydration
Hg conversion	
$StCl(s) + Hg^0 \rightarrow StHgCl(s)$	Hg^0 adsorption
$StHgCl(s) + HCl \rightarrow StSA(s) + HgCl_2 + H$	Oxidation with desorption
$StHgCl(s) \rightarrow StSA(s) + HgCl$	Desorption
$StCl(s) + HgCl_2 \rightarrow StHgCl(s) + Cl_2$	Back adsorption

a) Converts open sites (StSA(s)) into chlorinated sites (StCl(s)).

The second stage describes the Hg transformations on the chlorinated sites. Hg adsorption is restricted to the chlorinated sites, because X-ray photoemission spectroscopy (XPS) analysis indicates the presence of Hg–Cl–C bonds on UBC sampled from flue gas [11]. The surface intermediate StHgCl(s) is either chlorinated further and released as $HgCl_2$ or released as HgCl to be fully oxidized in the gas phase. While these two steps are global processes in our mechanism, this stage has been resolved in detail by Olsen and coworkers, as described elsewhere in this volume. Hg^{2+} can also back adsorb onto a chlorinated site on UBC.

The shifts in rate-limiting steps are evident in Figure 25.2 as shifts in the Hg speciation. UBC chlorination dominates through the superheaters and into the ECN. As the appearance of Hg^{2+} without any Hg_p signals the first Hg transformations, the conversion rate is initially adsorption controlled, as expected at high temperatures. Further along the quench cycle, Hg_p appears as evidence of a more balanced conversion under chemical reaction control. Within the APH and into the ESPc, Hg_p continues to accumulate while both vapor species diminish, which signals desorption control. Further into the ESPc, essentially all chlorinated surface area on UBC is removed from the flue gas (although only the maximum accumulation of Hg_p is shown in Figure 25.2) which, along with the low temperature, terminates the Hg transformation chemistry. The time to remove sufficient chlorinated carbon surface from the flue gas to quench Hg chemistry is a small fraction of the total transit time through an ESPc, because most fly ash is recovered in the first and second upstream fields.

The tendency for progressively greater Cl concentrations is also shown in Figure 25.2. Greater Cl levels shift the Cl adsorption equilibrium toward larger populations of chlorinated sites on UBC, which promotes faster Hg^0 oxidation at high temperature but the same accumulation of Hg_p at low temperature, due to the slower adsorption of Hg^{2+} compared to Hg^0. Consequently, the same Hg is removed in the ESPc, and there is substantially less Hg^0 in the stack emissions. The tendency for progressively greater LOI levels would be completely analogous for the vapor species, and more LOI would also enhance Hg_p provided that the flue gas contained sufficient Cl to actually expand the population of chlorinated sites.

This same reaction mechanism describes the markedly enhanced Hg removals for ACI with untreated and brominated carbons with three important differences, two of which are seen in Figure 25.3. The first is that carbon sorbents have surface areas from 500 to 1200 $m^2\,g^{-1}$, which are 2–40 times greater than UBC specific surface areas. The second difference is that the chlorination stage is shifted to much cooler temperatures because ACI is usually positioned immediately downstream or, less frequently, immediately upstream of the APH. As this location is hundreds of degrees cooler than where inherent UBC is chlorinated, we were surprised to see that our chlorination mechanism remained accurate in ACI applications after only very small adjustments to the rate constants. If the sorbent is halogenated before injection, then the chlorination step is simply omitted altogether. The third difference is that progressively greater ACI concentrations generate much more Hg_p at the expense of both Hg^0 and Hg^{2+}. In general, the back

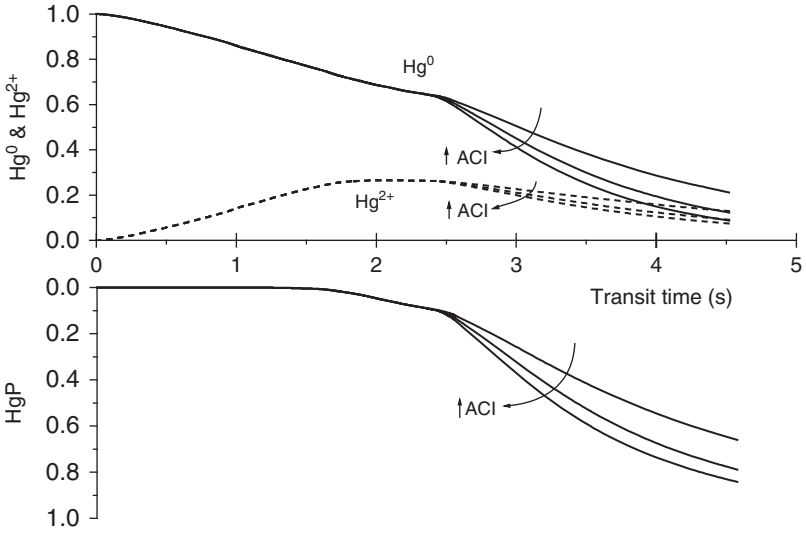

Figure 25.3 MercuRator™ Hg speciation for untreated ACI at 3, 6, and 9 lb/MMacf for 7% LOI from a bituminous coal that released 17 ppm HCl in an ESPc-only cleaning system.

adsorption of Hg^{2+} onto vacant sites tends to be much more important with sorbent than with inherent UBC, simply because the vacant site population is almost always much greater in ACI applications. For this same reason, Cl availability often limits the asymptotic, ultimate removal for even the largest ACI concentrations when applied with low-rank fuels. The asymptotic removals with high-Cl, high-rank fuels tend to approach 95%, where the difference with complete removal is thought to reflect imperfect particle dispersion (mixing of the sorbent) in turbulent flow fields. But asymptotic removals are often no greater than 65–75% with low-rank fuels, because Cl availability limits the size of the population of chlorinated sites. Under these circumstances, further increases in the ACI concentration simply redistributes the same population of chlorinated sites among a larger number of sorbent particles, without increasing the population size.

Another potentially critical limitation of ACI performance is described by the third stage of our in-flight mechanism, inhibition by SO_3. During gas quenching, whenever the local flue gas temperature cools below the SO_3 dew point, sufficient H_2SO_4 – the product of SO_3 hydration – condenses onto any accessible surface to equalize the dew point to the local temperature. According to our analysis [6], the surface area of all fly ash, not just UBC, participates in the condensation. The portion that condenses onto sites on both UBC and carbon sorbents inhibits heterogeneous Hg conversion chemistry. The loss of activity is determined by the condensation of H_2SO_4 onto the population of sites that can potentially be chlorinated on the basis of the total surface area. Once covered by H_2SO_4, these sites no longer participate in any Hg conversion chemistry. SO_3 condensation first diminishes the population of chlorinated sites (just as a lower ACI concentration would) which, in turn, is responsible for less Hg_p; hence, lower Hg removals, as seen in

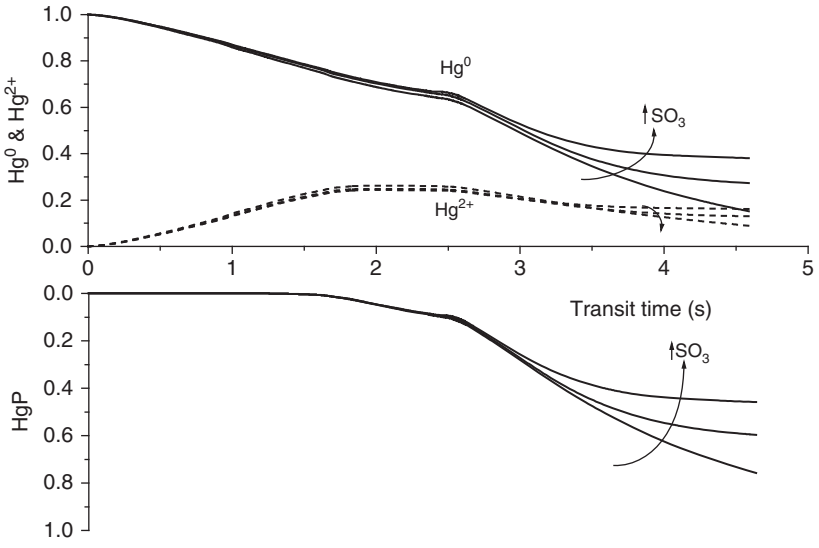

Figure 25.4 MercuRator™ Hg speciation for untreated ACI at 6 lb/MMacf for 7% LOI from a bituminous coal that released 17 ppm HCl in an ESPc-only cleaning system that generated 9.5, 27, and 32 ppm SO_3.

Figure 25.4. Temperatures from the back-end of the APH into the PCD are critical, because Hg removals can be cut in half by this form of inhibition. Accordingly, either ACI is not recommended with high-S fuels, or high sulfur trioxide levels are mitigated possibly through alkaline sorbents or additives.

When a cleaning system uses ESPh instead of ESPc, Hg removals will be markedly lower because an ESPh operates at temperatures well above the onset of Hg_p production; that is, before the mechanism starts shifting toward desorption control. If it uses FF instead of an ESPc, then all Hg transformations upstream of the FF remain the same, but the behavior within the FF is dramatically different, as seen in Figure 25.5. Very little chemistry occurs during the several seconds needed to transport the flue gas into the filtercake on the filter bags. But immediately after the flue gas contacts the filtercake, there are step changes in the levels of Hg_p and Hg^{2+}, with complete elimination of Hg^0 (via enhanced gas-solid contact between flue gas and the sorbent due to formation of a packed bed-type configuration). The exorbitant surface area of the filtercake is responsible for the near-critical behavior because, on a volumetric basis, the surface area of UBC in a filtercake is five orders of magnitude greater than the surface area of suspended UBC in flue gas for a case with 5 wt% LOI from a coal with 10% ash. Preliminary analysis showed that the Hg conversion chemistry is confined to a relatively thin outer layer of the filtercake, across which the Hg speciation relaxed to the composition for an adsorption equilibrium. Because the layer is relatively thin, it is not necessary to resolve the extent of Hg conversion through the filtercake; we simply evaluate the Hg speciation for adsorption equilibrium. The equilibrium

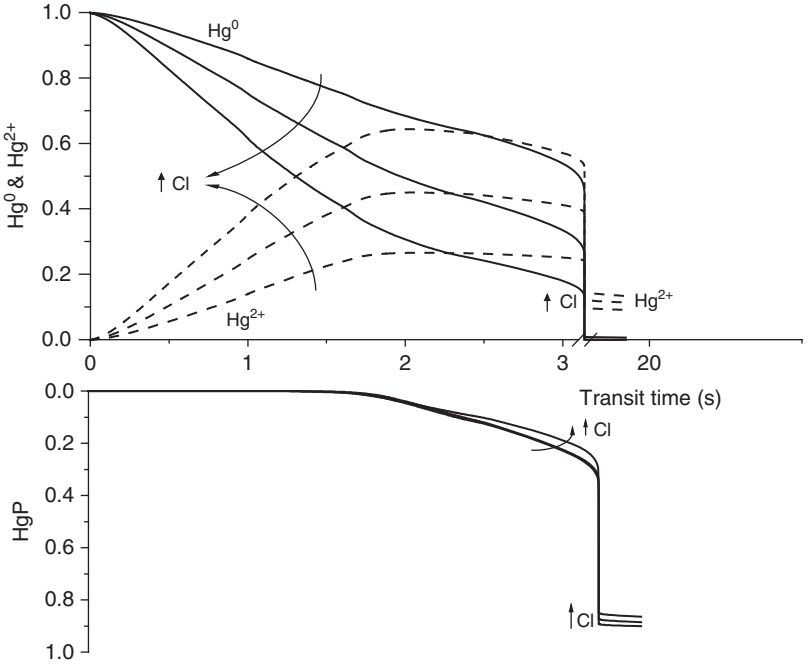

Figure 25.5 MercuRator™ Hg speciation for 7% LOI from a bituminous coal that released 17, 34, and 64 ppm HCl in a FF-only cleaning system.

speciation is not necessarily dominated by Hg_p, because the levels of Cl and carbon surface area determine the proportions of Hg^0, Hg^{2+}, and Hg_p. As seen in Figure 25.5, progressively more Cl shifts the equilibrium speciation toward Hg^{2+} at the expense of Hg_p while Hg^0 is always miniscule.

According to our interpretation, in-flight Hg transformations with Cl species are determined by only the heterogeneous reaction mechanism. This is because the extremely low concentrations of Cl atoms and Cl_2 under commercial gas cleaning conditions cannot drive the two-step, autocatalytic cycle whereby Cl-atoms partially oxidize Hg^0 into HgCl which, in turn, is fully oxidized into $HgCl_2$ by Cl_2 to restore the original Cl atom [12]. Even in homogeneous Hg oxidation mechanisms with somewhat different primary conversion channels, the extent of homogeneous Hg oxidation is negligible compared with measured values under commercial cleaning conditions.

However, in-flight Hg transformations with Br species must be attributed to both homogeneous and heterogeneous reaction mechanisms. As seen in Figure 25.6, simulations with only a homogeneous Hg/Br reaction mechanism [13] demonstrate one of the most distinctive features of Hg oxidation by Br species. For a typical thermal history along a gas cleaning system and with 9.4 ppm Br in flue gas, the predicted extent of Hg oxidation approaches 70%. In contrast, the comparable performance with 20 ppm HCl is no Hg oxidation

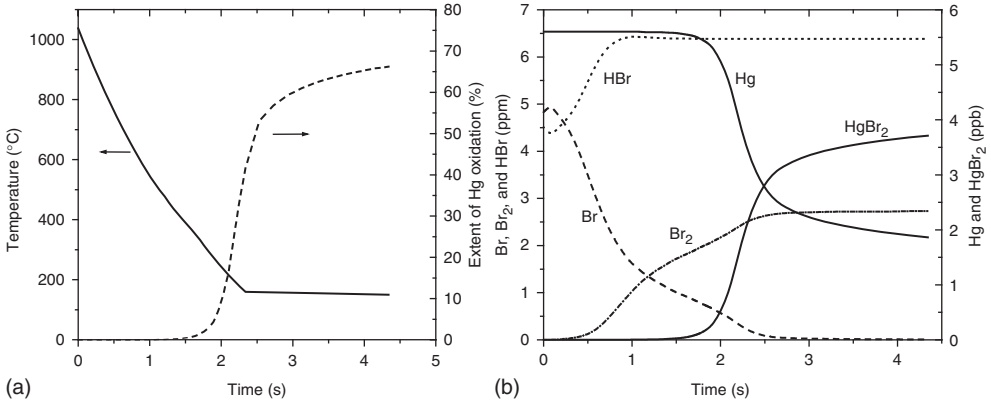

Figure 25.6 (a) Solid curve: typical thermal history for a gas cleaning system whose only APCD is an ESPc and (dashed curve) predicted extent of homogeneous Hg oxidation with 9.4 ppm Br in flue gas. (b) Solid curves: Hg vapor speciation and (dashed curves) Br speciation for the same conditions.

whatsoever. Homogeneous Hg oxidation by Br begins to produce $HgBr_2$ as the flue gas cools below 500 °C and accelerates sharply when the temperature cools below 300 °C. At higher temperatures, the instability of an HgBr intermediate fails to sustain $HgBr_2$ production.

At the furnace exit, Br atoms are present in concentrations that are comparable to HBr levels, in marked contrast to the much lower concentrations of Cl atoms at these conditions. The primary reason that Br is a much more effective Hg oxidizer than Cl is that HBr dissociates into the most reactive atomic species much more extensively than HCl at typical post-flame conditions. As flue gas moves further into the gas cleaning system, Br atoms rapidly recombine through the back-end heat exchangers, first, into HBr, then, into Br_2, so that the HBr concentration plateaus at 600 °C and the Br_2 concentration plateaus at 160 °C. As the flue gas cools in the APH and further downstream, the $HgBr_2$ concentration surges. $HgCl_2$ is not produced because homogeneous Hg oxidation by Cl species is too slow under these conditions. All these species approach ultimate steady concentrations in the ESPc because of the low temperatures.

To account for the impact of variations in UBC levels on Hg transformations by Br species, we supplement the homogeneous reaction mechanism with a heterogeneous mechanism that is completely analogous to the heterogeneous mechanism for Cl species in Table 25.1 [13]. The key difference between the contributions from the in-flight mechanisms on UBC for Br and Cl species is that the much higher concentration of Br atoms promotes heterogeneous recombination into Br_2. This process maintains much smaller populations of brominated sites on the UBC than the chlorinated sites. Consequently, the contribution of heterogeneous in-flight chemistry with Br species is smaller, and much lower levels of Hg_p form at the lowest temperatures of interest. This prediction is consistent with several field test results in which Br addition strongly

enhanced Hg^{2+} levels but left Hg_p levels unchanged. Unfortunately, contradictory findings have also been reported, which are compounded by as-yet unresolved interferences in semi-continuous emissions monitor (SCEM) detectors by Br species. We currently expect Br addition to promote substantial homogeneous Hg^0 oxidation through the ECN and upstream of an SCR with little effect on Hg_p levels, because of the heterogeneous recombination of Br atoms into Br_2. However, such observations must remain tentative until the measurement issues are rectified.

In a similar manner, brominated carbon sorbents are analyzed with the analogous heterogeneous mechanism for Br species, without any bromination stage, and with minimal contributions from homogeneous Hg/Br chemistry, because of the low gas temperatures at ACI locations.

25.3.3 Hg^0 Oxidation across SCR Catalysts

The oxidation of Hg^0 across the promoted V_2O_5 catalysts on SCR monoliths is completely independent of its in-flight oxidation on UBC. In fact, the catalytic oxidation channel often provides the fastest means to oxidize Hg^0, especially in the presence of Br species, which may seem surprising because no SCR has yet been designed or optimized to oxidize Hg^0. Extents of Hg^0 oxidation of 90% or more are routinely recorded in full-scale field tests [14], provided that the flue gas contains abundant Cl- or Br-species and that the SCR provides sufficient reactivity, favorable mass transport rates, and ample residence time for the chemistry to proceed to near completion. When these conditions are satisfied, SCR/ESP/FGD combinations are the technology of choice for Hg control because they require no special operating procedures or reagents to lower Hg emissions, except when Br- and Cl-species are injected to counteract the inherent halogen deficiencies in low-rank coals.

Our first reaction mechanism for catalytic oxidation described simultaneous NO reduction and Hg^0 oxidation in terms of lumped catalyst reactivities that resolved film transport of reactants onto the external catalyst channel wall from an overall chemical reactivity [15]. The key features were a competition between NH_3 and HCl for surface sites, and an Hg^0 oxidation reaction on chlorinated catalyst sites. This competitive adsorption subdivides the catalyst into two stages. An entry stage sustains NO reduction with high concentrations of adsorbed NH_3, but the population of chlorinated sites remains very small as long as the HCl concentration is much lower than the NH_3 concentration. This small population oxidizes small proportions of the Hg^0. Once the NH_3 has been consumed, a trailing stage is chlorinated much more extensively and thereby able to rapidly oxidize Hg^0. This mechanism interpreted extents of Hg^0 oxidation by Cl species in laboratory-, pilot-, and full-scale SCR units for the complete domain of utility gas cleaning conditions, and was recently expanded for oxidation by Br-species [16]. The strong coupling between NO reduction and Hg^0 oxidation via competitive adsorption of

NH_3 and HCl was also independently validated with an extensive series of laboratory tests [17].

Additional modeling work expanded the original lumped analysis in two ways into a legitimate multipollutant analysis [18]. First, simultaneous SO_2 oxidation was incorporated and, second, the analysis resolves internal pore diffusion across the catalyst wall thickness from the intrinsic reactivity of adsorbed species on the catalyst surface with a conventional Thiele analysis, to directly relate catalyst morphology and composition to the multipollutant performance of the SCR reactor. Consequently, the analysis directly relates factors that can be manipulated in the design of SCRs – the size and shape of monolith channels, the composition, and pore size characteristics of the catalyst layer, and the temperature – to the multipollutant performance for specified ranges of flue gas composition and flow rate. It is especially well suited to predicting the performance of a particular SCR across broad domains of flue gas conditions for current and foreseen specifications on fuel quality and furnace firing conditions, and also to optimize SCR design parameters to meet specifications on Hg^0 oxidation with new and replacement SCR catalysts. The goal is to enable plant operators to take better advantage of fuel switching opportunities by calling for additives or operational adjustments that will enhance Hg removals while maintaining high NO_X removals and acceptable SO_3 levels.

The NO reduction mechanism was developed and fully validated for commercial SCR catalysts by Tronconi and coworkers [19], based on submechanisms for film transport, an Ely-Rideal (ER) reaction mechanism with NH_3 chemisorption (gas phase NO reacting with adsorbed NH_3), and pore diffusion. Similarly, the SO_2 oxidation mechanism was also adapted from Tronconi's work [20], albeit with no mediation by any transport phenomena. Our original mechanism for catalytic Hg^0 oxidation has been incorporated into this validated framework to account for the mediation of competitive HCl and NH_3 adsorption by pore diffusion. A simple premise connects NO and SO_2 conversion to the Hg^0 oxidation behavior on SCRs: That HCl, HBr, and Br_2 compete for surface sites with NH_3, and that Hg^0 contacts these halogenated sites either from the gas phase or as a weakly adsorbed species. On the assumption that the competitive adsorption coverages are independent, the rate expression for adsorbed Hg oxidation is given by

$$r_{\mathrm{Hg}} = {}^{\mathrm{Cl}}k_{\mathrm{Hg}} C^{S}_{\mathrm{Hg}} \Theta_{\mathrm{Cl}} + {}^{\mathrm{Br}}k_{\mathrm{Hg}} C^{S}_{\mathrm{Hg}} \Theta_{\mathrm{Br}} = \left[\frac{{}^{\mathrm{Cl}}k_{\mathrm{Hg}} K'_{\mathrm{HCl}} + {}^{\mathrm{Br}}k_{\mathrm{Hg}} K'_{\mathrm{HBr}}}{1 + {}^{H}K'_{\mathrm{NH_3}} C^{S}_{\mathrm{NH_3}}} \right] C^{S}_{\mathrm{Hg}}$$

As the surface coverages of the halide species are independent, the net rate is the sum of independent contributions from Cl and Br, and the original mathematical form of the analysis of only Cl species can be retained. The effective rate constants on the right contain the concentrations of HCl, HBr, and Br_2, which are uniform across the SCR in the steady state.

The common characteristics among the reactivities for NO reduction, SO_2 oxidation, and Hg^0 oxidation are that (i) NH_3 strongly inhibits all three processes and (ii) all rates are directly proportional to the concentrations of the primary reactant.

Otherwise, SO_2 oxidation is weakly promoted by NO and O_2, and weakly inhibited by moisture, whereas Hg^0 oxidizes in proportion to the surface coverages of halide species supplied via adsorption of the halogen vapors. These coverages vary along the catalyst length even while the concentrations of halogen vapors remain uniform because they are not consumed in any chemical process other than Hg^0 oxidation, and the Hg^0 concentration is orders of magnitude smaller than all other reactant concentrations. Several analytical solutions were integrated into the analysis to avoid a computationally expensive 2D simulation along and into the catalyst wall, as elaborated elsewhere [18].

According to both of our analyses, the various SCR design specifications and operating conditions can be understood in terms of how they affect the lengths of the two stages for NO reduction and for the oxidation of Hg^0 and SO_2. Factors that accelerate the transport rates of reactants onto the catalyst walls, such as smaller channel pitches and converting from square to circular channels, shorten the length of the NO reduction stage and thereby promote Hg^0 oxidation. Factors that enhance surface halogenation, such as higher inlet halogen concentrations and lower NH_3/NO ratios, also promote Hg^0 oxidation. Br species dramatically accelerate Hg^0 oxidation rates on some catalysts by as much as a factor of 40 compared to the rates for Cl species [16]. The design analysis also showed that shifting the pore size distribution toward macropores in a final catalyst layer appears to be an effective means to directly enhance Hg^0 oxidation. According to our calculations, this strategy will not increase NH_3 slip, because it raises the effectiveness factor for NO reduction, nor will it increase the extent of SO_2 oxidation by a significant amount, because transport effects are negligible in SO_2 oxidation. But it does have the potential to significantly enhance extents of Hg^0 oxidation, all other SCR operating conditions being the same. Most of these benefits were realized in the increase in macroporosity from 5% to only about 15%, which makes this strategy potentially easier to implement. Increases in the micropore size also enhance Hg^0 oxidation, presumably due to the associated increases in the effective diffusivity of Hg, but the impact is not nearly as large as that for increases in macroporosity.

Perhaps the most important result is that SCR design specifications and operating conditions are at least as important as the halogen concentrations, simply because the domain of these specifications across the industry is enormous. Our database on Hg^0 oxidation across full-scale SCRs covers temperatures from 335 to 395 °C; gas hourly space velocity (GHSV) from 1800 to 4700 h^{-1}; HCl concentrations from 1 to 130 ppm; Br concentrations from 0 to 50 ppm; inlet NO concentrations from 280 to 900 ppm; and NO reduction efficiencies (or NH_3/NO ratios) from 0 (for out-of-service SCRs) to 0.95. SCRs from four catalyst vendors represent plate-monoliths with pitches to 11 mm and honeycomb monoliths with square and triangular channels of pitches to 10 mm. As seen in Figure 25.7, the predictions from the lumped analysis are generally within 10% of the measured values for all cases except EES8U13, even though the measured extents of Hg^0 oxidation vary from 20% to more than 90%. Such performance could not possibly

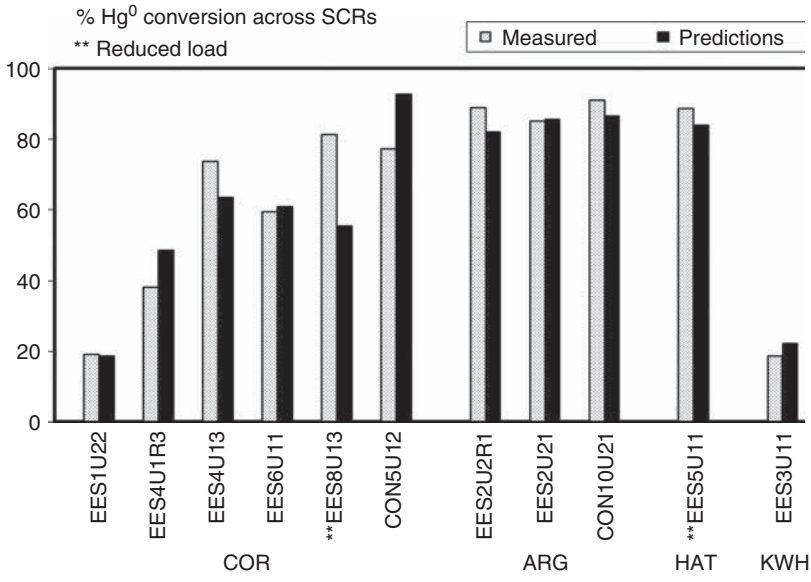

Figure 25.7 Evaluation of extents of Hg^0 oxidation across various full-scale SCRs from MercuRator™ (solid) with measured values representing four catalyst vendors (gray).

be achieved unless the impact of the operating conditions and design specifications was accurately described, in conjunction with the appropriate dependencies on the halogen concentrations.

25.3.4 Hg Transformations within WFGDs

The Hg field-testing literature shows that WFGDs usually capture at least 90% of the Hg^{2+} in flue gas, but virtually none of the Hg^0, because Hg^0 is insoluble in aqueous solutions. However, several full- and bench-scale tests have documented Hg reemission whereby the Hg^0 concentration at the FGD exit is greater than that at the inlet, suggesting that some of the Hg(II) in the scrubber solution must be reduced and reemitted as Hg^0 vapor. Hg reemissions have also been observed in natural waters and atmospheric cloud and rain-water cycles [21–23], where S(IV) species promote the reduction of Hg^{2+}. Bench-scale studies under well-controlled scrubbing conditions showed that Cl^- and O_2 suppress reemission, whereas Ca^{2+} and Mg^{2+} species promote it.

We recently developed a quantitative analysis that identifies and rank-orders the factors involved in Hg reemission during wet FGD scrubbing, to support efforts to mitigate Hg reemission from full-scale, commercial wet FGDs. To simulate Hg transformations WFGD scrubbers, one must first model SO_2 absorption to describe the major solution species (S, Ca, Cl) and their variations with FGD operating conditions (L/G, droplet diameter, T). The conventional simulation strategy

builds numerous equilibrium constraints into a mass transport analysis of the exchange of species from the flue gas into the spray droplets along an absorber tower, with simultaneous limestone dissolution and sulfite oxidation within slurry droplets. Given the absorber temperature and the inlet compositions of flue gas and slurry, the conventional FGD analysis predicts the correct pH and reasonable SO_2 absorption rates along the absorber. It also depicts realistic tendencies for variations in the inlet SO_2 level, and identifies distinctive conditions where elevated HCl levels will reduce SO_2 removal efficiencies by 5–10%, and greater SO_2 removal for smaller slurry droplets, all else the same.

While the conventional FGD analysis relates gross FGD operating conditions to SO_2 absorption efficiencies, it is unsuitable for trace metal transformations, especially for Hg reemission. The reason is that conventional formulations implicitly assume that all oxygen is consumed in sulfite oxidation at the liquid interface on a slurry droplet, and evaluate the rate of sulfite oxidation as an average based on bulk liquid concentrations. The requisite analysis for Hg^{2+} chemistry and, presumably, other trace metal transformations must automatically shift the redox potential of bulk liquid in the spray from oxidizing to reducing through a balance among the finite-rate reagent fluxes that participate in sulfite oxidation. Our SO_2 capture analysis allows oxygen to penetrate through the liquid film and accumulate in the bulk liquid if its concentration exceeds the stoichiometric requirement for bisulfate oxidation. We also propose a finite-rate reaction for Hg(II) reduction that depends on temperature, pH, and S(IV) species which, in the absence of sufficient oxygen, promote Hg(II) reduction to Hg^0 vapor.

The computerized implementation covers the process chemistry occurring in both a counterflow absorber and slurry holding tank [24]. The tank analysis determines the required limestone feed rate for a given tank residence time distribution (RTD) and the solids size distribution into the spray nozzles within the absorber. It also determines how much liquid must be extracted to maintain a target Cl concentration in the tank. The absorber analysis determines the SO_2 capture and the compositions of liquid and solids that return into the holding tank. Given the absorber temperature and the inlet compositions of flue gas and slurry, the analysis predicts the SO_2 capture efficiency, complete slurry composition and flue gas composition, slurry pH, the quantitative enhancement of mass transfer by acid dissociations in the slurry, and the relative contributions of liquid and gas resistances to the overall mass transfer rate. All quantities are resolved as functions of distance along the absorber axis.

For the operating conditions and bulk species concentrations reported for a full-scale limestone WFGD, the analysis correctly predicts that SO_2 was continuously removed along the length of the absorber, whereas most of the Hg was removed in the lower section at a much greater efficiency than SO_2 removal, owing to the high aqueous solubility of $HgCl_2$. For the baseline case with 20% Hg^0, the predicted reemission gradually increased to 20%, and the total Hg removal reached only 65%.

According to the analysis, aqueous Hg species segregate into two groups, Hg–Cl species and Hg–S(IV) species. How variations in the scrubber operating conditions shift the proportions of these two groups is critical, because only the

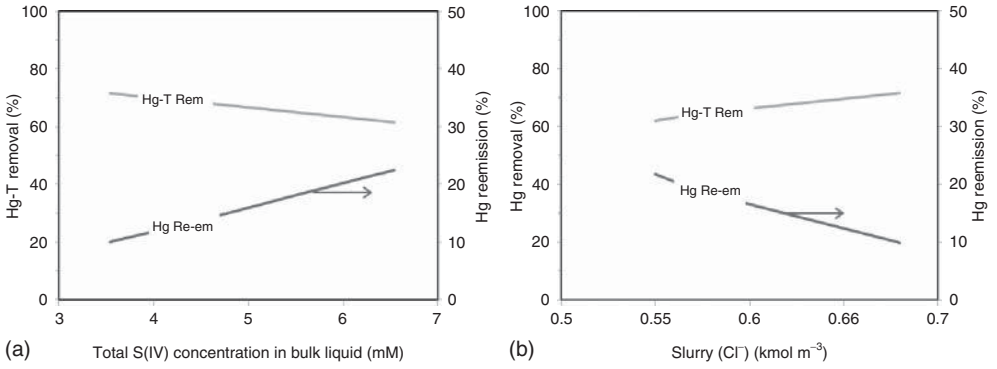

Figure 25.8 Effect of bulk liquid (a) S(IV) and (b) slurry Cl^- concentrations on total Hg removal (left *y*-axis) and percentage Hg reemission (right *y*-axis).

Hg–S(IV) species can be reduced and subsequently reemitted as Hg^0 back into the flue gas. The two most important factors are shown in Figure 25.8, which shows the total Hg removals and extents of Hg^0 reemission for concentration ranges of S(IV) and Cl^- species. As the S(IV) concentration was increased from approximately 3.5 to 6.5 mM, the Hg removal decreased from 72 to 62% with an increase in Hg reemission by a similar percentage. For a twofold increase in S(IV) concentrations, the Hg–S(IV) fraction in the solution at the absorber exit increased from 14 to 36% with a corresponding decrease in Hg–Cl levels. The predicted Hg reemission therefore linearly tracks the Hg–S(IV) levels. Conversely, for progressively greater Cl^- in solution, the Hg(II) species preferentially partition into Hg–Cl complexes that reduce reemission, which is consistent with the observations in bench- and pilot-scale experiments. As the Cl^- concentration was increased from 0.5 to 0.68 kmol m^{-3}, the Hg–Cl ions increased from 66 to 84% with a corresponding decrease in Hg–S(IV) complexes. The change in Cl^- did not affect Hg^{2+} absorption as it was in excess of 99% in all cases. The increased partitioning of Hg(II) into Hg–Cl complexes decreased reemission by 11% and increased the Hg removal from 62 to 72%.

Most additives to control Hg reemission from scrubbers, such as Na_2S_4, TMT-15™, and NaHS, release S(II) ions in the slurry and precipitate Hg as HgS(s). We examined the addition of small amounts of S(II) into the base case scrubber solution and simulated Hg capture. Even at 1 μM concentrations of the additive, all the Hg(II) precipitated as HgS(s), which establishes the maximum Hg^{2+} concentration in the solution as only 10^{-33}. According to our simulations with 80% $HgCl_2$ in the flue gas, essentially all Hg(II) was retained in the solid phase. These predictions are consistent with the B&W tests at Endicott station [25], where the addition of NaHS almost completely suppressed Hg reemission and the extent of reemission did not bear any relation to the additive feed rate. We also simulated the addition of S(II) under oxidizing conditions where the pH was increased to 6.5 and the S(IV) concentration was reduced to the point where oxygen was in excess, to characterize lime-based WFGDs. Under such conditions, equilibrium shifts the added S(II)

species to their oxidized forms, which prevents any precipitation of HgS solids. This is consistent with B&W tests at the Mg/lime WFGD at Zimmer station [25], where adding NaHS did not improve the baseline Hg-T capture efficiency even at high additive feed rates.

At this point in its development, our FGD scrubbing analysis predicts reasonable extents of Hg removals and Hg reemission under realistic FGD operating conditions, without any parameter adjustments. Most Hg^{2+} in flue gas is captured near the flue gas inlet at the bottom of the absorber, but Hg reemission can occur along the entire absorber at a rate that accelerates slightly along the upper elevations. Predicted Hg removals are insensitive to droplet diameter, whereas smaller slurry droplets reemit more Hg because they sustain faster absorption of all the reagent gases involved in Hg(II) reduction. The total S(IV) species concentration in the slurry promotes reemission; conversely, the analysis correctly predicts less reemission for greater Cl^- concentrations in the slurry, in accord with a well-established tendency. Simulations with added S(II) species, as released from commercial additives to suppress Hg reemission, correctly gave complete precipitation of Hg(II) as HgS(s). These predictions are consistent with full-scale field tests where the addition of NaHS almost completely suppressed Hg reemission and the extent of reemission did not bear any relation to the additive feed rate.

25.4 Summary

Collectively, the reaction mechanisms described in this chapter cover all the most common fuels, firing configurations, and gas cleaning configurations, and enable accurate estimates for Hg emissions rates from virtually any commercial power plant. Such estimates are the most expedient and economical means to evaluate potential Hg control technologies, both inherent and external. The fact is that even many individual power plants and, certainly, regional utility operations use so many fuel types that testing all of them becomes a practical impossibility. And such variations will only expand in the foreseeable future as operators develop strategies to comply with new regulations and new fuel sources open up.

Beyond the predictive capabilities resting upon these mechanisms, this level of analysis has clearly exposed the determining factors for Hg emissions. In-flight Hg transformations are determined by halogen concentrations, the halogenated surface area on UBC and carbon sorbents, the type of PCD, and, in ACI applications, the ACI concentration. Unless halogens are added to compensate for low inherent coal-Cl, the enormous inherent variability of coal-Cl levels is a primary consideration, and this variability can only be established by measurements because it is completely independent of all other coal properties. Chlorinated surface areas on UBC reflect the furnace firing configuration, fly ash LOI, and, especially, the coal rank. These influences tend to counteract each other insofar as low-rank coals give UBC with very high specific surface areas but generate very low LOI levels. Conversely, high-rank coals give UBC with low surface areas but generate much

higher LOI levels. Even so, it is impossible to accurately depict in-flight Hg transformations without an accurate account of all three influences on the chlorinated surface area. ACI with untreated carbon sorbents mitigates the inherent variations in chlorinated surface area, but does not necessarily eliminate the halogen dependence. This limitation is clearly seen in the much-lower-than expected asymptotic Hg removals for ACI with many low-rank coals. ACI with brominated carbon is the only current means to completely circumvent these limitations. Unfortunately, even this "universal" solution may be diminished by SO_3 inhibition. Whenever flue gas SO_3 levels are high enough to drive the SO_3 dew point below the local gas temperature in the APH and further downstream, condensed H_2SO_4 will deactivate halogenated sites on UBC and carbon sorbents, whether or not they have been brominated. As this inhibition can cut Hg removals in half, ACI is not recommended with high-S fuels, unless sorbent additives or sulfur trioxide mitigation are implemented.

In cleaning systems that exclusively rely on in-flight Hg transformations to control Hg emissions, relatively very high LOI levels are needed to generate sufficient UBC to produce appreciable Hg_p levels that can be removed in the PCD, even with high-Cl coals. Therefore, impending Hg emission regulations can only be met with ACI. Whether or not the sorbent is brominated, Hg removals for ACI upstream of a FF are significantly greater than ESPc removals, and this scheme requires much lower ACI concentrations to achieve a targeted Hg removal. This is because the enormous volumetric surface area in an FF filtercake brings the Hg speciation to adsorption equilibrium, while ESPs rapidly eliminate all the chlorinated carbon surface area from the flue gas and shut down the Hg conversion chemistry. Our analysis indicates that the only PCD-only cleaning configuration that can match the Hg removal performance of an SCR + ESPc + WFGD configuration is when ACI is positioned between an ESPc and a FF (Toxecon™-I).

The Hg^0 oxidation performance of SCRs is no less variable than the in-flight transformations, because SCR design specifications and operating conditions are at least as important as the halogen concentrations. This variability reflects the fact that none of the SCRs in service were designed, let alone optimized, to oxidize Hg^0. The essential feature is that NH_3 adsorption inhibits the adsorption of the species involved with Hg^0 oxidation, which subdivides the catalyst into two stages. An entry stage sustains NO reduction with high concentrations of adsorbed NH_3 but too few chlorinated sites to sustain Hg^0 oxidation. Once the NH_3 has been consumed, a trailing stage is chlorinated much more extensively and thereby able to rapidly oxidize Hg^0. The various SCR design specifications and operating conditions can be understood in terms of how they affect the lengths of these two stages. Factors that enhance surface halogenation, such as higher inlet halogen concentrations and lower NH_3/NO ratios, also promote Hg^0 oxidation. Br species dramatically accelerate Hg^0 oxidation rates on some catalysts by as much as a factor of 40 compared to the rates for Cl species. The analysis also shows that shifting the pore size distribution toward macropores in a final catalyst layer appears to be an effective means to directly enhance Hg^0 oxidation.

The WFGD analysis predicts Hg reemission along the entire absorber, but not in the slurry holding tank for a limestone, forced oxidation system. The total S(IV) species concentration in the slurry promotes reemission; conversely, the analysis correctly predicts less reemission for greater Cl^- concentrations. Simulations with added S(II) species, as released from commercial additives to suppress Hg reemission, correctly gave complete precipitation of Hg(II) as HgS(s). These predictions are consistent with full-scale field tests where the addition of NaHS almost completely suppressed Hg reemission and the extent of reemission did not bear any relation to the additive feed rate. But this analysis needs additional validation with data from full-scale WFGDs before it can deliver accurate quantitative interpretations.

Abstract

Chloride (Cl^-) is a major anion found in all natural waters. It occurs naturally and is also a relatively minor contaminant. Chloride concentrations in Illinois range from less than 0.1 milligrams per liter (mg/L) in precipitation to close to 100,000 mg/L in Paleozoic brines. Chloride is non-toxic to humans, although there is a secondary drinking water standard of 250 mg/L. It is, however, deleterious to some plants and aquatic biota, thus the Illinois Environmental Protection Agency (IEPA) has set an acute standard of 500 mg/L for surface waters in Illinois. Chloride is also a very corrosive agent, and elevated levels pose a threat to infrastructure, such as road beds, bridges, and industrial pipes.

Some streams and aquifers in Illinois have naturally elevated Cl^- concentrations due to surface or near-surface discharge of Paleozoic brines. Of greater concern to water resources in Illinois are anthropogenic sources of Cl^-, including road salt runoff, sewage, water conditioning salts, and fertilizer. Chloride concentrations are elevated in most water bodies in the Chicago region, primarily due to road salt runoff. Concentrations have been increasing since approximately the 1960s, and in general, concentrations continue to increase. These elevated Cl^- concentrations may pose a risk to infrastructure as well as aquatic to ecosystems.

Introduction

Chloride (Cl^-) is a naturally occurring major anion found in all natural waters. Chloride behaves as a conservative ion in most aqueous environments, meaning its movement is not retarded by the interaction of water with soils, sediments, and rocks. As such, it can be used as an indicator of other types of contamination. Anomalously high concentrations can act as an "advance warning" of the presence of other more toxic contaminants. Concentrations of Cl^- in natural waters can range from less than 1 milligram per liter (mg/L) in rainfall and some freshwater aquifers to greater than 100,000 mg/L for very old groundwaters within deep intracratonic basins (Graf et al., 1966; Psenner, 1989). Its concentration in precipitation in mid-continental regions (far from oceans and other salt sources) is almost always less than 1 mg/L, and often less than 0.1 mg/L (NADP, 2011). Upon contacting land surface, Cl^- concentrations in water increase as a result of interaction with soils, rocks, and biota (waste products), as well as the effects of evaporation. Chloride is the most abundant ion in seawater, with a concentration greater than 19,000 mg/L (Stumm and Morgan, 1996). Extremely elevated levels of Cl^- in surface water are generally due to significant evaporation (e.g., the Dead Sea has a Cl^- concentration > 230,000 mg/L).

Chloride is non-toxic to humans, but elevated levels make water unpotable due to the salty taste. In the U.S., there is a secondary (non-enforced) drinking water standard of 250 mg/L, but in areas of the world with water scarcities, drinking water can have considerably greater concentrations of Cl^-. Chloride is corrosive to steel, thus it may corrode pipes in water treatment and industrial plants. Because it imparts a salty taste to water and is corrosive, elevated Cl^- levels in drinking water supplies can lead to increased treatment costs. Elevated Cl^- in surface water has been linked to damage of terrestrial and aquatic plants and aquatic animals at concentrations as low as 210 mg/L (Environment Canada, 2001; Hart et al., 1991; Kaushal et al., 2005; Wilcox, 1986). The U.S. Environmental Protection Agency (USEPA) recommends a chronic criterion for aquatic life of a four-day average Cl^-concentration of 230 mg/L with an occurrence interval of once every three years (USEPA, 1988). The recommended acute criterion is 860 mg/L, which relates to a one-hour average concentration with a recurrence interval of less than once every three years. The Illinois EPA (IEPA) uses an acute criterion of 500 mg/L, but there is no chronic standard. The government of British Columbia has proposed a lower maximum Cl^- concentration of 600 mg/L and a 30-day average concentration of 150 mg/L to protect freshwater life (Nagpal et al., 2003). Increased Cl^- concentrations in some environments have killed off native vegetation and allowed invasive salt-tolerant species to thrive (Panno et al., 1999).

The objective of this report is to characterize the sources, distribution, and trends of Cl^- in the waters of Illinois, including rainwater, lakes, rivers and streams, groundwater, and wetlands.

Acknowledgements

This study was funded by the state of Illinois. We thank the institutions and individuals who provided data as well as additional information: Metropolitan Water Reclamation District of Greater Chicago (MWRDGC) (Jennifer Wasik), Lake County Health Department (Michael Adam and Kathleen Paap), Illinois State Water Survey (ISWS) (Vern Knapp), and IEPA (Missy Cain and Kevin Zidonis). Peng Wang, Ran Xu, and Mei Zhou, members of Adam Martinsek's STATS 427 class at the University of Illinois, helped with some of the statistical analysis. Tom Holm and Mike Machesky (ISWS) provided helpful comments. The views expressed herein are those of the authors and do not necessarily reflect the views of the Illinois State Water Survey, Illinois State Geological Survey, or the University of Illinois at Urbana-Champaign.

Natural Sources of Chloride

Precipitation

Chloride in precipitation and dry deposition originates from marine aerosols or volcanic gases. Naturally-occurring Cl^- concentrations in rainwater and snowmelt can be several mg/L near the coastal regions of the U.S. due to the contribution of seawater aerosols (Figure 1). Chloride concentrations in mid-continental regions are much lower. Concentrations in Illinois are typically less than 0.1 mg/L (NADP, 2011).

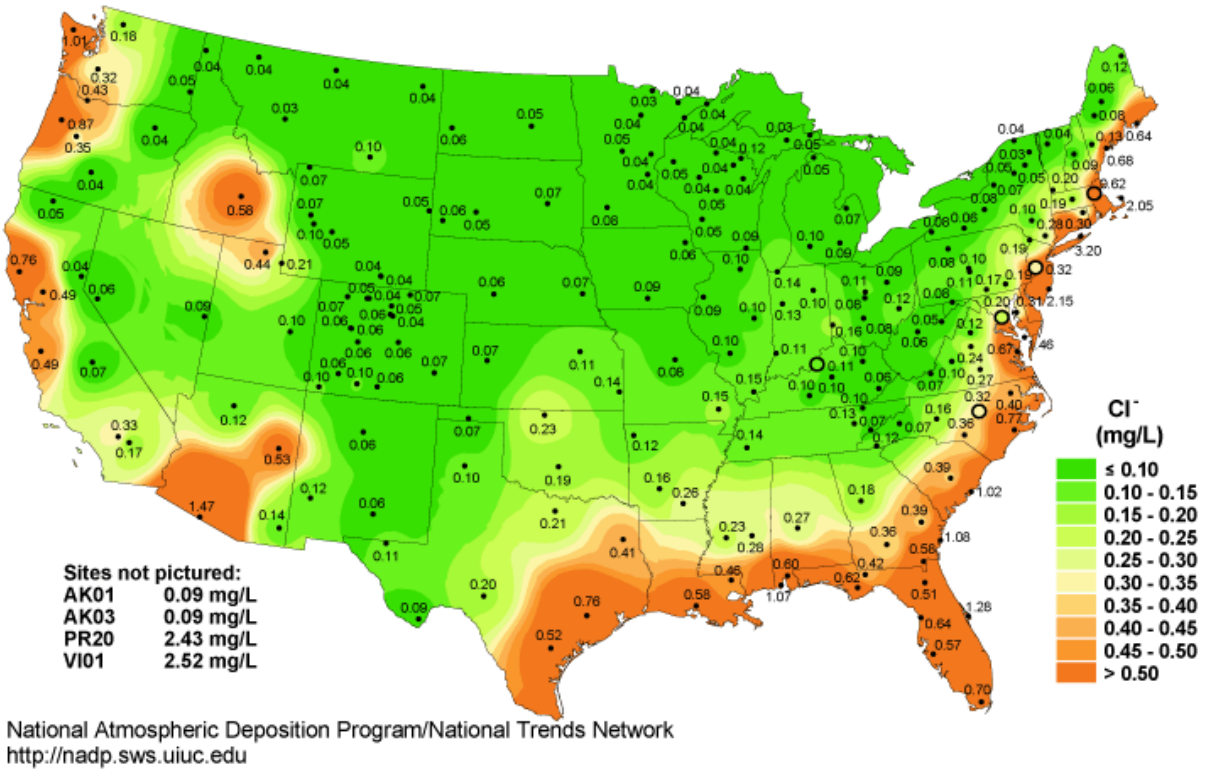

Figure 1. Chloride concentrations in U.S. precipitation for 2009. Map from NADP, 2011.

Rock-Water Interactions

Once rainwater and snow fall to the ground, evaporation and evapotranspiration tend to concentrate the Cl^- in soil water to levels ten or more times their original concentration. Rock-water interactions such as mineral dissolution and desorption within the soil zone and groundwater can further increase Cl^- concentrations.

The largest source of Cl^- in the Earth's crust is the mineral halite (NaCl) in evaporate deposits, which formed over geologic time by the evaporation of seawater. Chloride is also found in other less common salts (e.g., potassium chloride [KCl] and calcium chloride [$CaCl_2$]) associated with these evaporite deposits. Because halite and other chloride salts are extremely soluble, they are not found in areas where there is active circulation of fresh water. There are no known halite deposits in Illinois, although there is evidence from breciated limestone that evaporates may have existed in the geologic past (Willman et al., 1975). Chloride is found in small amounts (1000 to 10,000 parts per million [ppm]) in some silicate and phosphate minerals, including biotite, amphibole, apatite, sodalite, and scapolite (Kamineni, 1987), but these are not common minerals in the sedimentary rocks and sediments of Illinois. Chloride is a minor constituent of sedimentary rocks such as limestone, sandstone, and shale (as well as granitic rocks), but typically at low concentrations. Krauskopf (1979) reported typical Cl^- concentrations of 150, 10, and 200 ppm for limestone, sandstone, and shale, respectively. Chloride is also present within some minerals as fluid inclusions and can have very high concentrations comparable to those of a concentrated brine; however, fluid inclusions are typically very small (a few microns in diameter) and impart very little Cl^- to circulating groundwater. Because of the lack of appreciable amounts of Cl^- in rocks and sediments of Illinois, soils, sediments, and rocks in the shallow subsurface in Illinois would not be expected to have appreciable amounts of naturally-occurring Cl^-.

There are, however, natural brines in Paleozoic sedimentary formations of the Illinois Basin that underlie the southern two-thirds of the state (Figure 2). Meents et al. (1952) sampled over 700 oil field brines in the oil-producing regions of Illinois, primarily in the southeastern quadrant of the state; more than 80 percent of the samples had Cl^- concentrations greater than that of seawater, with a high of ~95,000 mg/L. Panno et al. (2006) summarized data from several studies in the Illinois Basin, and calculated a median Cl^- concentration of 64,600 mg/L, about three times the concentration in seawater.

Naturally saline groundwater in Illinois is very old. The chemical and isotopic compositions of brines in the Illinois Basin suggest they were formed as a result of the partial evaporation of seawater short of the precipitation of halite (Walter et al., 1990; Stueber and Walter, 1991; Kesler et al., 1995). Deeper groundwater in Precambrian granitic bedrock is even more saline, intensified by very long-term rock-water interactions at much warmer conditions than those encountered nearer the surface. Groundwater in the deeper parts of the Paleozoic and crystalline basement bedrock of the Illinois Basin is typically a hypersaline, calcium (Ca)-sodium (Na)-Cl-type brine with total dissolved solids (TDS) concentrations greater than 100,000 to over 250,000 mg/L (Horita, 2005).

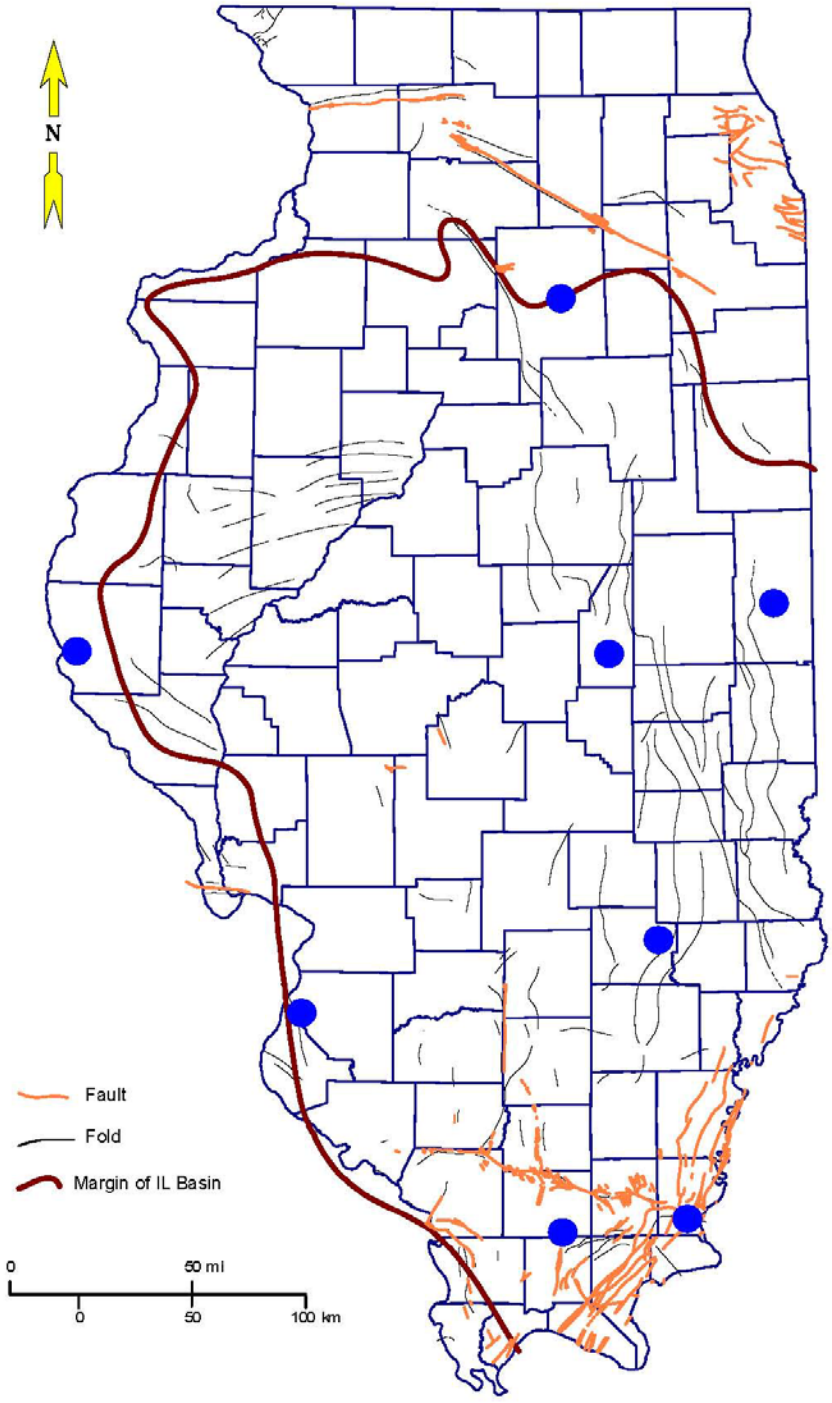

Figure 2. Illinois Basin. Blue circles indicate location of saline springs. Figure from Panno et al. (in preparation).

Saline groundwater in Illinois is under pressure, and at many locations it discharges into shallower aquifers or at the land surface as saline springs (Bartow et al., 1909; Willman et al., 1975; Cartwright, 1970; Panno et al., 1994, 2006). Bedrock discharge into the Mahomet Aquifer in Piatt County in east-central Illinois increases the Cl^- concentration from less than 10 mg/L to concentrations as high as 500 mg/L (Hackley et al., 2010). Thirteen samples of brine-affected groundwater collected by Panno et al. (2006), primarily in the southern part of the state, had a median Cl^- concentration of 474 mg/L. In some parts of Illinois, especially in the south, these deep brines discharge to surface waters, increasing the natural Cl^- concentration. For example, the North Fork of the Saline River in southeastern Illinois, named for its natural saltiness, had a median Cl^- concentration of 109 mg/L between 1978 and 1997 (USGS, 2009).

Background Chloride Concentrations

Despite the existence of saline seeps in Illinois, the vast majority of groundwater has relatively low concentrations of Cl^-, especially in major aquifers. In a study of shallow groundwater (< 100 meters) in northern Illinois, Panno et al. (2006) determined that Cl^- concentrations in shallow aquifers ranged from less than 1 to 15 mg/L. They suggested that concentrations greater than 15 mg/L indicated contamination from human sources. This threshold is probably similar (or lower) for aquifers in the rest of Illinois as well, where urbanization is less (Panno et al., 2005). Prior to human alterations to the landscape, almost all water discharging to surface streams in Illinois passed through the subsurface (i.e., groundwater), and a large majority still does. Thus pristine surface waters in Illinois should have Cl^- concentrations < 15 mg/L. Lusk Creek, for example, which flows through the undeveloped Shawnee National Forest in southern Illinois, had a median Cl^- concentration of 2.3 mg/L between 1978 and 1997 (USGS, 2009).

Anthropogenic Sources

Schlesinger (2004) estimated that more than 140 teragrams (140 trillion kilograms) of Cl^- are annually cycled through various reservoirs on Earth, almost all of it due to human activities. Anthropogenic sources include human sewage, livestock waste, water conditioning salt, synthetic fertilizer (primarily KCl), brine disposal pits associated with oil fields, chemical and other industries, and, in snowy climes, road salt runoff. From a volume standpoint, the most important anthropogenic sources of Cl^- to waters in Illinois are fertilizer, road salt, water conditioning salt, sewage, and livestock waste (Table 1). Chloride concentrations for potential contamination sources of Cl^- in Illinois are shown in Table 2. Once in groundwater, Cl^- and other contaminants can persist for many years if travel times are slow. For example, Howard et al. (1993) estimated that if road salting was stopped immediately in the Toronto area, it would be decades before the Cl^- concentrations returned to pre-1960 levels in shallow groundwater. In rural areas, agricultural sources of Cl^- are of greater importance. Oil field-related contamination problems have occurred primarily in the southern two-thirds of Illinois.

Table 1. Annual Chloride Fluxes in Illinois

Source	*Flux (metric tons)*
Treated Wastewater	
MWRDGC	175,000
Remainder of state	125,000
Atmospheric	18,000
Road Salt	471,000
Water Conditioning Salt	135,000
Fertilizer (KCl)	373,000
Livestock	139,000
Lake Michigan withdrawals	34,000
Groundwater withdrawals	
Public supply wells	12,500
Industrial/commercial	5,300
Irrigation	10,000
Oil-Field Brines	23,000

Note: The treated wastewater fluxes do not include road salt inputs.

Human Waste

The median Cl^- concentration in treated wastewater (TWW) discharging from the Stickney wastewater treatment plant (WWTP) in Chicago (the largest in the U.S.) between 2000 and 2008 was 145 mg/L (based on weekly sampling) (MWRDGC, 2010) (Table 2). Kelly et al. (2010) got similar results in samples collected on three dates between 2003 and 2005 from two Metropolitan Water Reclamation District of Greater Chicago (MWRDGC) WWTPs (Stickney and Calumet); they reported a median Cl^- concentration of 141 mg/L. Kelly et al. (2010) also collected samples from the Peoria WWTP, which had Cl^- concentrations that ranged from 113 to 291 mg/L. TWW is generally discharged directly into surface waterways in Illinois.

Livestock Waste

Animal waste contains elevated concentrations of Cl^-; Panno et al. (2006) measured levels as high as 1980 mg/L (Table 2). Because of this, even relatively small concentrations of livestock can create a local problem for shallow groundwater. Large confined animal feeding operations, which can concentrate thousands of animals in a relatively small area, have the potential to produce more widespread contamination of shallow groundwater, streams, and rivers (Wing et al., 2002; Showers et al., 2008).

Road Deicers

The chemical industry and governmental departments handling road ice control are the major importers and consumers of halite in the U.S., accounting for about three-fourths of its total use (Kostick, 2008). Road salt has been linked to groundwater degradation in many urban and roadside areas in snowy climes (Amrhein et al., 1992; Bester et al., 2006; Howard and Haynes, 1993; Huling and Hollocher, 1972; Pilon and Howard, 1987; Williams et al., 2000b). Significant application of road salt began after World War II and accelerated rapidly from the 1960s (Figure 3) (Salt Institute, 2009). Chloride concentrations have been increasing in surface waters and groundwater in urban regions of the northern United States and Canada since the 1960s, primarily due to road salt runoff (Godwin et al., 2003; Howard and Haynes, 1993; Kaushal et al., 2005; Kelly, 2008; Novotny et al., 2009; Kelly et al., 2010).

Two road salt runoff samples collected by Kelly et al. (2010) dripping off road bridges in Pekin and Willow Springs, IL, had very high concentrations of Cl^-: 1572 and 8930 mg/L, respectively (Table 2). Chloride concentrations in road salt runoff samples are extremely variable due to variability in application rates, snowfall amounts, melting rates, etc.; the values measured by Kelly et al. (2010) fall within the range of values reported by others (Amrhein et al., 1992; Environment Canada, 2001; Greb et al., 2000; Pilon and Howard, 1987). Road salt also can increase Cl^- concentrations in precipitation. For example, Williams et al. (2000a) characterized road salt aerosol in suburban areas west and south of Chicago, and measured Cl^- concentrations up to 9.4 mg/L in samples collected after snow events. They also found that Cl^- concentrations in snow samples decreased exponentially with distance from major highways.

Road salt runoff that recharges the soil zone and shallow groundwater can produce very high concentrations of Cl^-. Kelly and Roadcap (1994) measured Cl^- concentrations in excess of 1,000 mg/L in several shallow (< 25 ft; 7.6 m) monitoring wells installed along the uncurbed Interstate 94 in south Chicago, including two exceeding 3,500 mg/L.

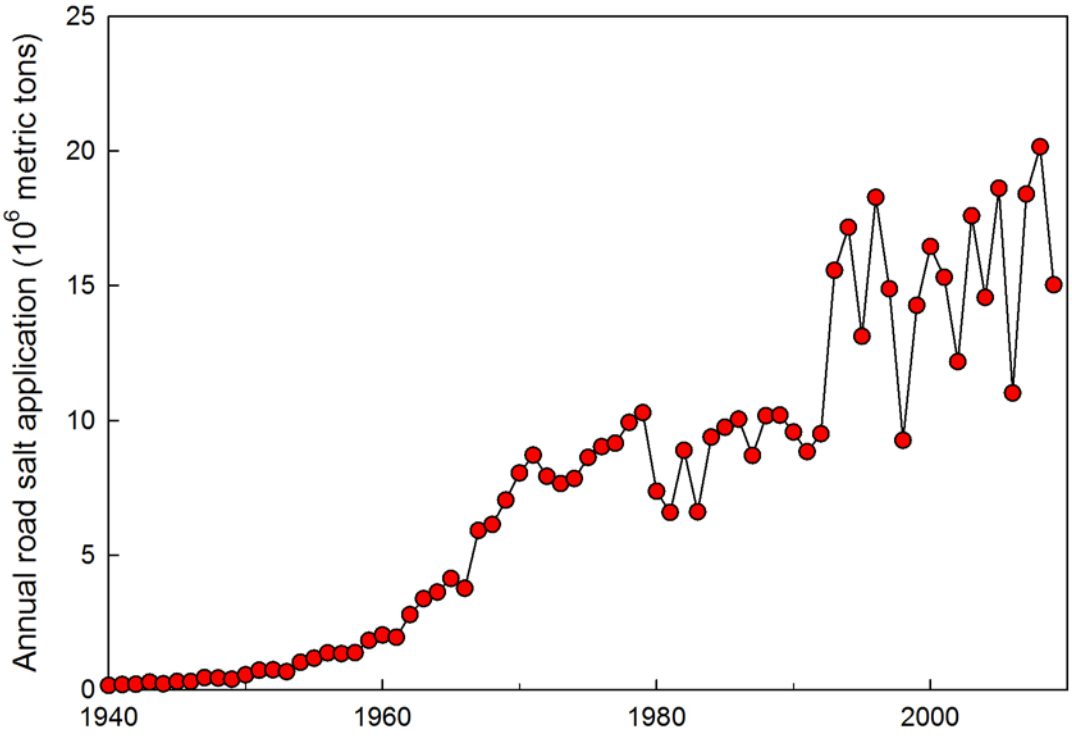

Figure 3. Yearly U.S. highway salt sales. Data from Salt Institute, 2011.

Water Conditioning Salts

In-home water treatment, specifically water softening, typically uses NaCl to recharge ion exchange columns in order to reduce hardness (Ca + Mg) by replacement with Na. For a family of three or four with moderately hard water, the recommended amount of NaCl for water softening is between 1.8 and 2.7 kilograms per day, or 600 to nearly 1000 kg of NaCl per year (Panno et al., 2005, 2007). If a household uses on-site wastewater treatment, the Cl^- is discharged to the shallow groundwater system via the leach field. If the household is connected to a community waste treatment facility, the Cl^- (which is not removed in the treatment process) is generally discharged to streams or rivers.

KCl Fertilizer

Illinois is a major producer of row crops, primarily corn and soybeans. KCl is the most commonly available potassium (K) fertilizer and usually the cheapest, thus it is widely applied in Illinois. Because it is spread over large areas (i.e., non-point source), its impact on soil water and

groundwater quality is less than more concentrated Cl^- applications, such as road salt. In much of Illinois, agricultural fields are tiled to facilitate drainage of soils, and these drain tiles are the major source of water to many streams in Illinois. Panno et al. (2005) and Kelly et al. (2010) collected samples from several tile drains in east-central Illinois, which represent shallow groundwater beneath row crop areas. Chloride concentrations in these tile drain samples ranged from 10 to 37 mg/L (Table 2). This is also approximately the same concentration range found in soil water in agricultural fields in central Illinois (W. Kelly, unpublished data).

Municipal Landfills

Panno et al. (2006) measured Cl^- concentrations in municipal landfill leachate as high as 6,170 mg/L. Roy (1994) reported the greatest Cl^- concentration recorded in municipal landfill leachate to be 27,100 mg/L. Potential sources of Cl^- in landfills include food scraps and pet wastes. Chloride concentrations in landfills are not static, but decrease with the age of the landfill (McGinley and Kmet, 1984; Ham, 1980; Lu et al., 1985). Farquhar (1989) reported that Cl^- concentrations in municipal landfill leachate tend to decrease asymptotically with time, with concentrations 1,000–3,000 mg/L during the first five years, 500–2,000 mg/L during years 5 to 10, 100–500 mg/L during years 10 to 20, and < 100 mg/L after that.

Oil and Gas Exploitation

Leakage of brine-holding ponds associated with oil wells has locally contaminated groundwater with high TDS waters in southeastern Illinois. Hensel and McKenna (1989) installed shallow monitoring wells around two brine-holding ponds in Clay County and measured Cl^- concentrations over 10,000 mg/L in several samples. They identified 384 holding ponds in their study area (~300 mi^2 in southeastern Clay County), so the potential for widespread groundwater contamination is significant and hundreds of acres of farm land were reported to have been made unsuitable for crops due to brine leakage and spillage. However, Hensel and McKenna (1989) found no widespread degradation of groundwater resources in the area.

Identification of Sources of Chloride

There are various methods for determining the source(s) of Cl^- in individual water samples, one of the best being halide ratios. In a recent investigation, Panno et al. (2006) collected more than 100 samples from various Cl^- sources (primarily in Illinois) and, by plotting Cl^- and bromide (Br^-) data on a Cl^- vs. Cl/Br diagram, were able to define domains that distinguish among the sources (Figure 4). TWW can plot outside the septic effluent source domain because there are often multiple sources of Cl^- in TWW. Chicago and many of its suburbs have combined sewers (sewage and storm water), and an average of about 30 percent of the water entering the Stickney WWTP is from storm runoff (J. Wasik, MWRDGC, December 1, 2006, personal communication). The highest Cl/Br ratios in TWW measured by Kelly et al. (2010) were during the winter, which was due to a dominant road salt component.

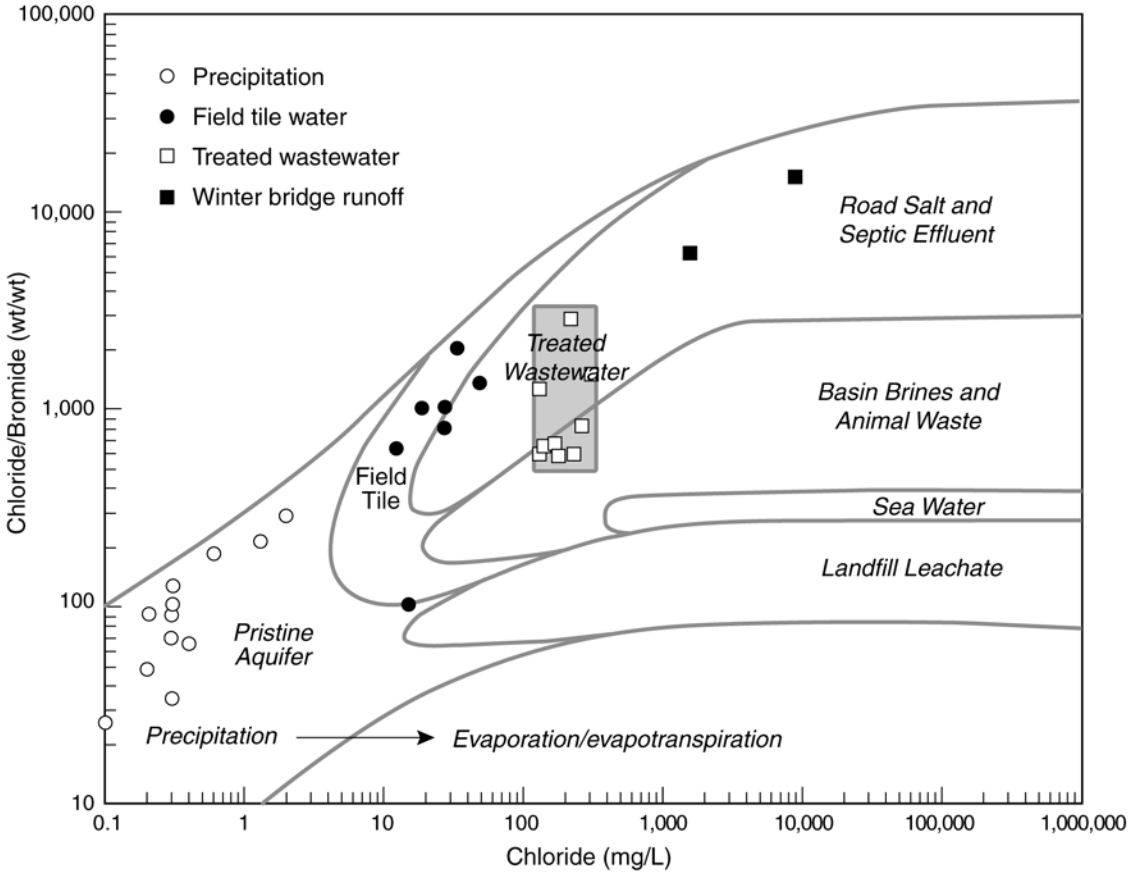

Figure 4. Cl/Br vs. Cl^- plot showing source domains (Kelly et al., 2010)

Annual Fluxes of Chloride in Illinois

The estimated annual flux of Cl^- in Illinois from various sources was determined using the methods of Kelly et al. (2010) (Table 2). They found that Cl^- in the Illinois River Basin was predominantly from road salt, TWW, and KCl fertilizer. An accurate estimate of how much road salt is applied in an average winter is difficult, due to the large number of government agencies and private entities that apply salt to roads and parking lots. Friederici (2004) and Keseley (2006) reported more than 250,000 metric tons of road salt is applied annually in the Chicago metropolitan region, but this is almost certainly an underestimate. Probably the best method for estimating road salt applications is to use road salt sales reported by the Salt Institute (Salt Institute, 2009) as a proxy. Using additional state data from Richter and Kreitler (1993) and Panno et al. (2005), Kelly et al. (2010) estimated that an annual average of 471,000 metric tons of road salt (equivalent to ~283,000 metric tons of Cl^-) were used in Illinois for the years 2002 to 2005, mostly in the Chicago region. Average annual road salt sales have increased since 2005, so the amount of road salt applied in Illinois has undoubtedly increased as well. The amount applied in a particular year generally depends on how much snow and ice fall during winter.

The Cl^- flux for TWW from the Chicago region can be calculated from WWTP discharge and Cl^- concentration data reported by MWRDGC (MWRDGC, 2010), but this calculation is complicated by multiple sources in TWW and the potential for "double counting" of sources. In addition to human waste, TWW includes industrial effluent, water conditioning salt, and road salt, as well as Cl^- present in drinking water sources.

Chloride fluxes from the Chicago WWTPs were calculated using Cohn's equation (Kelly et al., 2010). Road salt contributions were removed from the WWTP loads by assuming that there was no road salt in TWW from May to October. Chloride loads during these months were divided by monthly discharges, and it was assumed that the same load per discharge ratio for non-road salt sources occurred between November and April. The remaining chloride loads between November and April (which varied between 17 percent and 50 percent of the total monthly load) were assumed to come from road salt and were removed from the TWW load calculations.

The seven MWRDGC plants account for almost 60 percent of the TWW discharged to surface water bodies in Illinois. To calculate the Cl^- flux for the remaining TWW, it was assumed that the effluent Cl^- concentration was the same as for the MWRDGC plants, resulting in a flux of 125,000 metric tons.

Human waste actually accounts for a small percentage of Cl^- in TWW. Adult humans excrete between 110 and 250 millimoles of Cl^- per day (3,900–8,860 mg day) (WebMD, 2011). Assuming 5,500 mg of Cl^- per day, a typical value for urine production (1.25 L/day), and a 2010 population of 12.83 million, results in about 32,000 metric tons of Cl^- from human urine annually in Illinois. Another approach taken by Mullaney et al. (2009) is to use per capita salt consumption based on the recommended daily adult sodium intake of 2,300 mg/d, which would include about 3,547 mg of Cl^-. A person on this diet would consume, and release, about 1.3 kg of Cl^- per year, which would be released by wastewater discharge. This would produce almost 17,000 metric tons of Cl^- in Illinois per year. Either estimate represents less than 10 percent of the Cl^- in TWW.

Chloride from water conditioning salt was also estimated from salt sales data. Between 2005 and 2008, approximately 3.2 million metric tons of salt (predominantly NaCl) was sold for water conditioning in the U.S. (Salt Institute, 2009). Assuming that water conditioning salt use was distributed equally across the U.S. based on population, approximately 135,000 metric tons of Cl^- is annually consumed in Illinois by water conditioning.

About 80 percent of corn fields and 30 percent of soybean fields in Illinois receive potassium chloride (KCl) annually (USDA, 2008). The amount of KCl applied in Illinois was estimated from state fertilizer sales data (USDA, 2008). Between 2005 and 2007, an average of 373,000 metric tons of Cl^- from KCl were purchased per year in Illinois.

Between 2005 and 2008, there were approximately 4.23 million pigs and 1.28 million cattle in Illinois (Illinois Agricultural Statistics Service, 2009). A pig produces about 3 gallons of waste a day and a cow produces 14 gal/day. Using Cl^- concentrations of 3,680 mg/L and 3,000 mg/L for pigs and cows, respectively (DeRouchey et al., 2003; Lengemann et al., 1952), an annual total of 139,000 metric tons of Cl^- was calculated to come from livestock.

For Cl^- from precipitation, a Cl^- concentration of 0.12 mg/L and an average annual precipitation of 102 centimeters (cm) were assumed (NAPD, 2011). This gives approximately 18,000 metric tons of Cl^-.

One source of Cl^- that may be overlooked is water extracted from Lake Michigan and groundwater for drinking, industrial, and agricultural purposes. Chicago and many of the inner suburbs obtain drinking water from Lake Michigan, which has a Cl^- concentration of approximately 12 mg/L. Because most of the water Illinois takes from Lake Michigan is discharged outside the Great Lakes Basin, Illinois is limited by U.S. Supreme Court decree to 3,200 cubic feet per second (cfs) (~2,900 billion L/yr) of water from the lake. Assuming Illinois diverts all of this each year, approximately 34,000 metric tons of Cl^- is removed from the lake. Most of this eventually finds its way into wastewater, which would be included in the TWW Cl^- flux, and eventually is discharged down the Illinois River.

Approximately 1,180 million gallons (4,470 million L) of groundwater are withdrawn daily in Illinois (Kenny et al., 2009). About 507 million gallons per day (mgd) (1,920 million L/day) are used for drinking and other household uses, 517 mgd for agriculture (irrigation and livestock), 128 mgd by industrial and commercial applications, 15.5 mgd by mining, and 7.2 mgd for thermoelectric. Most extracted groundwater is not returned to the ground, but eventually finds its way to surface waters. In communities with sewers, most drinking water eventually finds its way into wastewater, which is then discharged to surface streams and rivers, eventually leaving the state. For homes and businesses with private wells and on-site sewage treatment (i.e., septic systems), extracted groundwater is discharged at or just below the ground surface, and most does not recharge underlying aquifers but is either evapotranspired or discharged to nearby streams or other surface waters. The same is true for irrigation water.

Groundwater withdrawal data are available for many public water supply wells and industrial/commercial wells. Of the top 200 pumped public water supply wells, 176 have been sampled sometime in the past 20 years, and the Cl^- concentration and withdrawal data from 2008 were used to calculate the mass of Cl^- removed. In order to not include potential surface contamination sources in shallow wells, it was assumed that the background Cl^- concentration was 15 mg/L in all wells $\leq$ 250 feet deep. These results were then used to estimate Cl^- fluxes

from the other approximately 2,500 public water supply wells for which we have withdrawal data. It was estimated that approximately 12,500 metric tons of Cl^- was extracted from public supply wells.

Sample results were available only for 13 of the top 200 industrial/commercial wells. For 184 of the other 187 wells, samples from a well located near to and at a similar depth to the well in question were found, and the Cl^- concentration from that well was used to calculate Cl^- fluxes. Using these data and the assumption that the background Cl^- concentration was 15 mg/L in all wells $\leq$ 250 feet deep gives an estimate of approximately 5,300 metric tons of Cl^- extracted annually from industrial/commercial wells.

In 2005, the U.S. Geological Survey estimated that approximately 479 million gallons of water were pumped from irrigation wells in Illinois (USGS, 2009). Withdrawal data from individual irrigation wells are lacking in Illinois. Because most irrigation wells are finished in relatively shallow sand and gravel aquifers, it was assumed that the Cl^- concentration was 15 mg/L. This gives a Cl^- flux of approximately 10,000 metric tons from irrigation wells.

It is difficult to get accurate estimates of how much water is withdrawn for oil and gas production. The most recent and most reliable estimates are from the 1980s, when Kirk (1987) reported that 25.5 million gallons per day (~9.3 billion gallons annually) were withdrawn. Almost all of this is reinjected for secondary oil and gas recovery. However, some of this brine was temporarily stored in ponds at the surface, and leakage to surface and shallow subsurface environments has been reported (Hensel and McKenna, 1989). Using the median concentration of 64,600 mg/L reported by Panno et al. (2006), and assuming leakage of 1 percent of the withdrawn brine, gives an annual Cl^- flux of approximately 23,000 metric tons.

Distribution and Trends in Chloride Concentrations in Waters of Illinois

Recent research has suggested that Cl^- concentrations in many water bodies in Illinois are changing (e.g., Kelly [2008] and Kelly et al. [in press]), thus any report on the distribution of Cl^- is a "snapshot in time," subject to change. This is especially true for rivers and shallow groundwater in urban and urbanizing areas, most notably the Chicago region. In order to fully understand the distribution of Cl^- in the waters of Illinois, a discussion of temporal trends must also be included. Trends in Cl^- concentrations in surface water and groundwater can reveal much about the origin, evolution, character, and movement of its sources. Such information is critical to predicting future changes in Cl^- concentrations.

Lakes

As mentioned previously, Lake Michigan currently has an average Cl^- concentration of 12 mg/L, its highest historical level. Concentrations have been slowly increasing since the late 1800s, due to human inputs to the lake (Chapra et al., 2009), with an increase of about 3 mg/L since the 1980s (USEPA, 2011a) (Figure 5). While the increase seems small, it represents an additional annual load of approximately 600,000 metric tons of Cl^- to Lake Michigan.

Natural lakes in Illinois are primarily found in the northern part of the state, especially Lake and McHenry Counties. Most lakes in downstate Illinois are reservoirs created by the

damming of streams and rivers. Their Cl^- concentrations are similar to those found in their stream or river supplies, potentially increasing in summer if there is significant evaporation.

Many lakes in Lake County have been monitored between April and October for dissolved solids since the late 1980s by the Lake County Health Department (LCHD). Chloride concentrations have been routinely monitored only since 2005, but specific conductance, which is highly correlated with Cl^- concentrations, has been monitored from the beginning. Specific conductance values have been increasing with time in most of these lakes (Figure 6). In 2010, the median Cl^- concentration in the 22 lakes being monitored by LCHD was 112 mg/L, with highest concentrations usually measured in the first sample collected (May). Between 2005 and 2010, Cl^- concentrations have generally dropped in many of these lakes, which has been attributed to dilution during the relatively wet summers in recent years (Figure 7) (M. Adams, LCHD, pers. comm.). There is anecdotal evidence that the increasing TDS levels in lakes at golf courses has forced their abandonment as sources of irrigation water due to the deleterious effects on turf. This in turn has led to drilling of new wells, increasing the amount extracted from aquifers in Lake County.

Rivers and Streams

Water quality data for streams and rivers in Illinois are available from several agencies, including the ISWS, USGS, MWRDGC, and IEPA. Chloride concentrations in streams in Illinois are highest in the Chicago region and lowest in streams in forested watersheds in far southern Illinois. The USGS has historical data from a number of streams and rivers throughout Illinois. A comparison of data sets from a time period with the greatest overlap of data (1990–1992) indicates that downstate rivers draining primarily agricultural watersheds (Kankakee, Spoon, La Moine) had median Cl^- concentrations < 30 mg/L (Table 3 and Figure 8). Even though the North Fork of the Saline River drains an agricultural watershed, it has natural sources of Cl^- (geological brine discharge) and thus had a significantly higher median Cl^- concentration (86 mg/L). The Sangamon River, which has several large cities in its watershed (Bloomington-Normal, Decatur, Springfield), had a median concentration (34 mg/L at its most downstream station, Oakford) higher than rivers draining primarily agricultural land. The Fox River, which drains some of the western suburbs of the Chicago region and receives TWW, had an even higher median concentration (70 mg/L at its most downstream station, Dayton). Major Chicago waterways, including the Des Plaines River and the Chicago Sanitary & Ship Canal (CSSC), had median values > 90 mg/L. The median Cl^- concentration in the Illinois River, which receives water from tributaries in the Chicago region as well as down-state, is > 60 mg/L at Peoria and upstream, dropping to around 50 mg/L near its discharge to the Mississippi. Figure 9 shows that there are large annual variations in Cl^- concentrations in rivers throughout Illinois.

The MWRDGC has been monitoring water quality monthly at surface water stations in the Chicago region since 1975, primarily in Cook County but also at a few stations in DuPage and Will Counties (Figure 10). Forty-one stations have been monitored relatively continuously since 1975, with more than 30 others having a shorter period of record. Median Cl^- concentrations in 2008 were > 150 mg/L at about 80 percent of the stations (Figure 11 and Table 4). The highest values tended to be in the smallest streams in northern Cook County, including Higgins Creek, Salt Creek, and Buffalo Creek, as well as the North Branch of the Chicago River. The stream with the lowest values appears to be the North Shore Channel, which receives significant flow from Lake Michigan.

The presence of trends in Cl^- concentrations were determined using Kendall's tau test at the 95 percent confidence level, and annual rates of change were estimated by calculating slope coefficients (β_1) on 5-point running medians (Helsel and Hirsch, 2002). Rivers draining the Chicago region, including the Illinois River, have increasing trends in Cl^- concentrations. Of the 41 stations monitored by MWRDGC since 1975, 35 had statistically significant positive trends in Cl^- concentrations, with a median increase of 2.7 mg/L per year (Table 5). Five stations had increases of greater than 5 mg/L/yr; two of these stations were in the North Branch of the Chicago River. Of a total of 78 USGS stations tested throughout the entire state, 36 had significant positive trends in Cl^- concentrations, and 10 had significant negative trends (Table 6). The positive stations included almost all the Chicago region rivers and canals (Des Plaines River, Fox River, Chicago River, Addison Creek, CSSC), as well as a number of down-state rivers, including the Kankakee, Rock, and Sangamon Rivers. All of the Illinois River stations, as well as those on the Mississippi and Ohio, had positive trends. The stations with negative trends were scattered throughout the state.

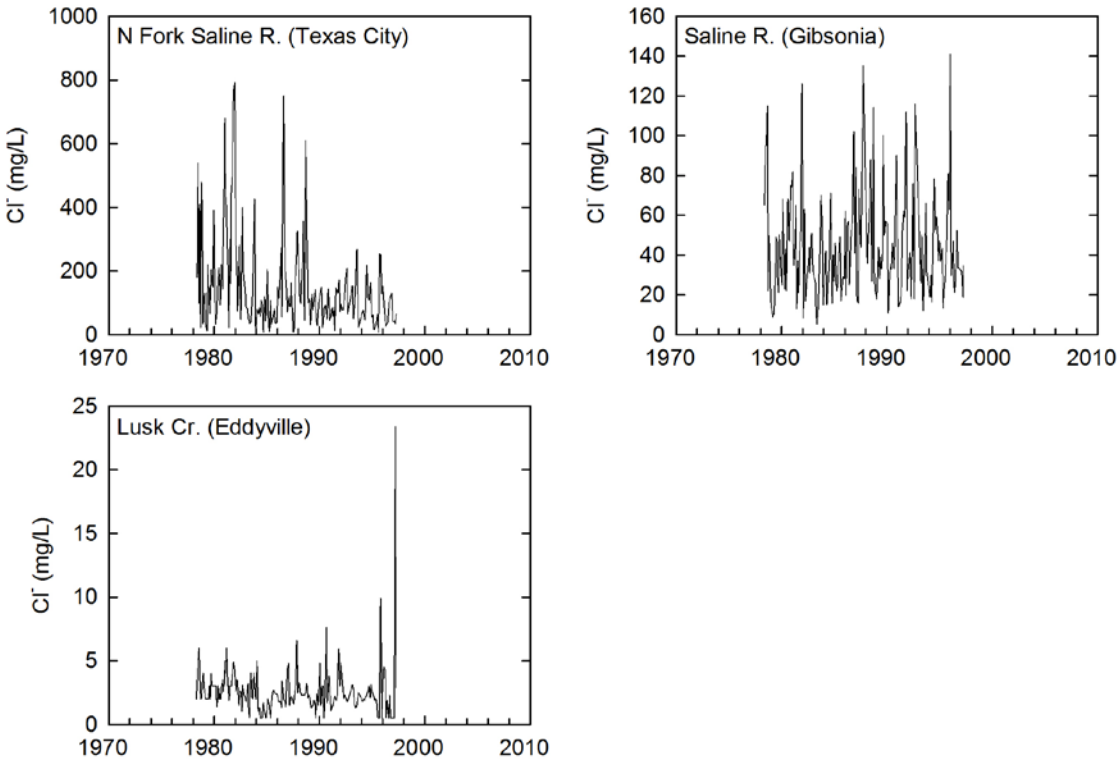

Figure 9. Continued

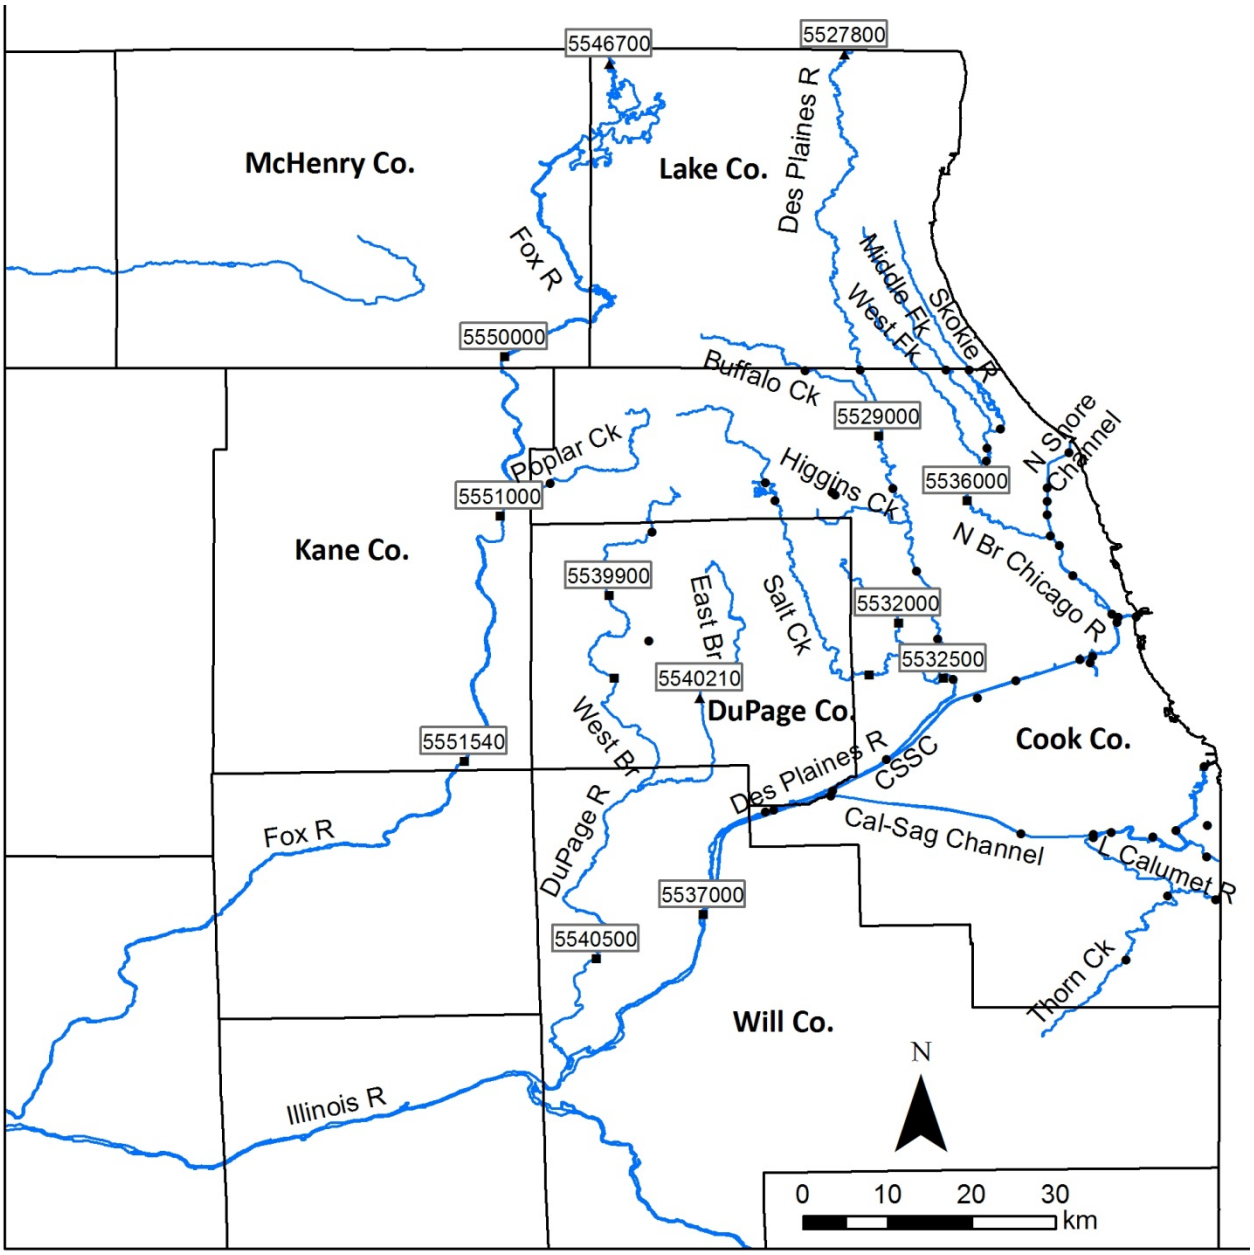

Figure 10. MWRDGC and USGS surface water monitoring stations evaluated in this study. Seven-digit numbers are USGS stations.

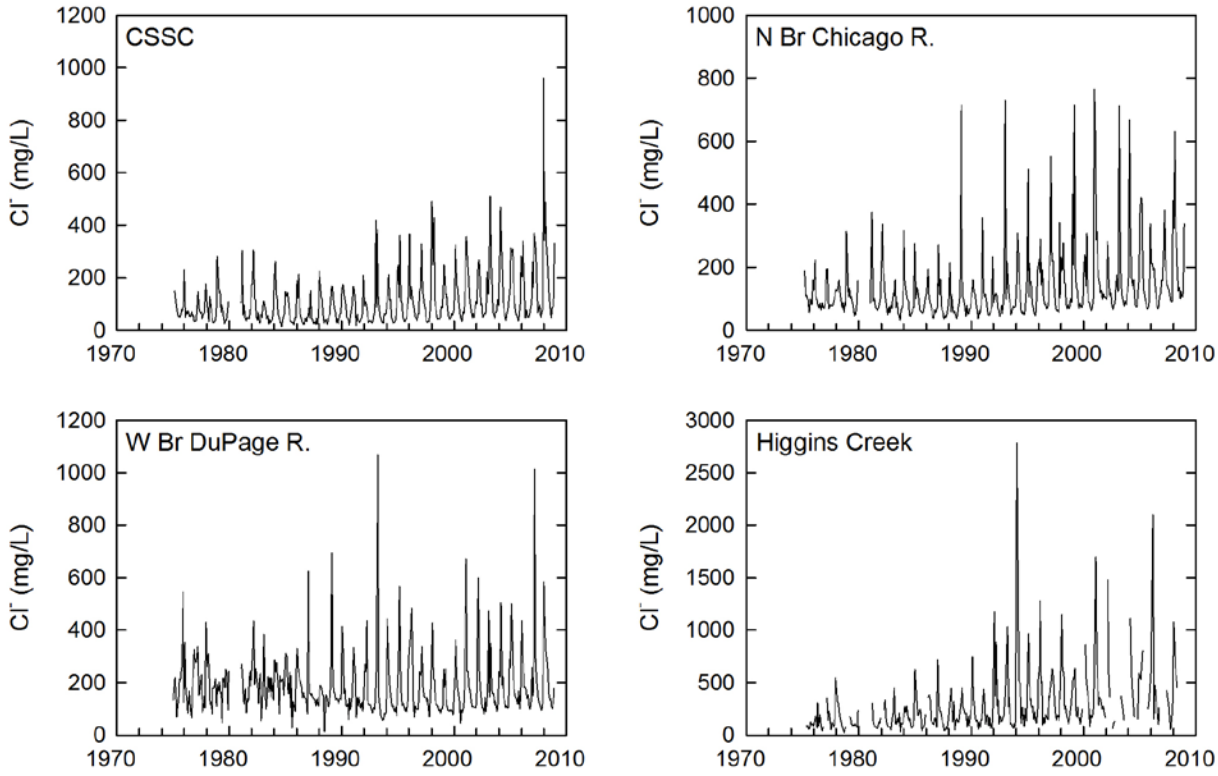

Figure 11. Chloride concentrations at selected MWRDGC monitoring stations in the Chicago region

There are clear seasonal differences in Cl^- concentrations for rivers where concentrations are increasing, with highest values between January and March (Figure 12). At 97 percent of the MWRDGC stations, the largest Cl^- concentrations were in the winter (January–March). At 83 percent of these stations, the winter concentrations were significantly greater (determined by ANOVA on ranks) than each of the other three seasons, and for 16 percent of these stations, concentrations were significantly greater than two of the other seasons. The spring months (April–June) generally had the second highest concentrations (88 percent of the stations), and for 53 percent of these stations spring concentrations were significantly greater than fall or summer. Concentrations were usually lowest in the summer (88 percent of stations). This seasonality is obviously due to road salt runoff. In snowy winters, large applications of NaCl produce Cl^- concentrations and loads in streams and rivers considerably higher than in winters with low snowfalls (Figure 13). It should be noted that during the months when Cl^- concentrations are lowest in the Chicago region (July–October), concentrations still are typically greater than 100 mg/L.

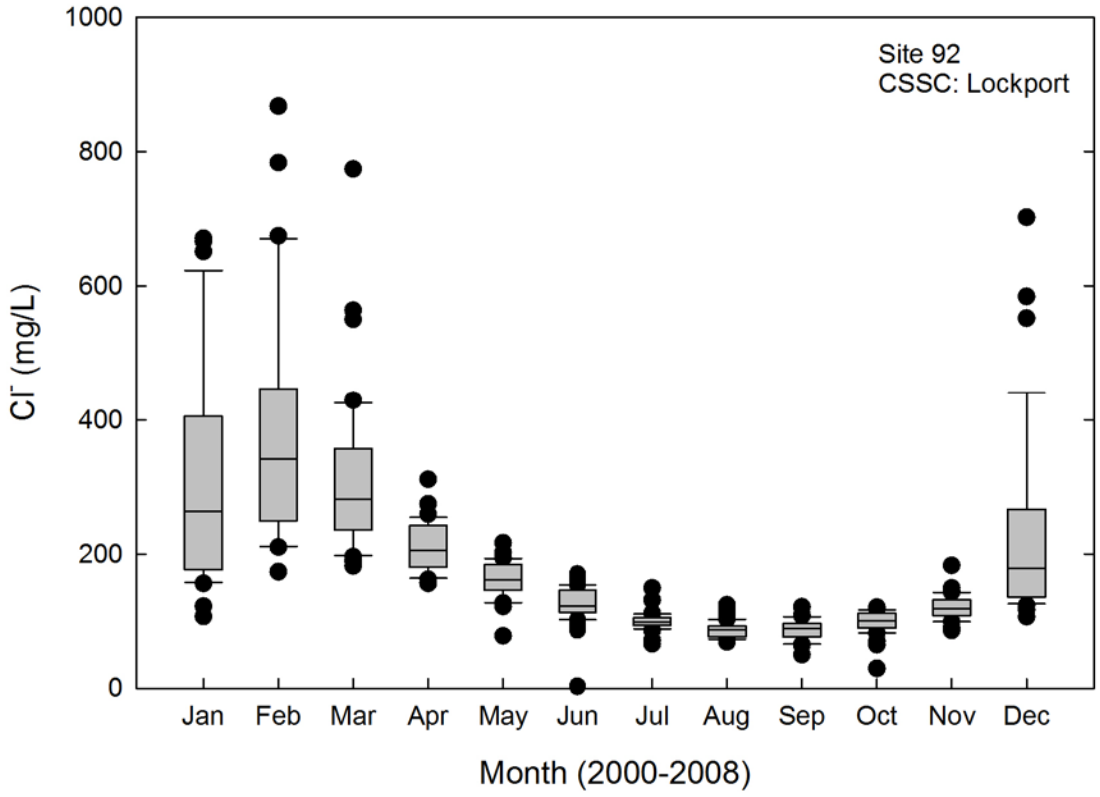

Figure 12. Chloride concentrations by month for MWRDGC station 92 (CSSC at Lockport) between 2000 and 2008. The site was sampled weekly.

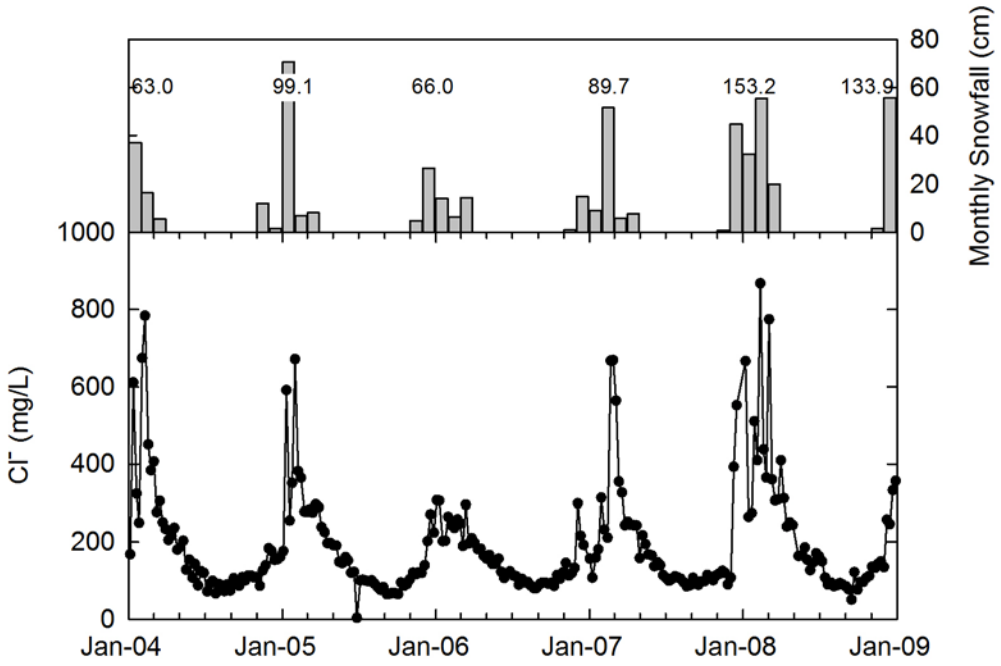

Figure 13. Chloride concentrations at MWRDGC station 92 on the CSSC at Lockport, IL, and monthly snowfall totals in Chicago (winter totals shown above bar). Snowfall data from NOAA, 2010.

Increasing trends in Cl^- concentrations are observed in all seasons at the MWRDGC stations, with the rates of increase following the same seasonal pattern as the concentration data, i.e., greatest increases in the winter and smallest in the summer (Figure 14 and Table 5). This is additional evidence that increases in Cl^- concentrations are the result of road salt runoff.

Rivers outside the Chicago region tended to have different seasonal patterns. Chloride concentrations in the Fox River were significantly lower between April and June than for both autumn and winter samples, and in the Sangamon River, concentrations were significantly lower between April and June than in all other seasons. For both these rivers, the highest Cl^- concentrations were typically measured between October and December. This may be due to leaching of fertilizer, which is typically applied in Illinois in the autumn after harvest. There were no significant seasonal differences for the Kankakee, Spoon, and La Moine Rivers.

Kelly et al. (2010) reported that chloride concentrations were significantly higher when river discharge was low, regardless of season. The USGS data sets showed the influence of discharge on Cl^- concentrations (Figure 15). For every station except CSSC reported by Kelly et al. (2010), Cl^- concentrations at low discharge (bottom 25^{th} percentile) were significantly greater than at high (top 25^{th} percentile) and intermediate (middle 50^{th} percentile) discharges, and concentrations at intermediate discharge were almost always significantly greater than at high discharge. For CSSC, Cl^- concentrations at low discharge were significantly greater than at intermediate discharge.

For the most part, discharge from tributaries to the Illinois River downstream of Chicago dilutes the concentrations of Cl^- and other ions originating from TWW and road salt. Road salt inputs are seasonally variable, with fluxes highest in the winter and early spring; the flux of contaminants from TWW should be less seasonally affected. Thus when the Illinois River discharge is low, there is less dilution of TWW downstream of Chicago. Therefore, Cl^-, which is elevated in TWW, becomes relatively elevated in the river because there is less dilution by downstream tributaries. This relationship can be seen in Figure 16, which shows the fraction of the Cl^- load at Peoria attributable to the load in the CSSC as a function of river discharge at Peoria. When discharge is low, it is not uncommon for more than 60 percent of the Cl^- load at Peoria to be attributable to what is coming out of the CSSC, which is predominantly TWW.

The longest record of data is the Illinois River at Peoria, which indicates that Cl^- concentrations have been steadily increasing since the 1960s (Figure 17). The annual increase since 1960 (from β_1 calculation) is 1.0 mg/L per year (mg/L/yr), and 3.1 mg/L/yr since 1990. Concentrations are highest in the winter and early spring months, and the variability in concentrations during these months has been increasing. The overall temporal increase in Cl^- concentrations is mostly due to increases during January through April; concentrations have increased at rates greater than 4.0 mg/L/yr in all these months since 1990. However, there were positive trends in all months except June, indicating that increases in Cl^- concentrations are due to factors other than just direct road salt runoff. Shallow groundwater in much of the Chicago region has elevated Cl^- due to road salt (Kelly, 2008), and most of this groundwater discharges to tributaries of the Illinois Waterway throughout the year, not just in winter. In addition, the increasing population and concomitant increase in residential acreage and sewage in the Chicago region is likely increasing the Cl^- load to the Illinois Waterway via TWW discharge. The influence of river discharge on Cl^- concentrations can also be seen in Figure 17. Concentrations were relatively low during flood years (e.g., 1972, 1993), and relatively high during droughts (1963–1964, 1977, 1980, 1988–1989).

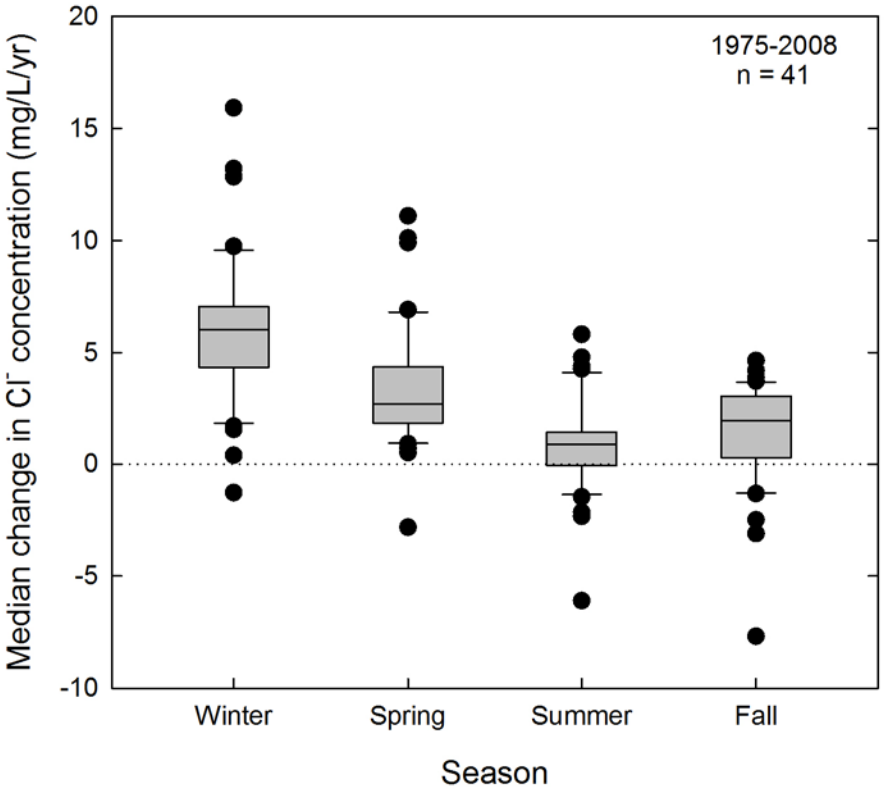

Figure 14. Box and whisker plot of median changes in chloride concentrations for 41 MWRDGC stations monitored between 1975 and 2008, divided by season. Changes calculated from slope statistic ($^{2}_{1}$) for linear regressions. Changes were significantly greater for winter compared to all other seasons, and for spring compared to summer and fall (ANOVA on ranks).

Groundwater

In this report, we use the hydrostratigraphic nomenclature developed by Meyer et al. (2009) to differentiate among aquifers in Illinois. In most of the state, the aquifers closest to the land surface are Quaternary in age. These are composed of unconsolidated sands and gravels deposited by glacial and alluvial processes. Bedrock aquifers in Illinois are all sedimentary rocks (sandstones and carbonates) of Paleozoic age, the youngest being Pennsylvanian and the oldest Cambrian. We divided the bedrock aquifers into three groups (Figure 18), from youngest to oldest: (1) the upper bedrock unit, primarily sandstones of Pennsylvanian and Mississippian age; (2) the Silurian-Devonian carbonate unit, primarily fractured dolomites; and (3) the Cambrian-Ordovician aquifers, which are primarily sandstones. The Cambrian-Ordovician group comprises several aquifers, but because wells are commonly open to more than one of these aquifers, we chose to group them together.

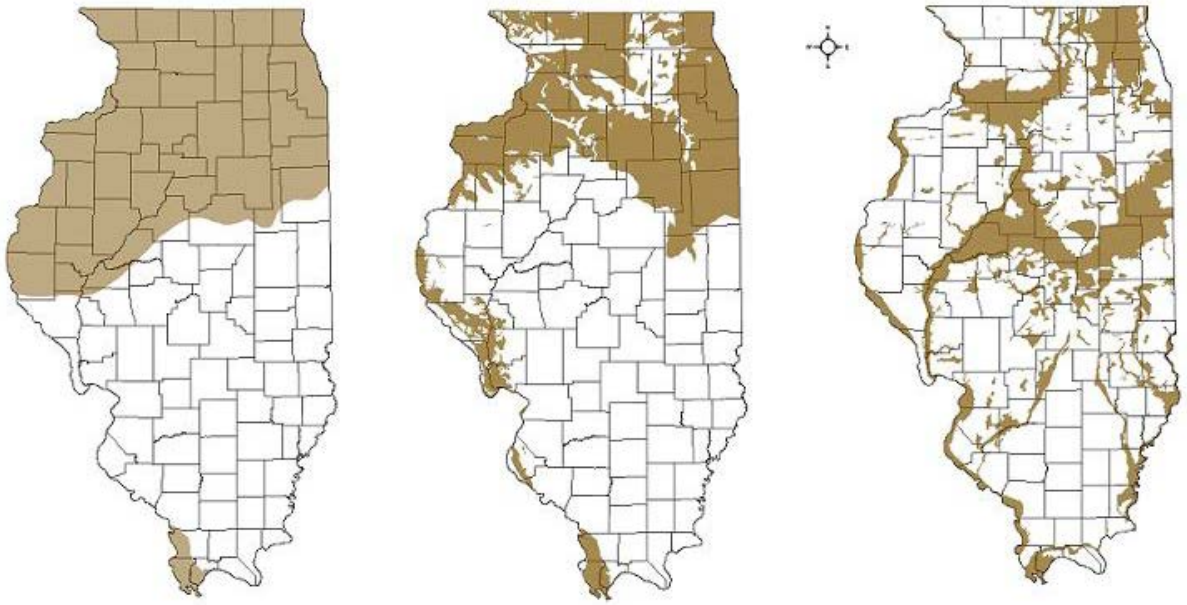

Figure 18. Extents of principal aquifer systems in Illinois (a) Cambrian-Ordovician bedrock; (b) shallow bedrock (Silurian-Pennsylvanian); (c) unconsolidated

Quaternary Aquifers

Sand and gravel Quaternary aquifers are found throughout Illinois (Figure 18c). Alluvial aquifers are found in river valleys; most aquifers in the southern third of Illinois are of this type. Glacial aquifers include buried bedrock valleys filled with sand and gravels and sand and gravel lenses within till deposits. The largest buried bedrock valley aquifer is the Mahomet Aquifer in central Illinois, and other major glacial aquifers are found in the northern half of the state. Chloride concentrations vary greatly in these aquifers (Figure 19).

In the Mahomet Aquifer (Figure 20), chloride concentrations are extremely low in the eastern part of the aquifer, and are < 1 mg/L in parts of Champaign County. Hackley et al. (2010) suggested that recharge from glacial meltwaters recharging the Mahomet aquifer in Champaign County near the end of the Wisconsin Glacial Episode (about 11,500 years BP) leached the fine sediments and sand and gravel of the recharge zone and the aquifer. This resulted in the anomalously low Cl^- concentrations. Near the border between Champaign and Piatt Counties, Cl^- concentrations abruptly increase, due to discharge of brine from Pennsylvanian bedrock. Concentrations then decrease gradually to the west due to dilution. In the western region of the Mahomet aquifer (Piatt, Macon, and DeWitt Counties) where Cl^- concentrations are highest, concentrations along the bedrock valley walls tend to be higher than in the central, thalweg part of the valley. This is likely due to proximity to bedrock discharge along the valley walls and greater dilution in the thalweg. The Mahomet is confined through most of its central and eastern extent, thus surface activities generally do not impact its water quality. In the Sankoty-Mahomet section (Mason and western Tazewell Counties), the Sankoty-Mahomet is unconfined and

surface activities can impact water quality. Elevated Cl^- concentrations in the East Peoria and Pekin regions are probably due to road salt runoff in those urban areas.

Other buried bedrock valley aquifers in Illinois include the Mackinaw and Princeton bedrock valleys northwest of the Mahomet Aquifer. Chloride concentrations are generally low in these aquifers. Burch (2004) reported a median Cl^- concentration of 10.8 mg/L (N = 30) in samples from the Princeton bedrock valley, which included several samples impacted by road salt runoff.

Chloride concentrations in glacial aquifers within till deposits vary greatly. For example, the Glasford Aquifer in central Illinois has Cl^- concentrations ranging from < 1 to about 100 mg/L. Sand and gravel aquifers in northeastern Illinois have been heavily impacted by human activities, with the most obvious sign being increasing Cl^- concentrations. Kelly (2008) showed that Cl^- concentrations in shallow groundwater in the Chicago region have been increasing since the 1960s when road salt began being used in earnest. Over half of the public supply wells finished in sand and gravel aquifers have statistically significant increasing trends in Cl^- concentrations. Widespread sampling of shallow aquifers (< 250 feet deep) in Kane County in 2003 indicated the role of urbanization on shallow groundwater quality (Kelly, 2005). Chloride concentrations were significantly higher in the eastern urban corridor compared with the remainder of the county, which was primarily rural (Figure 21). Figure 21 clearly shows that urban land use increases Cl^- concentrations but rural land uses do not.

Mullaney et al. (2009) reported on Cl^- in unconsolidated glacial aquifers of the U.S. and found that land use significantly affected Cl^- concentrations. Shallow monitoring wells in urban areas had significantly greater Cl^- concentrations (median = 46 mg/L, n = 317) than in agricultural areas (median = 12 mg/L, n = 430), and both were significantly higher than wells in forested areas (median = 2.9 mg/L, n = 50). Their source analysis suggested that Cl^- in urban settings was dominated by deicing and/or water softening salt.

Chloride concentrations in alluvial aquifers in southern Illinois are generally low (< 30 mg/L), with a few exceptions. The Rock River valley in Rockford has higher Cl^- concentrations (generally > 50 mg/L), reflecting greater urbanization and heavier amounts of snow and thus road salt runoff. Chloride concentrations also are higher in the American Bottoms area across the Mississippi River from St. Louis, again reflecting the large degree of urbanization. In areas where there are no aquifers, primarily the southern half of Illinois, large-diameter dug and bored wells are used. These wells are vulnerable to surface contamination. Chloride concentrations in these areas vary widely, probably reflecting the local land use activities that impact the wells.

An important control on Cl^- concentrations in Quaternary aquifers is depth. In general, the shallower the aquifer, the more vulnerable it is to surface-derived contamination. Figure 22 shows Cl^- concentrations for wells 50 feet or less. In contrast, Figure 23 shows Cl^- concentrations for wells greater than 250 feet. Figure 24 shows a box-and-whisker diagram of Cl^- concentrations as a function of depth. Results from ANOVA testing indicated that Cl^- concentrations in each depth range were significantly greater than all deeper groups.

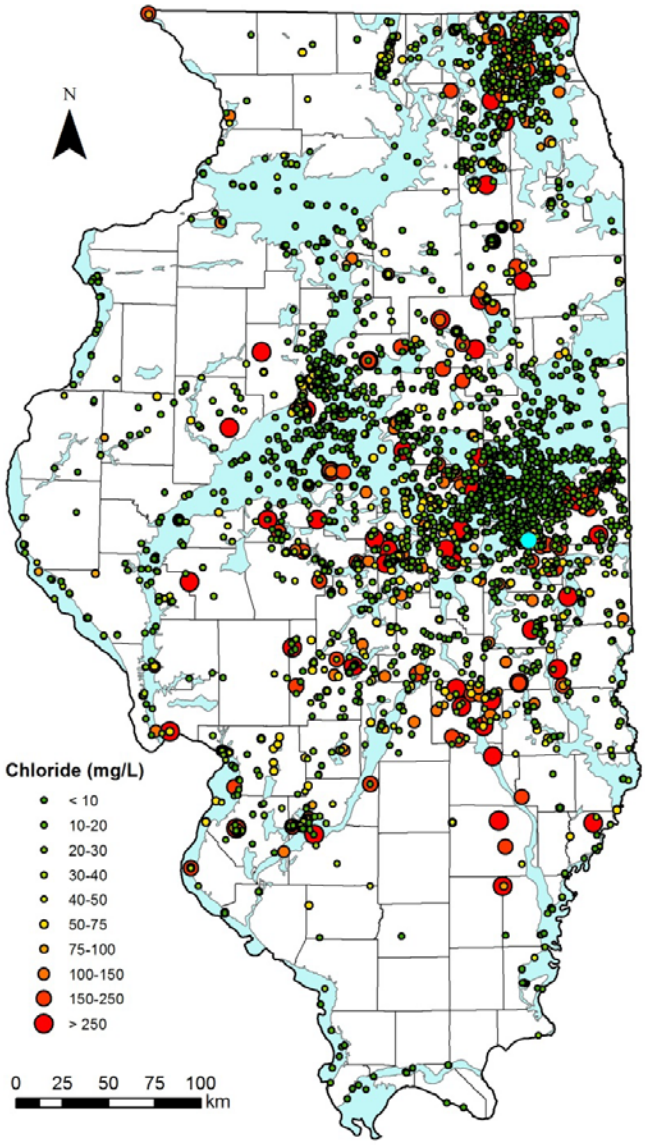

Figure 19. Chloride concentrations in wells open to Quaternary sand-and-gravel aquifers. Locations of significant Quaternary sand-and-gravel aquifers indicated by light blue.

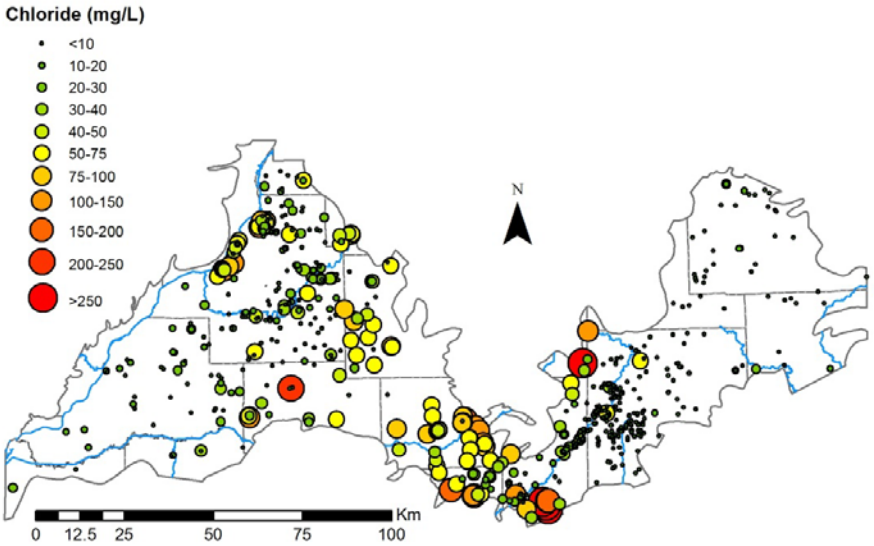

Figure 20. Chloride concentrations in the Mahomet Aquifer

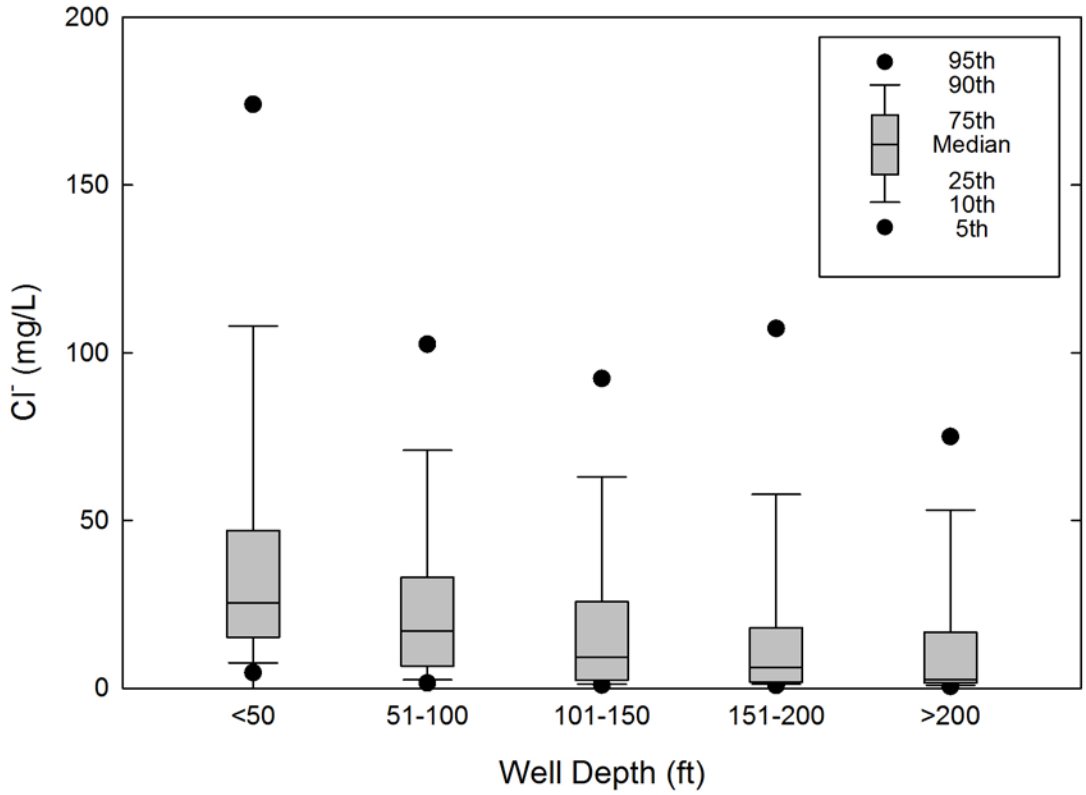

Figure 24. Box-and-whisker diagram for Cl^- concentrations in Quaternary aquifers in Illinois as a function of well depth. Concentrations are significantly greater for each depth group compared to all deeper groups.

Bedrock Aquifers

Bedrock aquifers in Illinois are found in the northern third of the state and along the Mississippi River (Figure 18). Aquifers in the upper bedrock unit are used in the southern two-thirds of Illinois. Chloride concentrations vary widely (Figures 25 and 26), and primarily appear to be a function of depth, i.e., the deeper the well, the higher the concentration (Figure 27). Very high concentrations are likely primarily due to natural sources, i.e., recharge from brines; Pennsylvanian formations are the primary oil producing units in Illinois. Some of these wells may also be exhibiting contamination from leaky brine holding ponds commonly associated with oil drilling activities (Hensel and McKenna, 1989). In the sinkhole plain of southwestern Illinois (Monroe, Randolph, and St. Clair Counties), Mississippian limestones exhibit karst features (sinkholes, caves). These aquifers are extremely vulnerable to surface contamination, but Cl^- is not an important contaminant in this primarily rural region.

Devonian and Silurian Age aquifers are important aquifers in Illinois, heavily used in northeastern and northwestern Illinois (Figure 26). They are primarily of carbonate lithology, the most productive being fractured dolomites. The heaviest use of these aquifers is in the Chicago

region, in DuPage, northern Will, southern and western Cook, and western Lake Counties. These bedrock units dip towards the south, and Cl^- concentrations are significantly greater in areas where the Devonian-Silurian aquifers are deeper (Figures 26 and 27). In northeastern Illinois, the tops of the bedrock aquifers are often in contact with sand and gravel glacial units. Wells are often screened in this interval due to its large hydraulic conductivity. These Silurian bedrock aquifers also show the increasing trend in Cl^- concentrations seen in the sand and gravel aquifers due to road salt runoff (Kelly, 2008). More than half of public supply wells finished in these aquifers tested by Kelly (2008) have statistically significant increasing trends in Cl^- concentrations.

The oldest aquifers in Illinois are found in the northern third of the state and are Cambrian and Ordovician aged. These aquifers are primarily sandstones and are heavily used in the northern part of Illinois, especially centered around Joliet and Aurora south and west of Chicago, respectively. In general, the salinity of water in the Cambrian-Ordovician aquifers is lowest in north-central and northwestern Illinois where the Ancell Aquifer outcrops at the surface and recharge is occurring (Figure 28). Salinity generally increases to the east and south in the direction of flow and stratigraphic dip. Below a latitude of about 40° the water in these aquifers is unpotable due to high TDS levels. Chloride concentrations tend to increase with well depth (Figure 29).

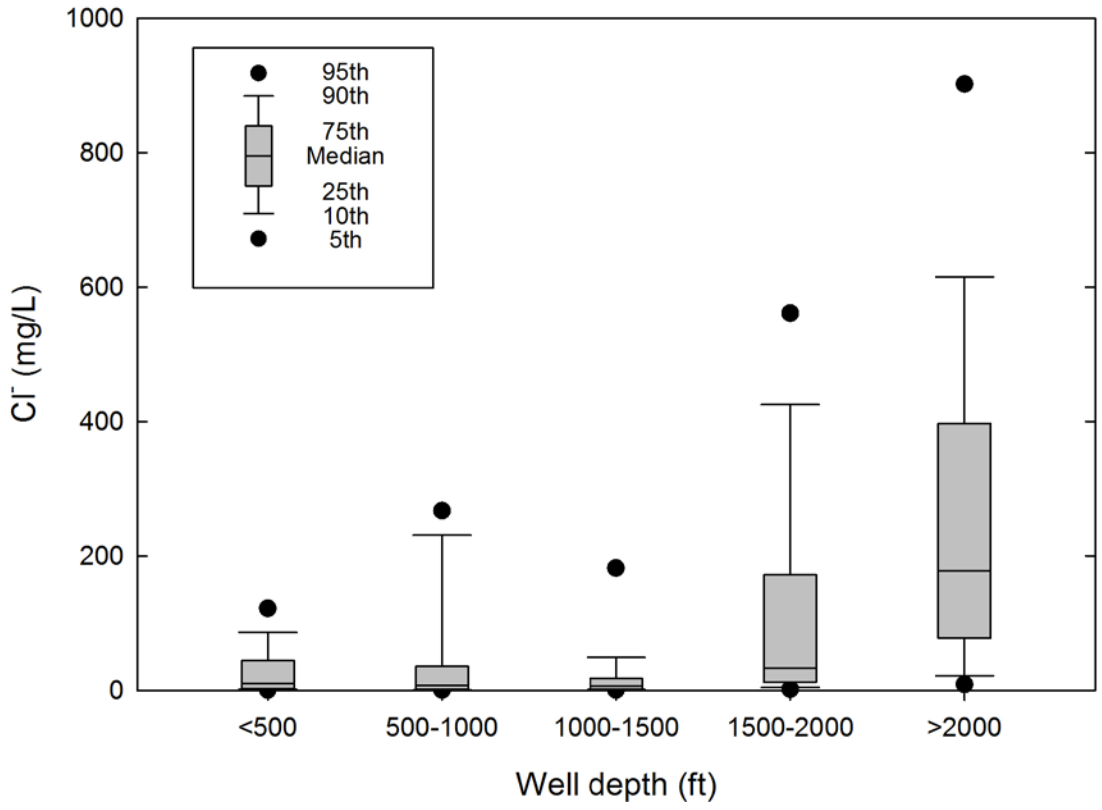

Figure 29. Chloride concentrations as a function of depth for wells completed in Cambrian-Ordovician bedrock aquifers. The two deepest groups have significantly greater concentrations than all three shallower groups (ANOVA on ranks).

Saline Springs

Panno et al. (2010) reported that there are about 30 saline springs throughout the Illinois Basin (most of which are in Illinois) that are coincident with geologic structures within and at the margins of the basin (Figure 2). Saline springs in Illinois have been identified by others (i.e., Bartow et al., 1909; Willman and Payne 1941; Panno et al., 1994, 2006, 2011). Discharge of saline groundwater may be found along the LaSalle Anticlinorium in the form of shallow wells, salt marshes, and springs at Starved Rock, Matheson, and Kickapoo Creek State Parks, and as bedrock seeps into the Mahomet aquifer in east central Illinois (Panno et al., 1994, 2006). Similar saline springs are found in southern Illinois along the Rough Creek-Shawneetown Fault Zone near Equality, and many of these sites are historic in that they were used by Native Americans and early settlers as a source of salt for meat preservation and other uses (Panno et al., 2006, 2010). Chloride concentrations in these springs can range from several hundred to greater than 30,000 mg/L in the case of the Vermilion Salines in Kickapoo Creek State Park (Panno et al., ISGS, unpublished data). The sources of these saline springs range from Cambrian- to Pennsylvanian-age formations (Panno et al., 2010).

Trend Analysis

Shallow aquifers in northeastern Illinois have been heavily impacted by human activities, with the most obvious sign being increasing Cl^- concentrations. Kelly (2008) showed that Cl^- concentrations in shallow groundwater in the Chicago region have been increasing since the 1960s. Over half of the shallow (< 200 ft; 60 m) public supply wells evaluated (N = 239) had statistically significant increasing trends in Cl^- concentrations, and there did not appear to be a leveling off of trends for the most recent samples (1990–2005).

Chloride concentrations have been increasing in shallow aquifers since the 1950s–1960s (Figure 30). The median Cl^- concentration steadily increased from 6 mg/L prior to 1950 to nearly 20 mg/L in samples from 1990 to 2005, and each time period had significantly greater concentrations than the previous time period except for the 1990–2005 group compared to the 1980s. The spread in concentrations has also been increasing, indicating spatial variability in sources of Cl^- contamination. Chloride had greater concentrations in the shallower (< 100 ft) wells than the deeper (100–200 ft) ones for all date groupings (Figure 31). These differences were statistically significant at most time periods for Cl^-. Concentration trends were generally the same for both the shallower and deeper wells. There were increasing trends for Cl^- concentrations for both shallower and deeper wells, with the median concentration increasing from 8 to 36 mg/L in the shallower wells and from 5 to 17 mg/L in the deeper wells from prior to 1950s–1960s to 1990–2005.

For individual counties, the greatest temporal changes for Cl^- were generally found in the western counties, DuPage, Kane, McHenry, and, to a lesser extent, Will County to the south (Figure 31) (Kelly, 2008). In DuPage County, the median values of all major ions tended to increase, especially Cl^-, which increased from 4 mg/L prior to 1950 to 101 mg/L in the 1990s and later, an increase of more than 2500 percent. Chloride in Cook County was highest in the 1990–2005 data group, but there was little change in the previous groups. No significant change occurred in Cl^- concentrations in Lake County during the entire time span.

Kelly (2008) reported there were significant temporal increases in Cl^- concentrations for the majority of the municipal wells tested (55 percent), and significant positive slope values were calculated for 57 percent of the wells (Figure 32). Chloride trends varied spatially; Lake and Cook Counties had relatively low percentages of wells with increasing Cl^- trends (39 to 45 percent) and slope values, while DuPage, Kane, and McHenry Counties had much higher percentages of wells with positive trends (55 to 71 percent) and slope values. Almost half (112 of 239) of the individual public supply wells tested had at least one sample collected between 1990 and 2005. The same trends for Cl^- were observed for the wells with the most recent data compared to the entire group of wells, suggesting that there has not been a leveling off in Cl^- concentrations in the 1990s or later (Kelly, 2008).

Wetlands

Wetlands are defined as lands that transition between terrestrial and aquatic systems where the water table is usually at or near the surface or the land is covered by shallow water (U.S. Fish and Wildlife, 2011). Wetland substrates can be either predominantly undrained hydric soils or nonsoils that are saturated or covered by shallow water at some time during the growing season. Wetland types found in Illinois include marshes, swamps, bogs, and fens (USEPA, 2011b). Water quality in wetlands should generally reflect their source water, whether it is shallow groundwater or surface runoff, but land use activities adjacent to wetlands can strongly influence concentrations of Cl^- and other aqueous species within the wetlands.

There have been few published studies that include water quality data, and specifically Cl^-, for wetlands in Illinois. There are some published data for fens and bogs in northeastern Illinois. Fens are essentially springs that receive a very hard Ca-HCO_3-type groundwater, while bogs receive surface water from more dilute runoff. Both types of wetlands are common in northeastern Illinois. Fens at Sterne's Woods State Natural Area near Crystal Lake and South Elgin Fen near South Elgin were found to be contaminated with road salt and septic effluent (Panno et al., 1999, 2006). One part of a fen at Sterne's Woods that was reported to be in near pristine condition had Cl^- concentrations between 8.8 and 44 mg/L. Two other fens affected by septic effluent and road salt had Cl^- concentrations as high as 339 mg/L and 283 mg/L, respectively. Septic effluent and road salt discharged into South Elgin Fen increased the Cl^- concentration to 116 mg/L (Panno et al., 2005). In cases where septic effluent discharged into fens, the diverse fen-wetland vegetation was replaced by a more salt-tolerant monoculture of cattails (*Typhaangustifolia*). Panno et al. (1999) reported that fen vegetation diversity was profoundly reduced when Cl^- concentrations exceeded 45 mg/L. Road salt runoff has reduced plant diversity in wetlands of northern Illinois, where very high Cl^- concentrations have produced wetlands that can only support cattails and other halophilic vegetation (e.g., *Phragmitesaustralis*).

Discussion and Conclusions

Prior to major settlements in Illinois, Cl^- concentrations in most shallow groundwater and rivers and streams were very low, probably < 10 mg/L, and in many cases much lower. The exceptions were areas where natural brines in Paleozoic sedimentary rocks discharged at or near the land surface. There were numerous saline springs that were exploited by Native Americans and early settlers for making salt. There are numerous streams and rivers in Illinois with names such as Salt Creek or Saline Branch, named because of the discharge of saline water in or near these streams.

Once Illinois became settled as the population grew, contamination of water began. Chloride was not an important component of contamination sources in the 19th century, with the possible exception of livestock waste. It wasn't until around the middle of the 20th century that the important sources of Cl^- contamination, i.e., water conditioning salt, KCl fertilizer, and road deicers, began to be used in large amounts in Illinois. Since that time, there has been an increase

in Cl^- concentrations in many water bodies in Illinois, and there does not yet appear to be any slackening in its increase in groundwater or surface waters (Kelly, 2008; Kelly et al., in press).

One of the most likely results of increasing Cl^- concentrations in surface waters is degradation of aquatic biota. We are unaware of any systematic studies of the effects of elevated levels of Cl^- on aquatic biota in the Chicago area, but it seems certain that there would be negative effects. Corsi et al. (2010) reported that seven of 13 streams in the Milwaukee, WI, area exhibited toxicity to water fleas (*Ceriodaphniadubia*) and fathead minnows (*Pimephalespromelas*) due to road salt runoff. They measured very high Cl^- concentrations in some of the streams (commonly > 1,000 mg/L and up to 7,730 mg/L).While these are higher than typically found in stations monitored in Chicago, some of the smaller streams occasionally had Cl^- concentrations > 1,000 mg/L, and smaller streams that are unmonitored undoubtedly experience even higher concentrations.

Chicago, many of its suburbs, and many other cities in Illinois have combined sewer systems, with storm water runoff being collected and treated at WWTPs. A large percentage of road salt runoff in the most urban parts of the Chicago region thus does not enter shallow groundwater but is diverted to streams and rivers in discharge from WWTPs. The rapid transfer of saline snow melt to streams and rivers in Chicago produces very high Cl^- concentrations in the winter. However, some road salt runoff ends up in the soil zone and shallow groundwater, and this could represent a relatively long-term source of Cl^- and other ions to surface water.

Methods and Advances in the Forensic Analysis of Contaminated Rivers

Jerry Miller[1,*]

[1]Department of Geosciences and Natural Resources, Western Carolina University, Cullowhee-USA

Abstract. Trace metals and metalloids are a common and persistent form of riverine (river) contamination and are derived from a wide variety of sources, including mining and milling operations, industrial activities, urban runoff, agricultural chemicals, and atmospheric pollution, among a host of others. Documentation of trace metal sources and dispersal pathways in riverine ecosystems is essential to mitigate their potentially harmful effects to human and ecosystem health and is often required from a legal (environmental forensic) perspective to assess liability for the costs of remediation. Unfortunately, documenting the sources and source contributions of trace metals in rivers has proven difficult, time-intensive, and costly. Herein, a four-component, interdisciplinary framework is proposed to efficiently identify the sources and source contributions of trace metals in alluvial sediments where multiple natural and/or anthropogenic sources exist. The components include (1) the analysis of the river's alluvial stratigraphic architecture and geomorphic history, (2) the temporal correlation of geochemically characterized alluvial deposits to potential anthropogenic trace metal sources, (3) the analysis of the spatial variations in selected geochemical parameters, and (4) the use of geochemical and/or isotopic tracers to quantitatively estimate the contributions of trace metals from the defined natural and anthropogenic sources. The four components are *not* intended to be exhaustive; the framework may require modification following multiple lines of evidence approach, in which additional methods and data are added to the investigation until there is confidence that all trace metal sources and their contributions have been effectively defined.

Keywords: **Environmental Forensics; Trace Metals; Contaminated Rivers.**

1 Introduction

Trace metals and metalloids (herein referred to collectively as trace metals) are one of the most common and persistent contaminants in riverine ecosystems[1–6]. In rivers characterized by "normal" Eh and pH conditions, trace metals are primarily sorbed onto sediments, particularly fine-grained, chemically reactive sediments, composed of clay minerals, iron (Fe) and manganese (Mn) oxides and hydroxides, and organic matter. As a result, 90% or more of the total trace metal load is typically transported with particulates by physical processes [7,8], and incorporated into channel bed, floodplain, and other types of alluvial (river) deposits [9,10]. These alluvial deposits, then, contain a record of the spatial and temporal variations in the quantity of trace metal inputs into, and transported through, the river system, and their analysis can provide insights into the degree to which anthropogenic activities including mining, agriculture, urbanization, and industry, among others, have contaminated the aquatic environment. Moreover, the river (riverine) sediments can be used to determine the source of trace metals within the river.

The determination of trace metal sources has become one of the most important components of river cleanup for two primary reasons. First, the success of a remediation program depends on identifying where the contaminants are coming from, and then reducing or eliminating their input into the aquatic environment. In fact, the improvements in water quality in many countries since the 1970s have primarily been related to the implementation of environmental regulations that restrict the input of contaminants to water bodies from identified sources, particularly those related to industrial or mining activities. Second, the determination of trace metal sources is often driven by the polluter-pays-principal in which the polluter is required by law to pay for the cleanup of the river such that it is returned a close approximation of its previous condition.

In the U.S., for example, the Comprehensive Environmental Compensation, Response and Liability Act (CERCLA), frequently referred to as the Superfund Program, was enacted in 1980 at the federal level to address the most contaminated sites across the country. State governments have also enacted hazardous waste site remediation programs largely patterned after CERCLA. The developed legislation at both the federal and state levels allows for the allocation of liability to potentially responsible parties (PRPs). These PRPs may include single or multiple person(s) and entity(ies) such as current and past site owners or operators, generators of chemical wastes, and those involved in or responsible for the transport of wastes between sites [11].

Across Europe, recent environmental legislation has largely been derived from European Union (EU) Directives. These directives do not specify the manner in which the laws are to be written, but direct Member States of the EU to develop regulations to achieve a particularly set of outcomes [12]. Of particular importance to our current discussion is the Environmental Liability Directive of 2004 that was intended to prevent and remedy environmental damage to both land and water resources that pose a threat to the ecosystem and human health [12]. The Directive enhances the 'polluter-pays-principle' in that it specifies that polluters should be responsible for implementing measures that prevent damage to natural resources and for remediating the damage that they have caused to the environment.

In order to carry out legislation based on the polluter-pays-principle, the source of the contaminant(s) must be identified and linked to the responsible party(ies). In some cases, such as where a single source of a non-naturally occurring chemical is dispersed by a limited number of processes, it may be a relatively easy task to identify the polluter. More commonly, however, water resources are contaminated by multiple entities that discharged varying quantities of contaminants to the environment. Some of these entities may no longer exist but were a historic waste generator. Further complicating the issue is that toxic trace metals occur naturally in the environment, raising the question as to what the contaminant level was prior to pollution, and for which the PRPs should not be held liable [13]. A fallout of these complex, legal cases is that a waste generator may not only question whether they are a responsible polluter, but whether they should be held responsible for all of the damage to a particular resource [13].

While scientists have been conducting investigations into contaminant liability issues for decades, the increasing need to apply their investigative techniques to legal issues led in the 1990s to the field of *environmental forensics*. Wenning and Simmons [14] defined environmental forensics as the "systematic examination of environmental information to determine sources of chemical contamination, the timing of releases to the environment, the spatial distribution of contamination, and the potential responsible party(ies)".

The field of environmental forensics has grown over the past 20-years into a scientific subdiscipline in and of itself. During this time, it has become clear that the determination of contaminant sources to riverine ecosystems is a difficult, and potentially expensive, task. Even where the contaminant source appears obvious, detailed investigations have shown that additional, unexpected sources of trace metals may exist. For example, numerous studies during the 1970s through the 1990s found increased inputs of mercury (Hg) to aquatic ecosystems in the Amazonian rainforest [15–18]. The assumption was that the increase in Hg inputs was related to widespread Hg amalgamation mining of placer gold deposits. Amalgamation mining involved the use of Hg to capture fine gold particles by forming dense amalgam grains that could be separated from the hydraulically lighter sediments. These amalgam grains were then heated (roasted), driving Hg off as a vapor and leaving a "purer form of the gold. In the process, Hg was lost to the riverine ecosystem. Malm [18], in fact, estimated that approximately 240 tons of Hg were released into the environment annually during the 1990s from mining operations in the Amazon of Brazil Amazon, Venezuela, Colombia, and Bolivia. Mercury was also found to be elevated in biota, including human hair, blood, and urine [15,16,19]. While gold amalgamation mining clearly contributed Hg to rivers in the Amazon (and many other places around the world), more detailed studies found that mining was not the sole source, or even the predominant source, of increased Hg inputs [20–23]. In fact, within some river basins, such as the Tapajós, Hg inputs were found to come primarily from the erosion of surface soils that had been enriched naturally by means of atmospheric deposition over geological time scales. The observed increases in Hg inputs to the studied rivers were induced, in part, by deforestation; only about 3% was derived from mining operations [22]. The point here is that while the termination of all Hg amalgamation mining may have slightly improved sediment and water quality, improvements would have been minimal because much of the Hg was derived from a separate, unexpected source.

The remediation of Contaminant Rivers is a major undertaking. In fact, rivers represent some of the largest Superfund sites in the U.S., and the costs of remediation are often in the hundreds of millions of dollars (US). As a result, significant effort has gone into developing methods to determine the source of contaminants, including trace metals, in rivers, most recently in the context of environmental forensics. The majority of the developed techniques rely on fingerprinting techniques that attempt to define trace metal sources by identifying one or more unique physical, mineralogical and/or chemical parameters that can uniquely distinguish a suspected source in the basin from all other sources. Fingerprinting techniques, however, are not the only methods that can be used to assess trace metal sources or their relative contributions to a river. A common question that arises, then, during the development of a remediation program is which methods are most effective at identifying trace metal sources in terms of both time and costs. Underlying this question is the understanding that whatever methods are used must withstand the scrutiny of legal debate which is often associated with remedial activities.

In this paper, a multidisciplinary four-component approach to the effective identification of the predominant sources of trace metals to river sediments is put forth. The approach is intended to integrate geomorphic, alluvial stratigraphic, and geochemical data that not only allows for the assessment of trace metal sources but insights into their transport and ultimate depositional locations of trace metals along the river valley.

2 Methodological Approach

Herein, it is argued that four types of analyses provide a time and cost-effective framework for the identification of trace metal sources and their relative contributions to aquatic environments. They include (1) the analysis of the river's recent alluvial stratigraphic architecture and

geomorphic history, (2) the temporal correlation of geochemically characterized alluvial deposits to potential anthropogenic trace metal sources, (3) the analysis of the spatial variations in selected geochemical parameters, and (4) the use of geochemical and/or isotopic tracers to quantitatively estimate the contributions of trace metals from the defined natural and anthropogenic sources (Fig. 1). The four included components are *not* intended to be exhaustive. In fact, the approach utilized at any given site should be based on the multiple lines of evidence concept, in which additional methods and data (not described herein) are added to the investigation until there is "sufficient" confidence that all trace metal sources and their contributions have been effectively defined.

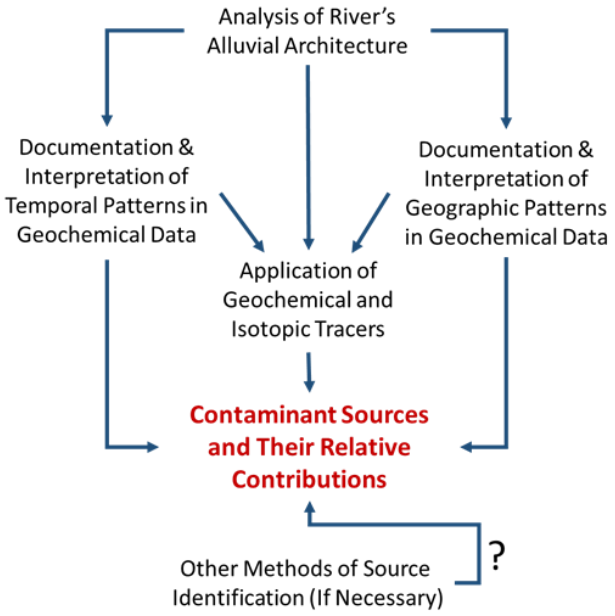

Fig. 1. Schematic diagram of the framework proposed for the assessment of trace metal sources and source contributions.

2.1 Analysis of a River's Alluvial Architecture and Geomorphic History

Rivers can be viewed, somewhat simplistically, as a network of channels that carry water and sediment from upland areas of a catchment to the basin mouth. Rather than being simple conduits, however, rivers continually erode and deposit sediments, both within the channel and, during floods, on the adjacent floodplain. These geomorphic processes create alluvial stratigraphic units (deposits) that not only consist of the sediments that enter the channel but sediment-associated trace metals. These alluvial (river) deposits, therefore, contain a record of trace metal inputs to the river [9,24,25].

Historically, the sampling of contaminated rivers largely ignored the fact that these alluvial deposits vary in terms of their sedimentological characteristics or age. However, more recent studies have shown that attempts to distinguish the relative proportions of trace metals derived from natural and anthropogenic sources are complicated by physical and biogeochemical processes that act on source materials as they are transported downstream through the river system. A particularly important process is hydraulic sorting that partitions the sediments, and the trace metal(s) they are carrying, into specific depositional environments within and along the river based on grain size and density [9]. Fine-grained sediments tend to be deposited in areas of low velocity, whereas coarser sediments in zones of higher velocity. The net effect of these processes is for trace metals to become partitioned during transport such that they are deposited into stratigraphic units characterized by distinct sedimentological traits that are characterized by concentrations that are significantly higher or lower than in the original source materials. In addition to hydraulic sorting, the original composition of the source materials may be affected by the addition of non-reactive constituents (e.g., organic matter, carbonates) into the deposited sediment, or by geochemical transformation processes including reductive/oxidative reactions (that may, for example, allow grains to be coated with Fe and Mn oxides and hydroxides). These processes are element-specific, and depend on the local climatic, hydrologic, and geomorphic setting [9,26]

The preferential deposition of source materials also occurs over larger spatial scales. For example, relatively narrow, steep valley reaches have been shown to produce zones of limited sediment deposition (referred to as transport zones), whereas wide, low-gradient reaches produce zones of deposition and contaminant storage (depositional zones). Thus, in some environments, trace metal concentrations and storage may vary downstream as a function of the river's overall geomorphology, and the geomorphic processes that occur along Specific River reach.

The primary goal of analyzing the river's alluvial stratigraphic architecture and history is to identify, characterize and map the distribution of distinct, sedimentary deposits along the river valley. These deposits can subsequently be dated, as described below. Provided that sediment-trace metal relationships are known, the collected information provides insights into where sediment-associated metals from a specific source are likely to be deposited. For example, mine and mill tailings from Cu, Pb, and Zn ores commonly contain significant quantities of sulfide minerals (e.g., galena, sphalerite, and pyrite). These relatively dense mineral grains are typically deposited with coarse-grained alluvial sediments. In fact, these sulfide minerals may form contaminant placer deposits along the river [9]. The same holds true for Au or Ag amalgam grains associated with amalgamation mining. In contrast, trace metals associated with chemically reactive, fine-grained sediments will likely be deposited in areas of relatively low flow, such as on floodplains or in oxbow lakes (Fig. 2). Therefore, by characterizing the sedimentology and distribution of the deposits, it is possible to hypothesize as to where trace metals from a potential source are likely to be concentrated.

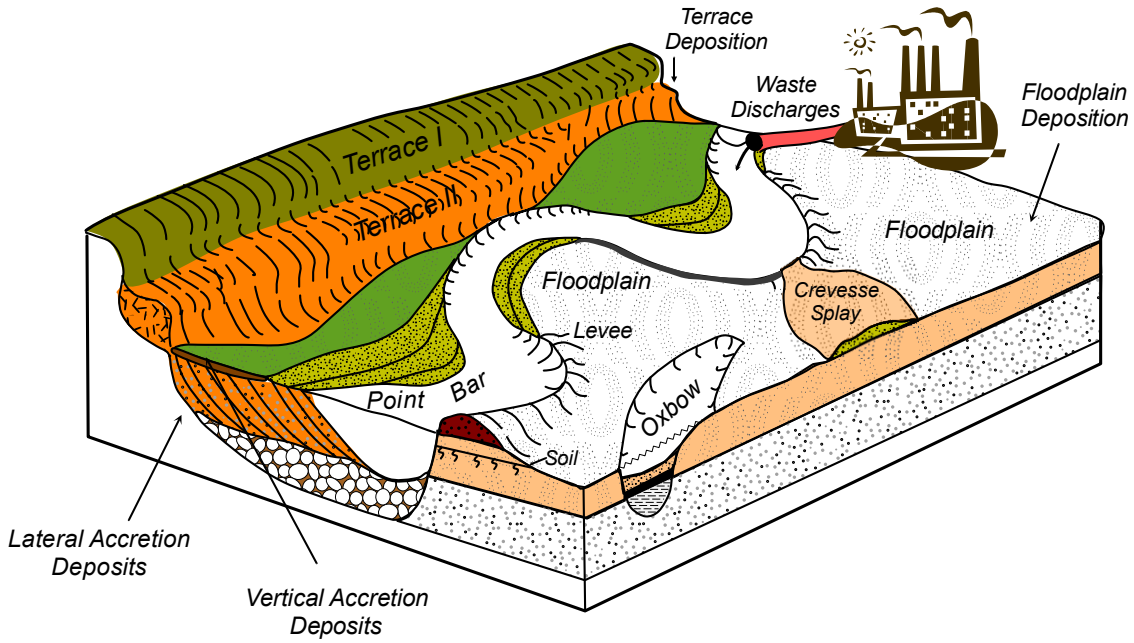

Fig. 2. Common types of alluvial deposits located along meandering streams. Each deposit (stratigraphic unit) possesses a unique sedimentology and, thus, trace metal content (figure modified from Miller et al. [37]).

In addition to the above, documentation of the river's alluvial architecture and history provides the foundation for the development of the temporal and spatial analyses described below. Thus, while such geomorphic and stratigraphic studies are often ignored in contaminant source analyses, they are critical components that should not be overlooked.

2.2. Temporal Studies

Once the alluvial stratigraphic deposits within the river valley have been defined and sedimentological and geochemically characterized, they can often be dated to determine their approximate age. Historically, absolute dating of the deposits primarily relied on radiocarbon methods characterized by a rather poor temporal resolution. However, deposit dating has significantly improved in recent years, and may include the use of other methods including ^{137}Cs and ^{210}Pb analyses, dendrochronology techniques, the analysis of historic artifacts and sequential aerial imagery, and, perhaps of most significance, optically stimulated luminescence (OSL) techniques, to mention a few (see Stokes and Walling, [27] for a more detailed review). As a result, it is often possible to constrain the age of alluvial stratigraphic deposits to a few years. This makes it possible to compare the geochemical (trace metal) content of the deposits, both temporally and geographically, to the location and history of suspected anthropogenic trace metal sources. As an illustration, the hypothetical stratigraphy of a river valley containing two potential sources of lead (Pb), is shown in Fig. 3. Stratigraphic units A1-A3 possess similar and relatively low Pb concentrations. The highest concentrations of Pb are found in unit A5, which was deposited between approximately 1900-1960, during which time an upstream industrial site (#1) was operating. This temporal correlation between high Pb concentrations in unit 5 and the industrial site #1 suggests that it contributed at least some of the increased Pb observed in unit A5. Given that industrial site #2 had yet to be built and was located downstream of cross-section B-B', it could not have contributed Pb to the site. Note, however, that the increase in Pb concentrations began to occur in unit A4, which predates the operation of industrial site #1, suggesting that another, unidentified source of Pb may have existed upstream of the cross-section B-B'. The illustration shows that it is important to develop chronologies of trace metal inputs for multiple locations. Selection of these sites should minimize the number of locations needed to effectively define inputs to the river from all potential trace metal sources. The historical record should also extend into the past for hundreds of years, if possible, to ensure that natural variations in trace metal inputs are adequately characterized.

The methods, assumptions, and uncertainties inherent in developing a record of the temporal variations in trace metal inputs to a river can be found in Macklin and Klimek [28], Hudson-Edwards et al. [29], Tobin et al. [30], Miller and Orbock Miller [9], Pease et al. [31], Du Laing et al. [32], Matys Grygr et al. [33,34], and Ferrand et al. [35]. In general, it involves three primary tasks, including the stratigraphic and sedimentological characterization of the river deposits, the sampling and geochemical analysis of the deposits for trace metals and other parameters, and the application of absolute dating methods to determine the approximate age of the deposits in "calendar" years.

Contaminant chronologies can be developed using any undisturbed sequence of river sediments, as well as sediments obtained from wetlands, lakes, and reservoirs that are physically linked to the river. Perhaps the most detailed chronological records have been developed using reservoir deposits and overbank floodplain deposits. The

latter deposits (also referred to as vertical accretion deposits) are characterized by successive thin layers of sediment produced by the deposition of suspended sediments from floodwaters that inundate the floodplain surface (Fig. 2). The process results in a sequence of layers in which younger sediments overlie older sediments producing a trend in which the age of the sediment systematically increases with depth. Unfortunately, the relationship between depth and unit age is not perfect because deposition only occurs during floods. Nonetheless, detailed records of trace metal loadings, as shown in Fig. 3, have been produced [28,35,34].

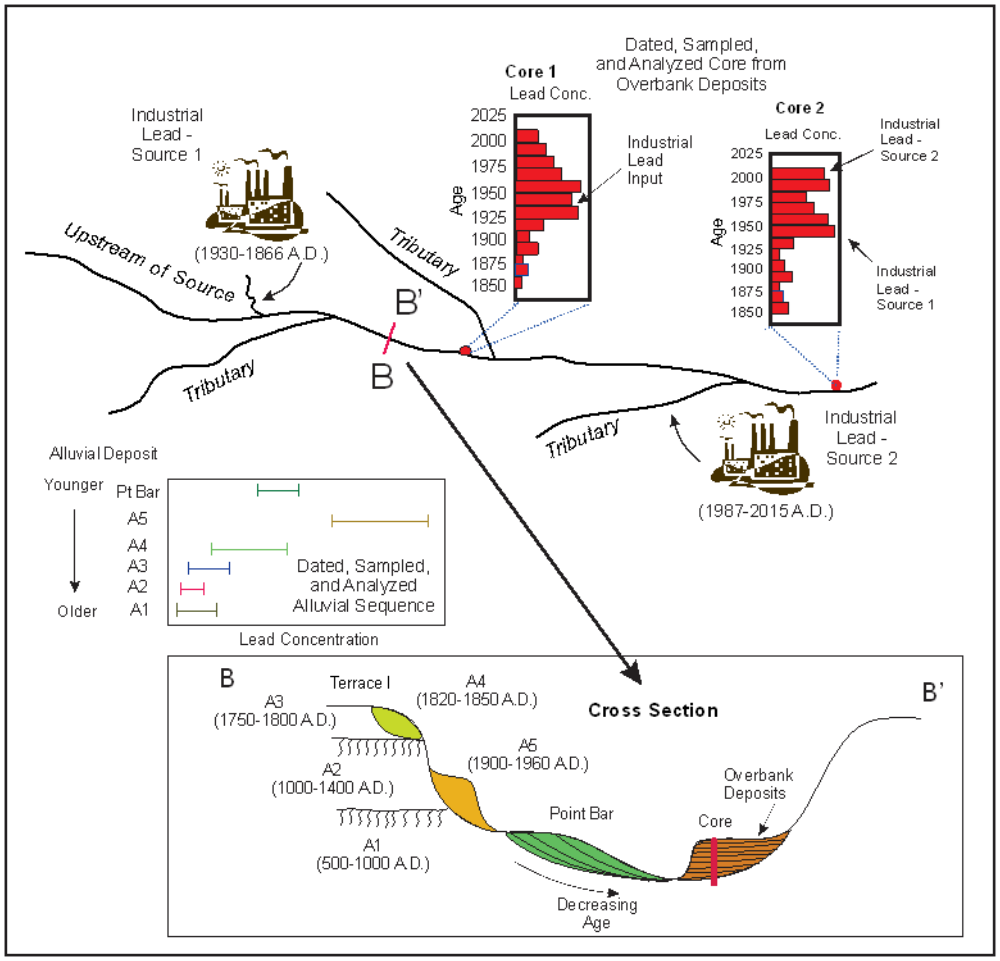

Fig. 3. Illustration of the spatial and temporal correlation of between alluvial stratigraphic units and industrial sources (figure modified from National Academy of Sciences [36].

2.3. Spatial Studies

One of the oldest and most extensively utilized methods of determining a point source of trace metal contamination is to examine its spatial distribution along the river. In most instances, the spatial distribution of the trace metal is examined in terms of its concentration in the channel bed or floodplain sediments. The presumption is that the highest concentrations of the metal will be located closest to the source, and decrease with distance from the site. In general, the spatial approach to source determination along rivers involves the collection and analysis of samples from multiple sites distributed along the channel and its associated features, and the subsequent plotting of the derived concentration data to document geographical patterns in elemental content. Point sources can then be identified by a distinctive trend in which low concentrations occur upstream of a source and abruptly increase in concentration where the trace metal(s) enter the channel. Concentrations subsequently decrease semi-systematically downstream from the source as a result of (1) the hydraulic sorting of contaminated particles, (2) dilution resulting from the mixing of contaminated particles with "clean" sediment from tributaries and eroded banks, and the dispersal of sediment-borne contaminants over a larger area, and/or (3) the deposition and subsequent storage of the contaminants within the channel bed or floodplain, a process that removes the contaminants from further transport. In addition, geographical patterns in alluvial sediments are often influenced by geochemical processes, such as precipitation, sorption on to reactive particles, and/or the oxidation/reduction of mineral grains. The accumulation of a contaminant in biota also has been cited as a control, but its influence is typically negligible along most rivers. In many cases, input from the identified source is supported by a comparison of the concentration of the contaminant within the suspected source materials. As an illustration, Fig. 4 shows the distribution of Pb and

Barium (Ba) along the Big River in southeastern Missouri. The abrupt upstream increase in Pb was interpreted to result from the influx of mining and milling wastes within the St. Francois mining district. Secondary increases in Pb spatially correspond to increases in Ba, which have been interpreted to represent the influence of Pb from earlier mining operations within the Barite mining district [38].

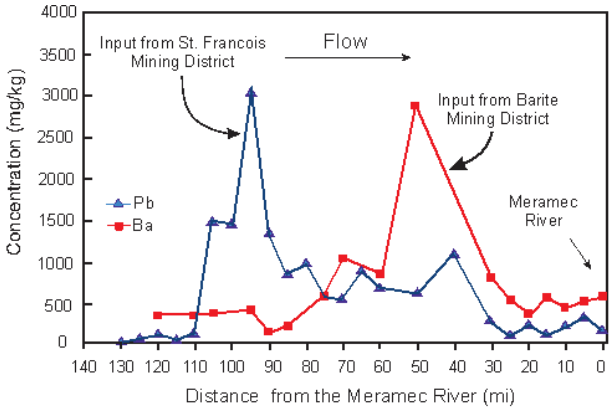

Fig. 4. Downstream trends in lead and barium concentration along the Big River, Missouri, USA. Abrupt increases in concentration reflect input of metals from mining operations (figure modified from Integral [38].

Although the spatial analysis of trace metal concentrations is easy to use and often provides important insights into the sources of trace metals to a river, the approach is plagued by the fact that the influx of trace metals from multiple sources can create overlapping spatial patterns that make it difficult to identify where the metals are derived. Such overlapping patterns are particularly common in mineralized river basins where metals may be derived from both mining wastes and mineralized rocks that underlie the basin. In fact, exploration geochemists often analyze spatial trends in trace metal concentrations in rivers to identify the location and grade of ore deposits. To help alleviate this problem, downstream variations in the ratios of trace metal concentrations may be used. For example, within the Rio Loa basin of northern Chile, Cu/Sb ratios were effective at differentiating between mining and geogenic trace metal sources. High Cu concentrations were associated with waste materials from local Cu mines, whereas elevated Sb concentrations were associated with natural mineralized rocks, particularly sediments derived from the El Tatio Geyser Basin [39]. In other instances, it may be possible to utilize the unique element or mineral associated with a specific source. The use of Ba along the Big River in Missouri is an example, as barite was not particularly prevalent in the mine wastes from the St. Francois mining district. Alternately, spatial trends in local enrichment factors (LEFs, see below) can be used to filter out the input of trace metals from natural sources, along with changes in the grain size and lithology of the source materials during transport through the river.

Another potential problem encountered while interpreting spatial data is that the deposition of sediment and sediment-associated trace metals may not decrease systematically downstream, but may reflect changes in flow conditions along with the drainage network (as observed for transport and sedimentation zones). Moreover, in mining areas, the influx of trace metals from mineralized rocks may produce downstream trends characterized by highly variable trace metal concentrations or ratios, as well as the preferential deposition of trace metals in deposits of specific grain size or density.

To compensate for the influence of grain size, density, or natural geogenic variability, spatial variations in concentration within the overbank deposits is often examined for a specific grain size fraction (such as the silt and clay-sized, <63 µm fraction), or a bulk concentration normalized by the percent of fine sediment in the sample [40]. An alternative approach used to differentiate between natural and anthropogenic sources of trace metals is to examine spatial variations in enrichment factors (EFs).

One of the most common methods of calculating EF values is the "double-normalization" technique, mathematically expressed as:

$$EF = (M/M_{ref})/(M/M_{ref})_{bc} \quad (1)$$

where M is the target trace metal of interest, M*ref* is a conservative reference element, and *bc* refers to the average concentrations of the target metal and reference element in uncontaminated background materials. Commonly utilized reference elements include Al, Fe, Li, Rb, Si, Ti, and, more recently, Co. Theoretically, the method addresses variations in both grain size and particle mineralogy. Aluminum, for example, is a significant element in aluminosilicate minerals, including fine-grained (<~2 µm) clay minerals, and therefore reflects both grain size and elemental composition of the sediment [26,41,42].

Historically, elemental average concentrations were based on those measured in continental crustal rocks (*bc,* Equation 1 [26,43,44]. More recent studies have shown, however, that the use of these elemental averages tends to result in large errors [44] because (1) the elemental concentrations determined from continental crustal rocks do not adequately represent that rocks that underlie the basin of study, and (2) the metal concentrations measured in the source metals rocks) will be altered by physical and/or biogeochemical processes, thereby changing the nature of the source sediments as they are transported downstream (as described earlier). Given these shortcomings, more recent studies have argued for the use of local enrichment factor (LEF) [26,43,44], in which:

$$LEF = M_S/M_{BG} \quad (2)$$

where M_S is the concentration of the target metal of concern in the sample, and M_{BG} is the concentration of the metal of concern in local, non-anthropogenically polluted, background sediments. M_{BG} is empirically predicted using a background function, such that:

$$M_{BG} = f(M_{ref}). \quad (3)$$

In most instances, background functions are defined by bivariate regression equations between the concentrations of the target metal in the unpolluted sediments and a parameter that accounts for changes in metal concentrations during sediment transport and deposition. The most common functions involve grain size, organic matter content, or the concentration of a conservative reference element. An advantage of calculating and using local enrichment factors in the development of trace metal chronologies is that they not only provide insights in when contamination occurred but the relative magnitude of the contamination that occurred in comparison to local background values.

It is important to recognize that the resolution of the spatial variations in downstream trends in trace metal concentrations, elemental ratios, and LEFs values depends on both the number and location of the samples that have been collected along the river. Differences in sampling frequencies and locations may yield differing results. It is therefore advantageous to collect as many samples as possible, particularly up and downstream of major tributaries.

2.4. Use of Geochemical Tracers to Determine Source Contributions

The approaches described above identify contaminant source(s) by spatially or temporally linking elevated concentrations (or differences in elemental ratios or LEFs) to suspected contaminant sources. Where multiple sources exist, the assumption is that the magnitude of the increases or decreases in metal values will provide *qualitative* insights into the relative contributions of contaminants from each of the delineated sources. While the approach is logically intuitive and easily understood, more quantitative estimates are often required, particularly when the analysis is being conducted as part of an environmental forensic investigation. During the past decade, there has been a dramatic increase in the use of environmental tracers to assess the provenance (source), movement, and fate of sediment and sediment-associated contaminants within rivers. With regards to alluvial sediments, a *tracer* is defined as a unique sediment-associated parameter or set of parameters that can distinguish a particular sediment type from other sediments in the basin. The tracer can, therefore, be used to track the movement and cycling of specific sediments from their point of origin through the river over varying temporal and spatial scales [37]. The term 'tracer' is often used synonymously with *fingerprint*. However, the term fingerprint is used in the geomorphological literature refer to a specific type of analysis (referred to as fingerprinting studies), which are described below. With regards to environmental forensic studies of contaminated rivers, the application of tracers or fingerprints has evolved significantly over the past decade and has now become the predominant method for *quantitatively* determining source contributions. With regards to alluvial (river) sediments, two types of analyses have evolved over the past two decades and, unfortunately, there has been little integration in the development of the two approaches. One approach involves the use of the concentration of multiple elements to create unique source area fingerprints and then applies statistically-based mixing models to the data. The second approach relies on the use of stable isotopic data, which is typically combined with analytical mixing models. Both types of investigation have benefitted greatly from recent scientific advances in analytical chemistry, which allows for the rapid analysis of large numbers of samples for a wide range of elements and measurements of isotopes that could not be analyzed in the past. Another important advantage of using geochemical tracers/fingerprints is that the analysis can be completed relatively quickly in comparison to many techniques, and can be applied to historic sedimentary deposits retrospectively to determine changes in sediment and contaminant provenance at a site through time.

2.4.1. Multi-elemental Fingerprinting Analyses

As the name implies, multi-elemental fingerprinting studies utilize variations in the concentration of multiple elements to develop a unique fingerprint for a specific sediment source and then allow sediment from that source to be distinguished from other sediment sources in the basin. It is worth noting that the method tracks the sediments associated with a trace metal source and not the trace metal of concern. Fingerprinting studies are most often applied to diffuse sources of sediment in the basin, although their application to other types of problems is increasing. Conceptually, fingerprinting studies are based on the fact that upland areas of a catchment can be spatially subdivided into specific sediment sources on the basis of its underlying geology or soil types. Each of these sediment sources can be eroded, after which the generated sediments are transported, often intermittently, to the river channel. As the sediments are transported downstream through the channel to a depositional point, the particles from all of the source areas are combined such that the sediments within the depositional unit represent a mixture of particles from all of the source areas in the basin. The physical and geochemical composition of this sediment mixture (which we will refer to as river sediment) depends on the composition of the source area sediments and the relative amount of sediment that is contributed to the deposit from each source area; if both are known, it is possible to predict what the composition of the mixture will be. In our case, however, the objective is to determine the relative amount of sediment, and sediment-associated trace metals, that a particular sediment source contributed to the deposit. This type of calculation represents a linear inverse problem [45]. The problem is typically solved using some form of inverse or unmixing model that requires that the composition of both the source and river sediments be known for a selected set of parameters, and then defines the mixing proportions from each source by adjusting the contributions such that the values of the parameters most closely match the values observed in the studied river sediment [45].

In general, the fingerprinting method involves five key steps (after Zhang et al. [46]): (1) delineation and

characterization of sediment sources within the basin, (2) the selection of the fingerprinting parameters (elements) that most effectively discriminate between sediments of the defined sources, (3) the collection of river sediment on the basis of the timeframe under consideration, and its subsequent characterization for the selected fingerprinting properties, (4) the determination of sediment provenance (source) using numerical modeling procedures, and (5) assessment of the uncertainty inherent in the modeling results. Although a wide range of physical, mineralogical, and geochemical parameters have been used as fingerprinting parameters to determine the source of the sediments and their associated metals [37, 47], most environmental forensic analyses utilize the concentration of multiple, conservative elements to develop an effective fingerprint.

Geochemical fingerprinting studies have been applied to a wide range of river sediments, and the river sediments that are selected determine the timeframe of the source analysis. The timeframe may range from recent, instantaneous suspended sediment samples collected during a specific part of a flood event to river sediments deposited within floodplains or riparian wetlands during an entire flood and that may be hundreds or even thousands of years old. In addition, overbank floodplain deposits or reservoir sediments can be incrementally collected and analyzed to determine changes in sediment source through time (Fig. 5).

The overwhelming majority of fingerprint studies have been conducted to determine the source of sediments and sediment-associated contaminants from diffuse sources located throughout a river basin. The approach, then, is perhaps most applicable to the assessment of trace metals from natural mineralized rocks as well as urban pollutants and agricultural chemicals (e.g, fertilizers, pesticides, sewage amendments). It is possible, however, to include point sources of trace metals in the analysis to determine their contribution to a river. Moreover, the approach has been used to assess the relative inputs from a point source by characterizing changes in elemental concentrations from up- to downstream of a contaminant input point. In most instances, the point in contaminant influx is taken to be the mouth of a tributary [48, 49].

A common criticism in the application of multi-elemental fingerprinting studies is that the statistical mixing models used to estimate the relative contributions of sediment from each of the defined sources resulted in values that were not unique. Rather, the results represented statistical estimates, for which there was an infinite number of possibilities. This problem has been referred to as the equifinality problem. Moreover, the results were often considered to possess considerable, but unquantifiable error, particularly where one source contributed little (~0 %) or all (100 %) of the sediment. During the past decade, considerable progress has been made in addressing this problem, and most statistical fingerprinting approaches are now able to quantify the uncertainty in the modeling results. In addition, the influence of grain size, organic matter content, and other factors on elemental concentrations has also been reduced. As a result, it can be argued that multi-element fingerprinting methods are highly effective.

2.4.2. Source Analysis using Isotopic Tracers

A wide range of stable isotopes have been applied to hydrological and geological investigations. The isotopes that have, perhaps, been most widely used are H, C, N, O, S, and Si. However, with regards to sediments, and the analysis of sediment and trace metal sources, radiogenic isotopes (e.g., Sr, Nd, and Pb) have historically been of most importance. Radiogenic isotopes are the daughter products of the decay of a radioactive parent. Their use as effective tracers stems from several key characteristics: (1) they can be accurately and precisely determined, (2) they exhibit isotopic abundances that vary widely within geological materials, allowing for the fingerprinting of both natural and anthropogenic materials, and (3) they are not significantly fractionated by physical, chemical or biological processes. This latter trait is important because the isotopic ratios (fingerprints) of the source sediments will remain largely intact during the erosion, transport, deposition, and diagensis of the sediment, allowing the isotopic composition of river sediments to reflect the mixing of materials from all of its sources within a river basin. With regards to environmental forensic investigations, the radiogenic isotopes of Pb have been the most extensively utilized. In fact, lead isotopes have been extensively used to determine the sources of Pb in a wide range of media, including air and aerosols, snow and ice, soils, lacustrine and reservoir deposits, wetlands and peat, plants, mosses, and tree rings, human tissues and blood and other biota (see Miller et al. [37] for extensive list of references). Moreover, because Pb is commonly associated in both Earth materials and man-made products with other toxic trace metals, Pb isotopes can often be used to assess the source of these other metals. A key advantage of using radiogenic isotopes, including those of Pb, is that they can provide quantitative estimates of the contribution of Pb in sediment as well as the other media of interest. It is for this reason that where possible, radiogenic isotopes, particularly those of Pb, should be applied in the forensic investigation of contaminated river sediments.

Given its widespread application, and its effectiveness at tracking sediment-associated Pb, Pb isotopes are discussed below as an example of how isotopic tracers can be applied to determine the source(s) and source contributions of Pb in river basins. More detailed reviews of the use of radiogenic isotopes in the environmental forensic investigation of contaminated rivers can be found in Miller et al. [37], whereas Bird [50] reviews the application of Pb isotopes to riverine environments.

Lead has three radiogenic isotopes, ^{206}Pb, ^{207}Pb, and ^{208}Pb, derived from the radioactive decay of ^{238}U, ^{235}U, and ^{232}Th, respectively; ^{204}Pb, has no known radiogenic parent. The isotopic abundances of Pb in geological materials are reported in terms of ratios (e.g., ^{206}Pb /^{204}Pb). For most environmental studies, only the radiogenic isotopes of Pb are used as geochemical tracers, in part, because the abundance of ^{204}Pb is relatively low, making it difficult to accurately measure. The analyses of sediment-associated Pb sources presume that the analyzed river sediment contains a mixture of Pb from all of the

potential Pb sources in the basin and that the relative abundance of the radiogenic Pb isotopes in the sediment depends on the relative contributions of Pb from each source. This assumption is nearly always met as the fractionation of Pb isotopes by physical, chemical and biological processes is negligible.

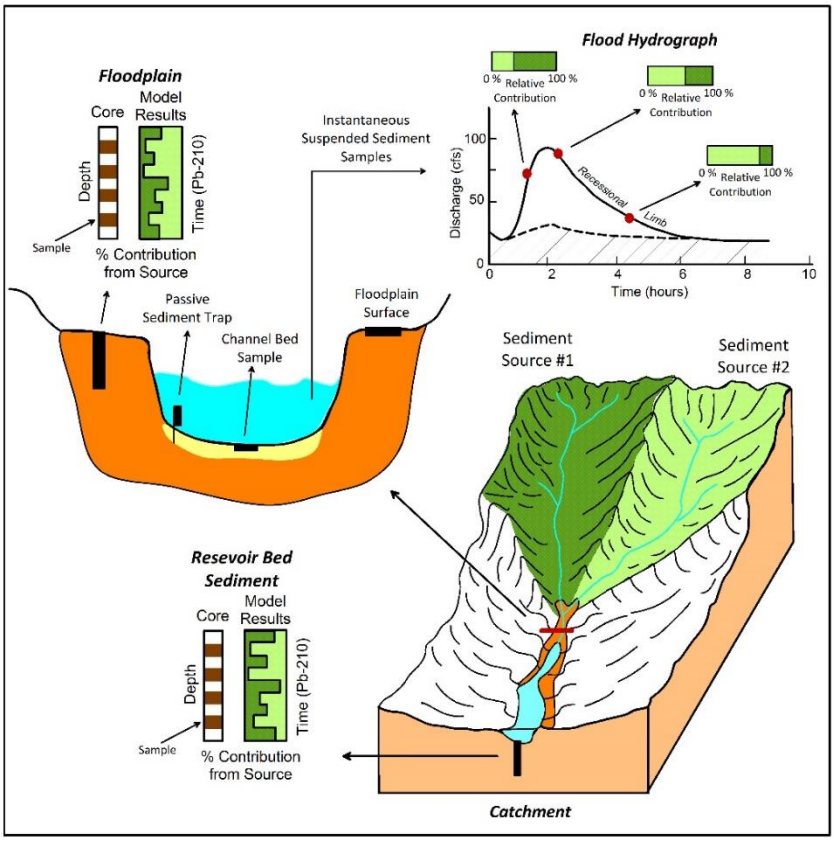

Fig. 5. Summary of commonly used sediments for the analysis of trace metal sources using multi-elemental fingerprinting methods (figure from Miller et al. [37]).

The quantification of Pb contributions from a particular source is often initiated by plotting the isotopic data collected from suspected Pb sources and the river sediments of interest on three-component (bivariate) scatter diagrams depicting differences between two isotopic ratios (Fig. 6) [51,52,50]. Ideally, Pb sources will exhibit a narrow range of isotopic ratios, which differ from the other suspected sources and from the sediments collected from within the river. In this case, the Pb isotopic ratios serve as effective fingerprints (tracers) of the suspected Pb sources. Moreover, if the isotopic ratios of the river sediments plot along a linear trend between two of these isotopic end-members, then the trend is interpreted as a mixing curve, and the Pb within the river sediments is assumed to be primarily derived from the sources that form the two end-members of the line. In many cases, one end-member of the mixing curve represents Pb from the bedrock that underlies the river basin, whereas the other represents Pb from a significant anthropogenic source [50]. The average signature of the "geogenic" Pb sources can be determined by analyzing uncontaminated alluvial sediments in the basin, such as sediments found in uncontaminated alluvial terraces (comprised of pre-historic sediments) [52], floodplain sediment found at depth within a sediment core that pre-dates anthropogenic contamination [48], or the direct analysis of the underlying bedrock [52].

As mentioned earlier, a significant advantage of using Pb isotopes as tracers is that accurate estimates of the relative contributions of Pb can be determined analytically. When there are only two sources of Pb, and the mixing curve is linear, the contributions from the two end member sources can be calculated using a simple binary model [48,53] that takes the form of:

$$\%A = \frac{\left(^{20x}Pb/^{20x}Pb\right)_S - \left(^{20x}Pb/^{20x}Pb\right)_A}{\left(^{20x}Pb/^{20x}Pb\right)_B - \left(^{20x}Pb/^{20x}Pb\right)_B} \qquad (4)$$

where $\%A$ is the contribution of source A in a sample and $^{20x}Pb/^{20x}Pb$ and $^{20x}Pb/^{20x}Pb$ are the average ratios in the sample (S) and the two end-member sources, A and B.

Within larger river systems contaminated by multiple anthropogenic Pb sources, well-defined mixing lines do not exist on binary scatter plots. In these cases, it is likely that multiple geogenic or anthropogenic Pb sources exist. As a result, estimating the relative contribution of Pb in the alluvial sediments of the river from the identified sources becomes more difficult. This problem has been overcome by subdividing and analyzing the data on the basis of located geographical areas or time periods (ref). In addition, the use of isotopic tracers can be combined with the multi-elemental approach describe above. For example, Bird et al. [54] used a two-tiered approach to assess the origins of Pb within sediments of the River Maritsa catchment of Bulgaria and Turkey. Lead isotopic

data were used to assess the contributions of Pb to the channel from mining operations within smaller tributary basins. However, at a larger spatial scale, where highly variable Pb isotopic values inhibited the use of a binary isotopic approach, the sources of the Pb were determined using multi-element geochemical fingerprinting methods (described in the section above).

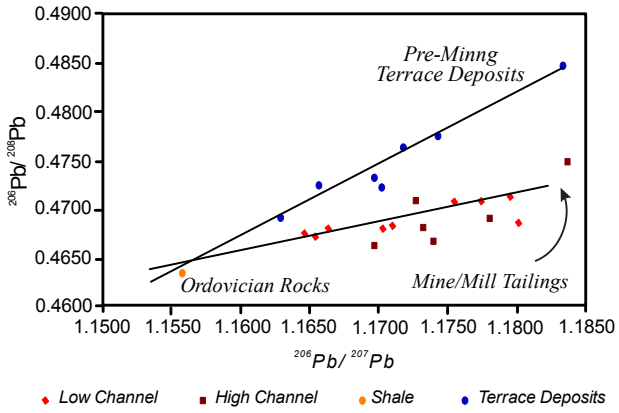

Fig. 6. Bivariate plot of lead isotopes. Background lead was characterized using samples from alluvial terrace deposits that predate mining. The onset of mining results in the influx of Pb from mine and mill tailings. The influx is reflected in a new source of Pb in the channel bed. Thus, samples plot along a new mixing line (figure modified from Miller et al. [52]).

Lead isotopic data are often combined with Pb concentration data (see, for example, Shepard et al. [55]). In doing so, it is possible to assess both changes the source of the Pb as well as the degree to which the Pb sources have contaminated the river. Moreover, because the predominant sources of Pb also served as the predominant sources of other toxic trace metals (e.g., As, Cd, Ni, Zn), Pb isotopes can be used to determine the sources of these metals as well. However, this is not always the case, and in some instances, the isotopic composition of Pb in contaminant sources cannot be distinguished from Pb naturally found in the underlying Earth materials. For example, within the Rio Loa basin of northern Chile, the Pb isotopic composition of Cu mine tailings and ore deposits was similar to that found in other rock types in the basin, including those associated with a local geyser basin, inhibiting the use of Pb isotopes as an effective tracer.

Before the 1990s, the investigation of many of the other isotopic systems (e.g., those associated with the transition and post-transition elements) was hindered by an inability to precisely measure their abundance in Earth materials. However, recent advances in analytical chemistry, including the advent of the MC-ICP-MS, have led to the precise measurement of a wide range of non-traditional stable isotopes, or non-CHONS (referred to because they are not one of the five most studied isotopic systems) [56]. The ability to accurately measure the isotopic abundances of these non-traditional isotopes in geological materials has opened up a whole new field of research into their use as tracers of contamination and to gain insights into biogeochemical processes. The intent with regards to environmental forensics is to develop direct methods to determine the source and cycling of toxic metals in sediments, soils, and water.

The application of these non-traditional isotopes as tracers of contaminant source in river sediments is much more complicated than that of Pb, and most other radiogenic isotopes. In the case of Pb, isotopic fractionation by industrial or biological processes is negligible; the Pb isotopic composition of man-made materials (e.g., as a battery) reflects the ore deposits from which the Pb was derived. Given that the Pb isotopic signature of the ores deposits typically differs from most other types of rocks, the Pb in man-made products is often unique. Moreover, Pb isotopic ratios measured within a sample of river sediment is a function only of the mixing of Pb from different sources, allowing for the relatively easy assessment of Pb contributions from each source. In contrast, the use of the non-traditional isotopes as a tracer is complicated by multiple physical and biological fractionation processes, which not only vary between elements, but the environmental conditions that exist within the river, and the physical, chemical and biological processes to which the metals were subjected. Thus, detailed investigations into the cycling of the utilized isotopes are required for their effective application. Nevertheless, several isotopic systems appear to hold significant promise with regards to the assessment of contaminated river sediments, including Cu, Hg, and Zn [37].

As an example, interest in the use of Zn isotopes as a forensic tracer in rivers stems from that fact that: (1) Zn occurs in a wide range of materials including mining and refining products and wastes, steel processing plants, coal-fired power plants, vehicles, urban waste incinerators, car tires, and other constituents in urban runoff , and (2) Zn is often associated with Cd and Pb in natural and anthropogenic materials, and can therefore be used to determine the source of these trace metals. The potential to use Zn isotopes to determine to the source of Zn in sediments and soils rests, in part, on the fact that the Zn isotopic composition of some anthropogenically produced materials can be distinguished from that occurring naturally in rocks and minerals. In addition, the fractionation of Zn is dominated by mass-dependent processes, such as evaporation, condensation, and electroplating, which when associated with industrial activities, can be measured. Fractionation may also occur at low temperatures during its biogenic uptake by micro-organisms and other biotas [57,58], diffusion processes [59], adsorption onto inorganic and organic surfaces[58,60], and mineralization [61,62] (Table 6.1). If these new isotopic abundances (following fractionation) can be linked to a specific industrial process, then it is possible to use Zn isotopes to determine where the Zn from that process is currently located along a river and how much of the total Zn was derived from it [63–65].

The use of these non-traditional isotopes as tracers of metals in riverine sediments is still in the developmental stages, and in spite of some notable successes, their use will likely be limited to a supportive role in environmental forensic investigations during the near future. Nonetheless, the fact that these non-traditional isotopic systems can provide a wealth of information on the

source, dispersal, and biogeochemical cycling of toxic trace metals that cannot otherwise be obtained, suggesting that their use is likely to grow exponentially in the coming years.

3 Conclusion

Environmental forensic investigations have increasingly relied on the use of geochemical and isotopic fingerprinting methods to determine the source and source contributions of trace metals in contaminated rivers. Recent advances in analytical chemistry have enhanced by the application of geochemical fingerprinting by allowing for the rapid, multi-elemental analysis of sediment samples, and by continually improving upon the accuracy and precision of measuring the isotopic abundances in Earth materials. In addition, it is now possible to determine the abundance of non-traditional isotopes in sediments. Although fractionation makes the use of these isotopic systems more complicated to use for source determination, recent studies show that some isotopes (e.g., those of Cu, Hg, and Zn) hold considerable promise with respect to river sediments. In light of the above, geochemical and isotopic fingerprinting techniques are likely to remain the method of choice to determine trace metal sources and source contributions riverine sediments. However, the use of fingerprinting techniques requires an understanding of the natural and anthropogenic sources that exist within the basin; sources cannot be fingerprinted if they have not been tentatively defined. Potential sources of trace metals within the basin can be qualitatively identified using the widely used and accepted, but underutilized spatial and temporal methods described herein. These temporal and spatial methods, when combined with an analysis of the river valley's alluvial architecture, not only provide insights into potential trace metal sources, but (1) the potential partitioning of source materials into specific depositional environments, (2) the distances and rates of trace metal transport, and (3) the location of geochemical hotspots along the river valley.

Where the above methods do not fully identify the sources or source contributions for trace metals to a river, it will be necessary to utilized other types of physical or mineralogical tracers or source attribution methods, such as the occurrence of unique minerals within a source materials, geochemical speciation data, particle size or microtextures, and/or geomagnetic information (see D'Daen et al. [47], for examples).

Geological Influences on Groundwater Quality

19

Samuel V. Panno and Keith C. Hackley

Introduction

The quality of groundwater is determined by the type and concentration of its chemical and biological constituents. These constituents, depending on their nature and concentrations, can produce water that is unsafe to drink or that has an objectionable taste or odor. Because naturally occurring substances are dissolved in or suspended as fine-grained solids in groundwater, in many cases, some water treatment is necessary before groundwater quality becomes acceptable for drinking purposes or industrial uses. This chapter discusses these naturally occurring substances, their common sources, and the general quality of the groundwater observed within the different aquifers in Illinois.

As municipal and industrial water supplies grew in importance during the early twentieth century, scientists began to study the chemical composition of groundwater and its relationship to the geological framework and associations with the host sediment or bedrock aquifers. The chemical interactions between aquifers and groundwater were identified during the first half of the century and rigorously examined during the latter half (Back and Freeze 1983). Water quality of municipal and private water supplies in Illinois has been routinely analyzed by the Illinois State Water Survey since its founding in 1895 as a means of tracing waterborne diseases (Illinois State Water Survey 2003). Today, studies of the chemical composition of groundwater are routinely performed on both public and private water supplies. The composition of groundwater is used to determine its potability and serves as a tool to determine the sources of naturally occurring and human-related contaminants.

Groundwater is derived from precipitation, such as rainfall or snow melt. Precipitation contains very low concentrations of dissolved minerals (approaching that of distilled water). The major ions—or electrically charged particles—present in rainwater and snow melt are calcium, magnesium, sodium, silica (as $Si(OH)_4$), sulfate, chloride, and nitrogen compounds (nitrate, ammonium, and organic nitrogen). The total concentration of all constituents typically is less than 5 to 10 mg/L (parts per million) (Table 19-1). The natural sources of these ions include airborne dust (calcium, magnesium, and silica) and aerosols from seawater (sodium and chloride), which are highest near the coastal areas (Drever 1997). The majority of the remaining ions are typically from airborne particulate matter and gases from industrial emissions, automobile exhaust, and the evaporation of volatile chemicals (e.g., anhydrous ammonia fertilizers). These latter constituents are discussed in Chapter 28, Karst Terrane.

Once rainfall and snowmelt seep into the ground, the water begins its journey to the water table through the connected pores and crevices in soil, unconsolidated sediment, and rocks. The water table is the elevation at which the geological sediments and rocks become saturated with water. Permeable sediments and bedrock below the water table constitute aquifers. Aquifers supply private citizens and municipalities with potable water and are also used as a source of water for irrigation and industrial purposes throughout much of the state.

Water is a solvent and, as such, is capable of dissolving and interacting with organic and inorganic components of soils, the minerals that make up unconsolidated deposits (e.g., sand and gravel), and with various types of bedrock. Dissolution of minerals within the soil, sediment, and bedrock is a slow process that can take days, years, or eons, depending on the solubility of the materials. These materials contribute to the amount of total dissolved solids (TDS) that are present in all groundwater. Major dissolved constituents of groundwater include the cations (positively charged ions) sodium, potassium, calcium, magnesium, and silica and the anions (negatively charged ions) bicarbonate, sulfate, chloride, and nitrate (Table 19-1). When trace-level ions, such as ammonium, iron, manganese, and arsenic, are present in relatively high concentrations, they create water-quality problems. These constituents come from the dissolution of rocks such as limestone and dolomite, the weathering of less-soluble rocks such as granite, the degradation of organic debris in the soil zone (e.g., trees and leaves), and man-made contaminants (discussed in Chapter 29, Pollution of Natural Waters).

In general, the chemistry of groundwater is controlled by the type of geological materials through which the water flows and the amount of time the water is in contact with these materials. For example, precipitation percolating into a limestone aquifer would dissolve the limestone (made of calcium carbonate), and the water (now groundwater) would contain predominantly calcium and bicarbonate ions. The dominant cations and anions are used to describe the gen-

eral chemical composition, or "type," of groundwater. For example, limestone aquifers contain "calcium bicarbonate type" groundwater, and deep, granitic rock eventually produces "sodium chloride type" groundwater.

Aquifers and Aquitards: Effects on Groundwater Quality

Aquifers in Illinois are made up of two types of material: (1) sand and gravel deposits found in association with glacial till or along stream valleys, and (2) porous and permeable bedrock units. Sand and gravel aquifers are scattered throughout the state, but the largest deposits occur in northeastern and central Illinois. Bedrock aquifers containing usable groundwater are located throughout the state, but potable water is found only in the bedrock aquifers of the northern third and, to a lesser extent, the western and southern parts of the state. For example, fresh groundwater with less than 1,000 mg of TDS/L can be pumped from wells over 1,000 feet (305 m) deep in the northern part of the state, but saline (salty) groundwater is encountered several hundred feet or less below the surface in southern Illinois (Lloyd and Lyke 1995). Groundwater from bedrock found in the southern two-thirds of the state is usually too saline for human use (Figure 19-1). Salinity of groundwater generally increases with depth. Bedrock aquifers in the northern portion include shallow carbonate rocks (dolomite and limestone) as well as deep sandstones that are primarily made up of quartz and silicate minerals. The bedrock aquifers in the western and southern parts of the state are primarily shallow carbonate rocks.

Sand and gravel deposits typically contain abundant clasts (i.e., sand grains, pebbles, and cobbles) of limestone and dolomite that dissolve much faster than do clasts of other composition (e.g., quartz). Consequently, calcite and dolomite, once dissolved, dominate the chemical composition of the groundwater in these aquifers, forming a calcium-magnesium bicarbonate type of groundwater (Table 19-1). Similarly, bedrock aquifers are often made of fractured limestone and dolomite, resulting in groundwater with the same general chemical composition as that found in sand and gravel aquifers. Groundwater circulating through fractured sandstone aquifers, such as the Aux Vases Sandstone in southwestern Illinois, typically form a sodium bicarbon-

Table 19-1 Chemical composition[1] of averaged rainwater samples and single samples of different types of groundwater in Illinois. All parameters are reported in milligrams per liter except pH.

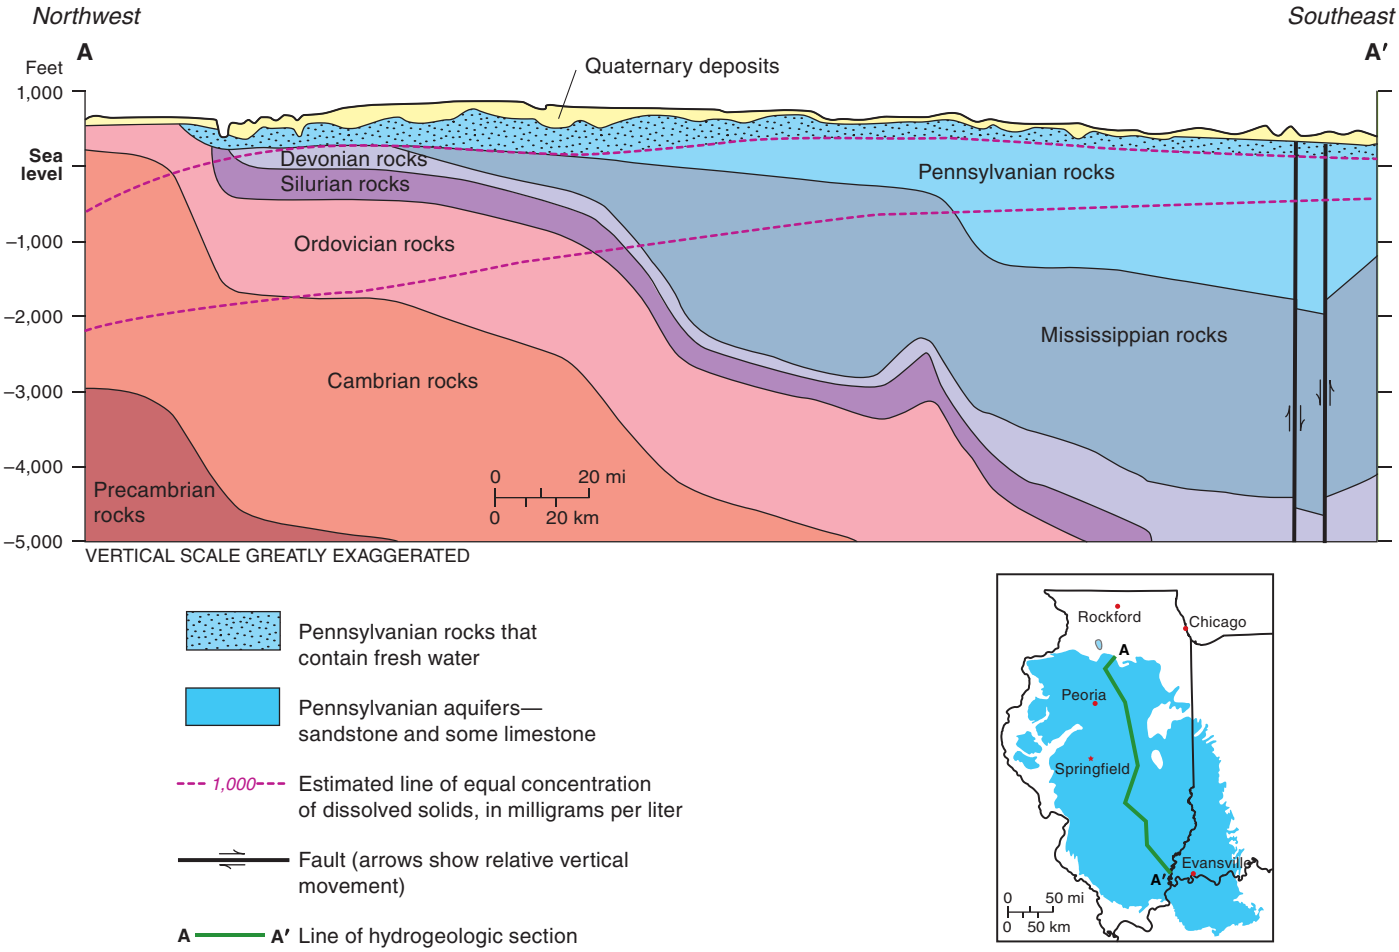

Figure 19-1 North-south cross section of Illinois showing estimated lines of equal concentration of total dissolved solids in groundwater (Lloyd and Lyke 1995).

ate type groundwater (Table 19-1). One way such groundwater is formed is for calcium bicarbonate groundwater to enter the sandstone, and, through ion exchange, calcium ions replace sodium ions on clay minerals (sodium is often present due to degradation of feldspars in the sandstone). This process is similar to that occurring when a water softener causes calcium and magnesium to exchange positions on a resin within the softener; the result in both cases is a "soft" sodium bicarbonate water.

Aquitards are those deposits or rocks that do not allow recharge water or groundwater to penetrate very easily (e.g., clay-rich glacial till and shale) (Chapter 18, Aquifers). These deposits or rock units protect groundwater from surface-borne contaminants, isolate groundwater from the atmosphere, and confine groundwater to a single aquifer or channel it to a series of connected aquifers. The isolation of groundwater for hundreds to thousands to tens of thousands of years can affect its chemistry by fostering reducing conditions, as is discussed later in this chapter. Additionally, the interaction of groundwater with the minerals of an aquitard can alter the chemical composition of the groundwater flowing through it and the chemical composition of adjacent aquifers. For example, recharge water interacting with the shale that bounds an aquifer often encounters the mineral pyrite (iron sulfide), which can be easily oxidized to form groundwater that has very high concentrations of sulfate (perhaps hundreds to thousands of milligrams per liter) (Table 19-1). Such sulfate-enriched groundwater, as it enters an underlying aquifer, can enrich the aquifer with sulfate even though there may have been no mineralogical source of sulfate in the aquifer.

Chemical Composition

There are a number of constituents that can be found in groundwater, and water quality depends on the type and concentration of these constituents. For example, groundwater in some locations is immediately potable; elsewhere it may have an objectionable taste and/or odor and may even be unsafe to drink. The U.S. Environmental Protection Agency (U.S. EPA) has developed a list of acceptable concentrations of natural and man-made contaminants for municipal drinking water. These standards, the National Pri-

mary Drinking Water Regulations (NPDWR), are enforced by the U.S. EPA (1991, 2009). National Secondary Drinking Water Regulations (NSDWR) are U.S. EPA guidelines pertaining to constituents of drinking water based on cosmetic effects, taste, odor, and appearance. Both guidelines may be found on the U.S. EPA (2009) Web site.

The chemical components that are typically measured to help determine the general quality of groundwater include suspended solids, hardness, sodium, chloride, fluoride, sulfate, chemicals associated with reduction-oxidation (e.g., arsenic, iron, manganese, nitrate, and ammonium), assorted minor and trace constituents, dissolved gases (e.g., air, carbon dioxide, methane, and hydrogen sulfide), and stable and radioactive isotopes. Some of these constituents are occasionally referred to as "contaminants," but they can be naturally occurring.

Suspended Solids

Suspended solids in groundwater are occasionally observed in wells tapping aquifers that have relatively large porosity and permeability (e.g., sand and gravel, karst limestone/dolomite). Suspended solids include soil and other fine-grained material (e.g., clay, silt, and organic debris) small enough to pass through the tiny spaces between sand and gravel and through crevices in carbonate rock. Suspended solids can also include compounds that may precipitate in the water as it is withdrawn from the aquifer due to dramatic changes in temperature, pressure, pH, or oxygen content. Examples of dissolved constituents that can emerge from apparently clear water are calcium carbonate, which forms small white flakes when dissolved carbon dioxide is released from the water, and iron and manganese oxides, which form orange and black granules or coatings when water is exposed to oxygen. Such materials can make the water cloudy and can affect its taste unfavorably.

An extreme example of suspended solids in groundwater comes from the karst aquifers of southwestern Illinois. Karst aquifers have large crevices and conduits that can carry relatively large concentrations of suspended solids in the water. Several wells in one subdivision in southwestern Illinois intersected crevices that were in direct contact with at least one large sinkhole. During and following large rainstorms, soil washed into the sinkhole(s) and through the crevices that led to the wells. Pumps in the wells sent the sediment-laden water, now a muddy slurry, into the plumbing systems of several houses, and mud oozed from the fixtures (Figure 19-2) (Panno et al. 1996). In most cases, however, suspended solids in groundwater are not so extreme and can be removed by commercially available filters.

Left and center: Water containing sediment from erosion of cropland adjacent to a sinkhole during and following relatively large rainfall events (1 inch [2.5 cm] or greater). Right: Fireplace ashes in water caused by dumping fireplace ashes into the sinkhole in the home's backyard. (Photograph by Joel M. Dexter.)

Rock-Water Interaction

The chemical characteristics of groundwater are determined by the interaction between groundwater and the minerals that make up the rock or sediment through which the water is moving (Figure 19-3). That is, the materials of the soil zone and the aquifer are dissolved and incorporated into the water moving through them. Some components may provide a characteristic taste to the water and some may make the water undrinkable based on taste, toxicity, or both.

Calcium, Magnesium, Bicarbonate, and Hardness

In areas where bedrock is dominated by limestone and/or dolomite or where sand and gravel aquifers contain abundant clasts of these carbonate minerals, the groundwater is typically a calcium bicarbonate type or calcium-magnesium bicarbonate type (Table 19-1; Figure 19-4). These rocks are dominated by calcite (calcium carbonate) and dolomite (calcium-magnesium carbonate), and both are soluble in slightly acidic rainwater (Table 19-1) and snowmelt and in carbon dioxide-enriched soil water (soil water made more acidic by the generation of carbon dioxide from root respiration and microbial degradation of organic debris). Carbonate minerals dissolve relatively fast when exposed to carbon dioxide-enriched waters.

Groundwater from aquifers made up of or containing carbonate rock is often referred to as "hard." Hard water contains calcium and magnesium that react with soap and produce soap scum or react with other anions to produce a solid scale or coating when the water is boiled and evapo-

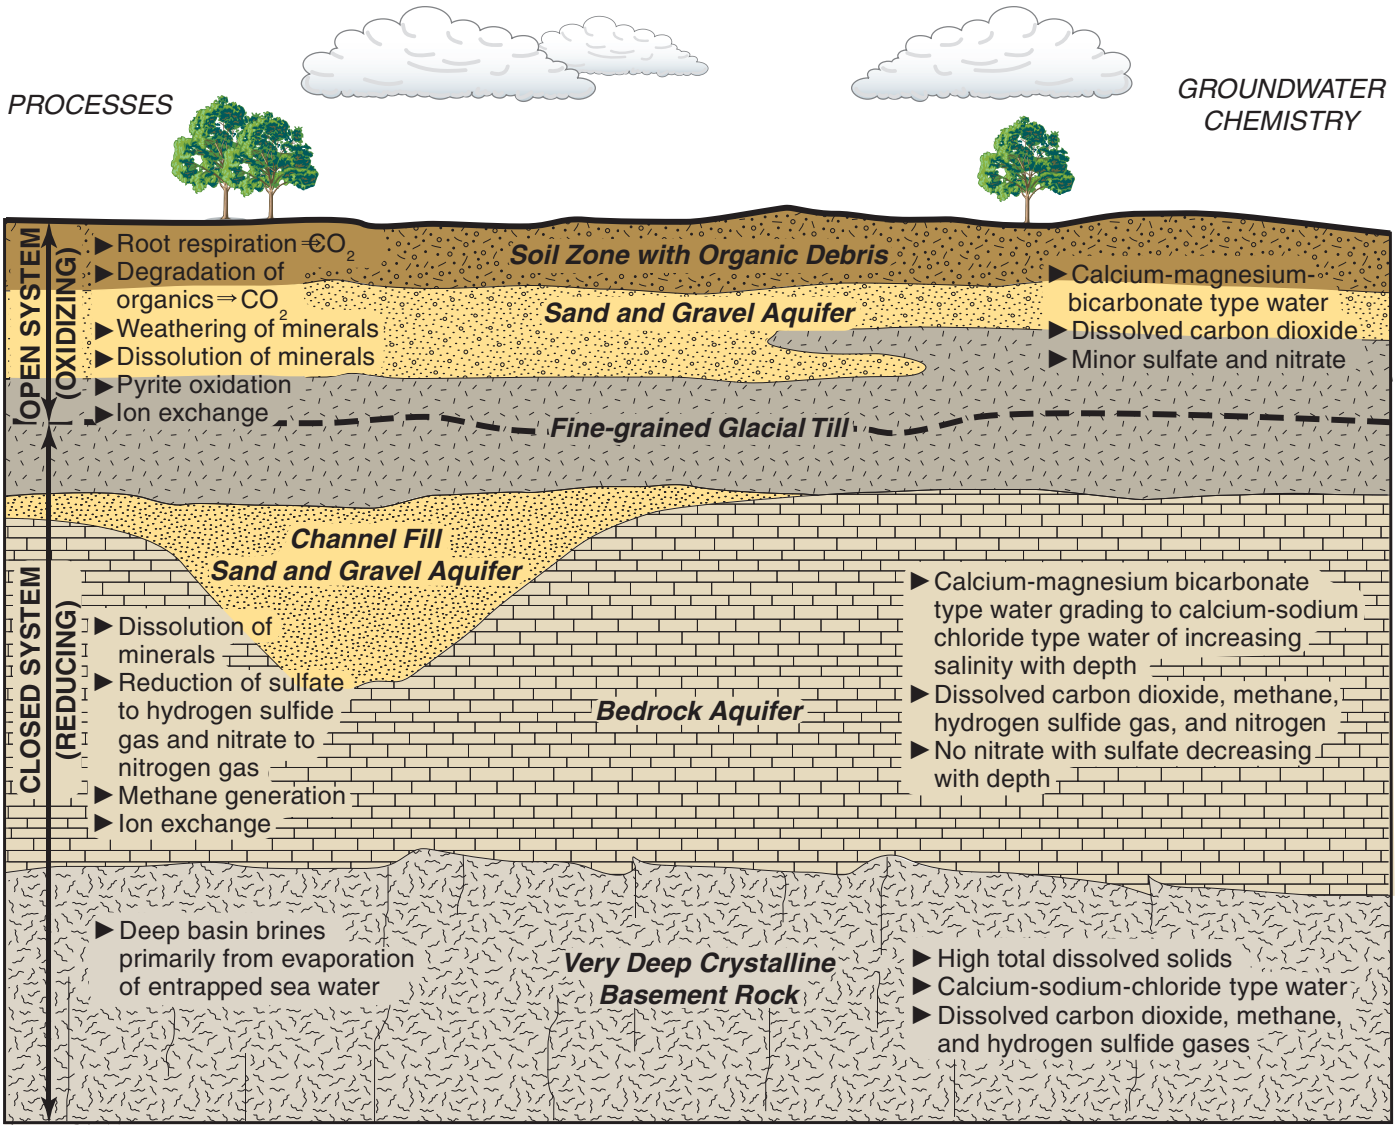

Figure 19-3 Conceptual model of the processes and chemical composition of groundwater in Illinois. Abbreviation: CO_2, carbon dioxide.

rated. Hardness and its components are not toxic, have no offensive taste or odor, and are under no U.S. EPA guidelines. Chemically, hardness is defined (Freeze and Cherry 1979) as (total calcium concentration × 2.5) + (magnesium × 4.1) and is expressed as milligrams per liter, or parts per million. For example, if water contains 5 mg of calcium/L and 5 mg of magnesium/L, then the hardness is 33 mg/L. Water with a hardness value greater than 120 mg/L is considered to be hard, and greater than 180 mg/L is considered to be very hard (Lehr et al. 1980). Because the presence of these minerals controls water chemistry, groundwater from carbonate mineral-rich aquifers is typically very hard. For example, the average hardness value for the groundwater of the karst limestone aquifers of Illinois is about 230 mg/L (Panno et al. 1996, 1997). Groundwater from sand and gravel aquifers in northern Illinois has hardness values of over 300 to 400 mg/L (Panno et al. 2005a).

The scale or coating from these dissolved minerals that can be found in pots used for boiling hard water and on the bottom of hot water heaters is a deposit of carbonate minerals. In some cases, hard water may be desirable because it tends to coat the interior of metal pipes containing copper or lead or joined by lead-bearing solder, thereby protecting the metals from leaching into the water supply (Lehr et al. 1980). However, continued coating of pipes with scale may eventually (after tens of years) constrict the interior of water pipes so that the water flow slows to a trickle. Hardness can be treated easily by commercially available water softening treatment systems. Water softeners typically consist of an ion-exchange system that exchanges sodium for calcium and magnesium. What enters the water softener as a hard, calcium-magnesium bicarbonate water discharges as a soft, sodium bicarbonate water.

Figure 19-4 Groundwater discharging from a spring at Weldon Springs State Park near Clinton, Illinois. The dilute, calcium-bicarbonate groundwater that is recharged in the higher elevations to the north percolates into and flows through a sand and gravel layer in glacial till and discharges as springs in the low-lying area of the park. A pipe was inserted into this spring's discharge point and channeled to this facade; unlike its Wyoming namesake, Illinois' Old Faithful flows constantly (Panno and Hackley 2001b). (Photograph by Samuel V. Panno.)

Sodium and Chloride

Water may be classified according to its TDS content (Table 19-2). In Illinois, most groundwater from shallow aquifers is fresh, whereas relatively deep groundwater from within the Illinois Basin is saline to briney. Water containing chloride concentrations of approximately 250 mg/L or greater may have a salty taste. This concentration is the U.S. EPA recommended limit for drinking water (U.S. EPA 1991, 2009); chloride concentrations exceeding 1,000 mg/L may be unsafe for human consumption (Lin 1977, Lehr et al. 1980, U.S. EPA 1991). Sodium concentrations are not regulated by the U.S. EPA. However, high-sodium intake may be associated with hypertension in some individuals (U.S. EPA 1991), and the sodium concentration in drinking water should be considered by those for whom dietary sodium is a concern (Haman and Bottcher 1986).

Most shallow groundwater is relatively fresh and typically has little sodium and chloride dissolved in it. Usually, naturally occurring sodium and chloride concentrations in sand and gravel aquifers in Illinois are between about 1 and 15 mg/L (Panno et al. 2006a). However, sodium chloride is present in large concentrations in groundwater from deep aquifers of northern Illinois, in parts of central Illinois, and many parts of southern Illinois (Clayton et al. 1966).

Table 19-2 Classification of groundwater relative to total dissolved solids (TDS) contents (Hem 1986).

Water classification	TDS (mg/L)
Fresh	<1,000
Slightly saline	1,000 to 3,000
Moderately saline	3,000 to 10,000
Very saline	10,000 to 35,000
Brine	>35,000

Much of the bedrock in Illinois, however, is part of an underlying midcontinental sedimentary basin known as the Illinois Basin. Sedimentary basins such as this contain abundant saline groundwater that typically increases in salinity with depth (Figures 19-1 and 19-3); in the case of the Illinois Basin, salinity increases to a depth of about 1.2 miles (2 km) or so before it levels out (McIntosh et al. 2002). The source of the salinity of this groundwater has generated much interest. Walter et al. (1990) and Steuber et al. (1991, 1993) suggested that the salinity was due to the evaporation of seawater short of the precipitation of halite in Silurian and Devonian strata and a mixture of evaporated seawater and dissolution of evaporites in shallower Mississippian and Pennsylvanian strata. Recent work by Hanor and McIntosh (2006) suggests that saline groundwater of the Illinois Basin underwent extensive alteration as a result of rock-water interaction and were transformed from sodium chloride brines to calcium-sodium chloride brines with salinities up to 200,000 mg/L TDS.

Saline springs can be seen along structural features, such as along folds and faults in the Starved Rock area (the Old Salt Well) in La Salle County, in southwestern Illinois in the vicinity of oil fields near Columbia in Monroe County, and in southern Illinois near the Equality Fault Zone and the town of Equality in Saline County (Figure 19-5). Water from these springs is about as saline as seawater with about 35,000 mg/L TDS and is dominated by sodium and chloride; seawater is dominated by sodium and chloride and contains about 34,477 mg/L TDS (Table 19-1).

Saline groundwater and brines can be brought near or to the land surface by natural conditions, such as migrating up prominent fractures and/or faults in bedrock, or by anthropogenic activities, such as exploration for and exploitation of petroleum. The mixing of upward-migrating saline groundwater with fresh groundwater from shallow aquifers can make groundwater from private wells undrinkable and can present a very expensive problem for municipalities. An example of saline groundwater seeping into a freshwater aquifer can be found in east-central Illinois where the Mahomet aquifer crosses a major, roughly north-south–trending structural feature called the La Salle Anticlinorium (Figure 19-6). Saline water seeps up into the base of the aquifer from bedrock at a depth of about 300 feet (91 m) below the land surface near the Champaign-Piatt County line. Groundwater that normally has chloride concentra-

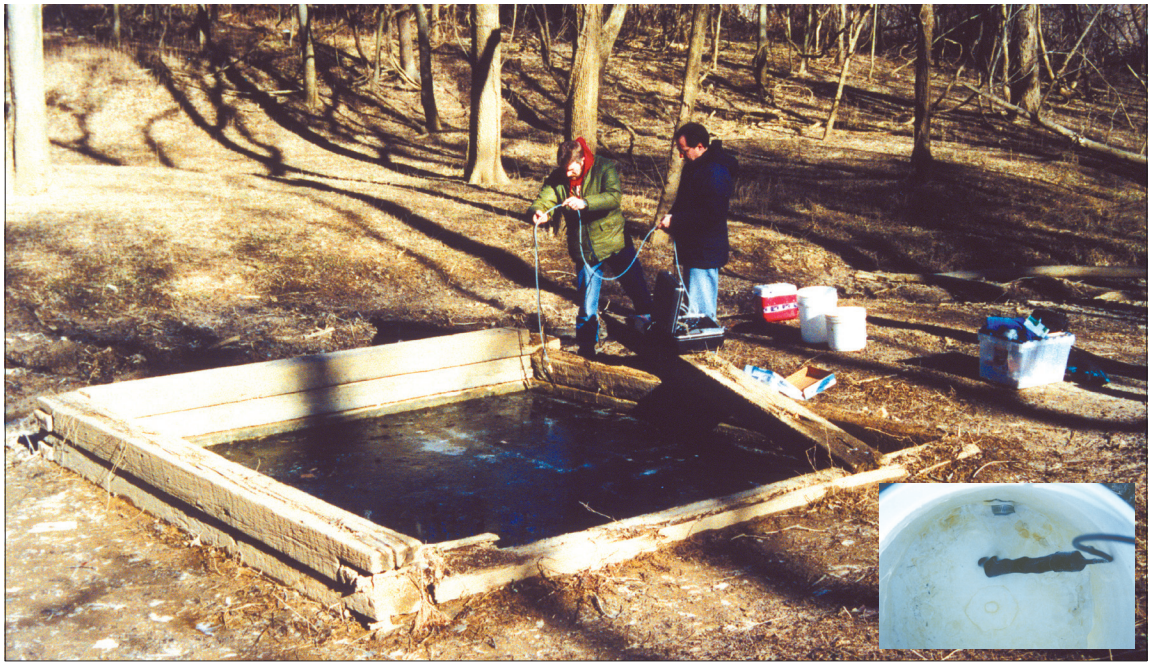

Figure 19-5 Equality Spring in Saline County in southern Illinois is a saline spring containing over 13,000 mg/L of sodium and chloride. The spring is over 6 feet deep (2 m), is encased by railroad ties, and was used as a commercial source of salt by early settlers of Illinois. (Photograph by Samuel V. Panno.)

tions less than or about 1 mg/L here exceeds 300 mg/L (Panno et al. 1994). Samples of groundwater from bedrock beneath the sand and gravel aquifer have chloride concentrations in the thousands of milligrams per liter (Panno et al. 2005a).

In addition, naturally saline springs in northern (e.g., Starved Rock State Park) and southern Illinois, usually located along fault zones or structural folds, discharge highly saline water into surface streams (Panno et al. 2005a, 2006a). Streams in areas where there are saline seeps have names such as the Saline River (Saline County) and the Salt Fork of the Vermilion River (Vermilion County). Because salt was an important commodity during early Illinois settlement by Europeans during the early 1800s, such seeps and their "salt works," initially used by Native Americans, became the nucleus of early settlements. Saline water was boiled in large iron kettles, and the residual salt was harvested and sold (Fliege 2002).

Fluoride

Fluoride typically is added to municipal water supplies because of its protective effects on teeth. However, fluoride in drinking water at concentrations greater than 3 mg/L can cause problems with tooth mottling, brown staining, and pitting in the teeth (dental fluorosis) in children with developing teeth (U.S. EPA 2009). The primary U.S. EPA drinking water standard is 4 mg/L. Fluoride concentrations greater than 4 mg/L can result in bone disease and bone and joint deformation (skeletal fluorosis) (Appelo and Postma 1994). The NSDWR for fluoride in drinking water is 2.0 mg/L (U.S. EPA 1991, 2009).

Groundwater from wells in most aquifers in Illinois has relatively low fluoride concentrations (usually about 0.5 mg/L) (Panno, unpublished data). Fluoride concentrations in groundwater are a function of the chemical composition of the groundwater and the presence or absence of fluorine-bearing minerals within an aquifer. Fluorine-bearing minerals include apatite (calcium phosphate), fluorite (calcium fluoride), and minerals that can exchange hydroxyl ions for fluoride ions (hornblende, mica, and clay minerals) (Hem 1986). Conrad et al. (1999) found that the greatest fluoride concentrations in Kentucky were associated with relatively deep, sodium bicarbonate-type groundwater with pH values between 7.6 and 8.0. The fluoride concentrations in Illinois aquifers are relatively low, in part, because calcium bicarbonate-type groundwater (found in limestone and sand and gravel aquifers of northern Illinois) limits the amount of the fluorite that can be dissolved (Hem 1986). Fluorite (calcium fluoride) deposits are found in southeastern Illinois within and near the town of Rosiclare, in Hardin County, site of the largest known fluorite deposits in the United States. Groundwater samples drawn from limestone for Rosiclare's municipal water supply contained 1.5 mg of fluoride/L (Panno and Hackley 2001a) (Table 19-1). Private wells that tapped into the groundwater of the Aux Vases Sandstone in southern Illinois have intersected groundwa-

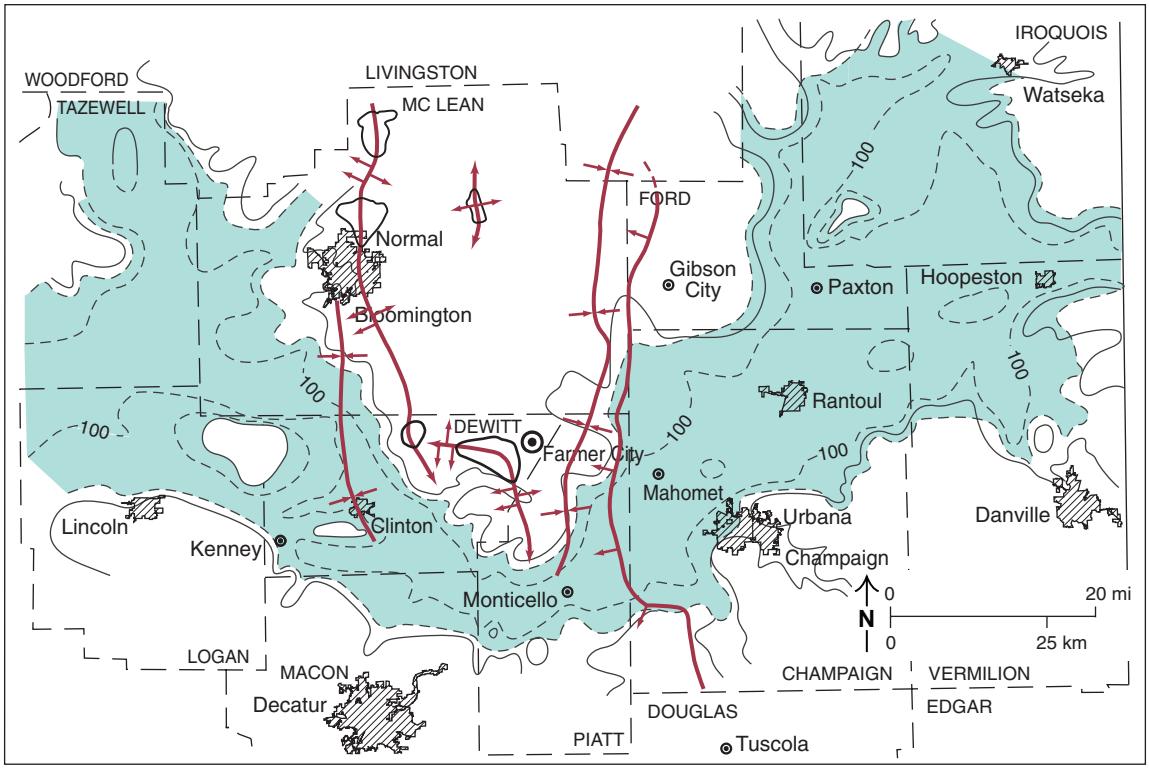

Figure 19-6 Saline groundwater can seep into a freshwater aquifer to contaminate it. Such a situation occurs in east-central Illinois where the Mahomet aquifer crosses the north-south cluster of folds known as the La Salle Anticlinorium. Dashed lines are thickness contours (in feet). (Modified from Panno et al. 1994.)

ter with fluoride concentrations as high as 9 mg/L (J. Bade, former sanitarian with the Monroe-Randolph Bi-County Health Department, personal communications 1997).

Sensitivity to Reduction-Oxidation

Oxygen

Oxygen, one of the most abundant elements on earth, very commonly combines with other elements. Depending on the nature of the bond, the bonded element is either reduced or oxidized. In simplest terms, reduction-oxidation (commonly shortened to redox) involves the gaining (reduction) or losing (oxidation) of electrons between elements, one of which is oxygen. The term "reduction" refers to the charge; an atom, molecule, or ion that gains an electron now has a reduced, or negative, charge. The loss of electrons through oxidation results in a positive charge. Redox reactions happen in pairs; there is no oxidation without a concurrent reduction. Redox-sensitive elements are those that either precipitate or dissolve in the presence or absence of dissolved oxygen and other electron-bearing, often oxygen-bearing, ions (e.g., nitrate and sulfate). The abundance of dissolved oxygen (and oxygen-bearing ions) usually decreases with depth and confinement of an aquifer. Groundwater in shallow, unconfined aquifers typically has dissolved oxygen contents similar to that of surface water (about 8 mg/L). Groundwater in deeper aquifers and shallow, confined aquifers has little or no dissolved oxygen because it is readily used up by bacterial activity and other oxygen- and electron-consuming chemical reactions that occur within the aquifers (e.g., decomposition of organic matter and oxidation of pyrite); such groundwater is referred to as being under reducing conditions. Consequently, redox-sensitive elements are more readily dissolved in deeper, oxygen-depleted groundwater.

Arsenic

Arsenic is an element that is soluble in water, is redox-sensitive, and occurs naturally in minute concentrations in groundwater. The routine ingestion of water containing very low concentrations of arsenic has been linked to skin disease and cancer (Smith et al. 1992). The arsenic standard for community supply wells has been lowered by the U.S. EPA from 50 to 10 µg/L (parts per billion) for finished drinking water (Vorman 2001). Health problems, such as arsenic-induced cancers, have resulted, in other parts of the world, from drinking water with relatively large concentrations of arsenic (e.g., Bagla and Kaiser 1996). Arsenic concentrations of shallow glacial and alluvial aquifers of Illinois range from less than 1 to as high as 107 µg/L; the greatest arsenic concentrations are in the southern part of the state and in the Mahomet aquifer (glacial drift aquifer) (Table 19-1) (Figure 19-7) (Warner et al. 2003).

Iron and Manganese

The solubilities of iron and manganese, metals that are commonly present in groundwater, are sensitive to changes in redox conditions. The concentrations of these metals are low in groundwater from shallow aquifers because the presence of dissolved oxygen in the water causes these metals to precipitate from solution. However, in deeper aquifers where dissolved oxygen has long been consumed by biological and chemical reactions, groundwater often contains abundant concentrations of dissolved iron and manganese (Table 19-1).

Groundwater containing relatively high concentrations of these dissolved metals may appear to turn yellow rapidly (within minutes) in a container. Such water can form orange to black coatings on porcelain fixtures and laundry due to precipitation of manganese oxides and iron oxyhydroxides upon exposure to oxygen (Figure 19-8). The presence of these metals in water can thus be a nuisance. Iron and manganese also can precipitate on well screens and eventually plug them. Such plugging is very likely one of the causes for reduced efficiency of a municipal well in an east-central Illinois municipal well field (Panno et al. 2005b). Iron and manganese can impart a metallic taste to water. The U.S. EPA limits for iron and manganese are 0.30 and 0.05 mg/L, respectively. The U.S. EPA limit is an NSDWR, based on taste and the problems just mentioned rather than on health risk (U.S. EPA 1991). Commercially available water softeners with salt and filters can effectively remove these metals.

Figure 19-8 Falling Springs, located near Dupo, in St. Clair County in southwestern Illinois, is an example of reduced groundwater. The spring discharges from a cave located 50 feet above the base of a cliff. As the groundwater is oxygenated, it precipitates manganese oxide and iron oxyhydroxide intermixed with calcite to form a black apron on the cliff. (Photograph by Joel M. Dexter.)

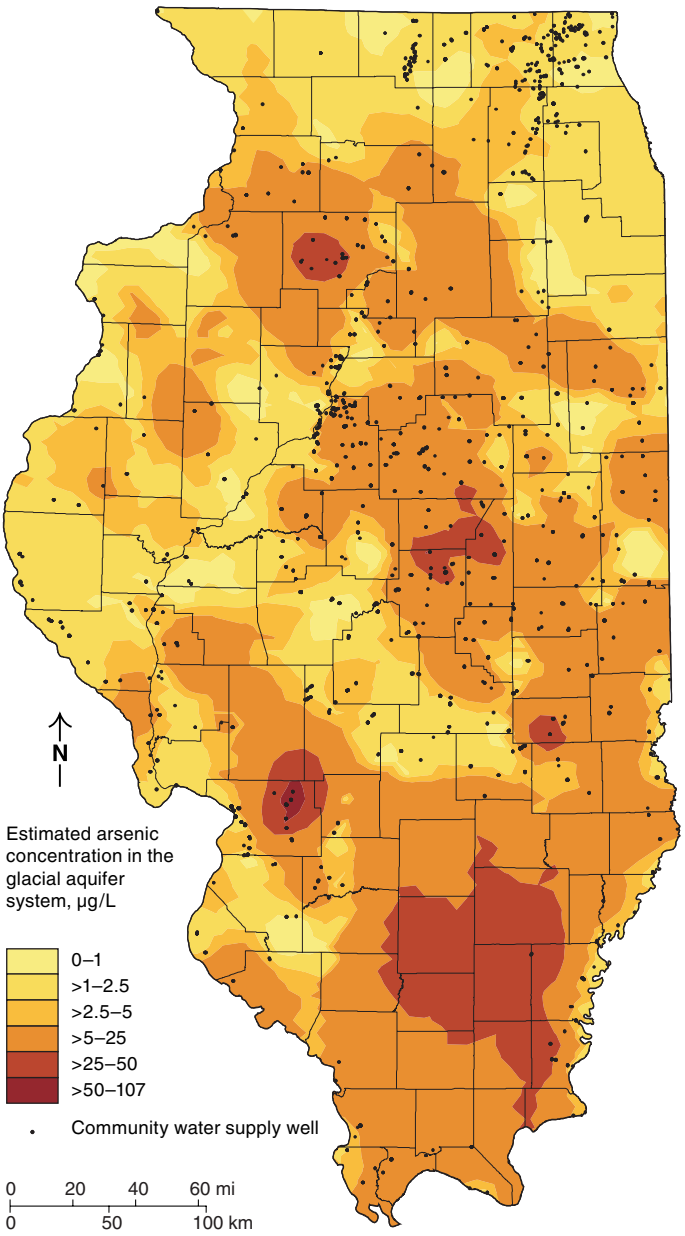

Figure 19-7 Contour map of estimated arsenic concentrations in Illinois groundwater (Warner et al. 2003).

Nitrogen Compounds

Nitrogen compounds (nitrate, nitrite, ammonium, and

organic nitrogen) are naturally occurring components of groundwater. Nitrate is the most common dissolved nitrogen compound in surface and shallow groundwater environments where the water is relatively oxidized. Usually the concentrations of these compounds are small. Naturally occurring nitrate concentrations (NO_3-N) are typically between 2.0 mg/L and 2.5 mg/L (Panno et al. 2006b). However, groundwater in some shallow aquifers in Illinois exceeds the U.S. EPA NPDWR of 10 mg of NO_3-N/L; water with concentrations at or exceeding 10 mg of NO_3-N/L may pose health problems. The potential sources of such high-nitrate concentrations are discussed in Chapter 29, Pollution of Natural Waters. Nitrate concentrations can be naturally reduced through denitrification, a process by which denitrifying bacteria convert nitrate to nitrogen gas. As a result, nitrate in groundwater is often stratified or layered; the greatest concentrations occur near the top of the water table and continually decrease with depth. Ammonium becomes more prevalent in the reducing conditions of deeper and confined aquifers. For example, the Mahomet aquifer of east-central Illinois has ammonium concentrations up to 6 mg/L (Table 19-1) (Hackley 2002). Roy et al. (2003) indicated that the source of ammonium in a deep sand and gravel of the Mahomet aquifer in east-central Illinois is the subsurface degradation of organic materials present in buried ancient soils (paleosols).

Sulfate

Sulfate is typically present in groundwater at concentrations in the tens of milligrams per liter, but it can be much higher. Sulfate concentrations of 250 mg/L or greater is a U.S. EPA NSDWR. Drinking water with such high sulfate concentrations may have objectionable taste and odor; however, there is no evidence of ill effects from drinking such water (Centers for Disease Control, U.S. EPA 1999). In Illinois, sulfate concentrations of several hundred to 2,000 mg/L were found from the deep bedrock Cambrian and Ordovician aquifers in northeastern Illinois (Gilkeson et al. 1981) and in east-central Illinois in the unconsolidated sands and gravels of the Onarga Valley portion of the Mahomet aquifer (Hamdan 1970). Gilkeson et al. (1981) determined that the large sulfate concentrations found in the Cambrian and Ordovician aquifers were from the dissolution of marine evaporites (the calcium sulfate mineral gypsum). Sulfate in the Onarga Valley is due to circulation of groundwater through the bedrock and the leaching of secondary sulfate minerals produced from pyrite oxidation (Table 19-1) (Panno et al. 1994, Hackley 2002).

Dissolved Gases

A variety of dissolved gases are commonly associated with groundwater (Figure 19-3): nitrogen, oxygen, carbon dioxide, methane, and hydrogen sulfide. Other gases that are often present but usually in low concentrations are the noble (inert) gases, hydrogen, chlorofluorocarbons, and radon. As water penetrates into the ground, gases typically found in the atmosphere are dissolved in the water. Thus, nitrogen is common in groundwater. Nitrogen also may be produced from microbial denitrification reactions. Due to biochemical reactions within the aquifers, oxygen is quickly consumed during oxidation of organic matter and other reduced compounds such as the sulfides found in the soils and deeper sediments. Carbon dioxide is added to the infiltrating water in the soil zone due to root respiration and oxidation of organic matter. The addition of carbon dioxide increases the carbonic acid, lowering the water's pH, which has important impacts on the solubility of the rocks and minerals through which the groundwater flows.

In reducing environments, hydrogen sulfide and methane become more prevalent. Hydrogen sulfide results in a rotten egg odor that is sometimes present in well water. The sources of hydrogen sulfide include the bacterial reduction of naturally occurring sulfate dissolved in groundwater and decomposing organic matter within confined aquifers or in aquitards. Although the odor is objectionable, the concentrations of hydrogen sulfide gas typically found in drinking water do not pose a health problem. Hydrogen sulfide can be tasted at concentrations at or exceeding 0.05 mg/L (Lehr et al. 1980). At concentrations of 0.2 mg/L, hydrogen sulfide can be corrosive to silverware, fixtures, and plumbing (Lin 1977). Most water treatment companies can install equipment capable of removing hydrogen sulfide from domestic water supplies using oxidation, chlorination, aeration, and filtration or ion exchange with chemically active compounds (Lemley et al. 1999, Ross et al. 1999).

Dissolved methane is quite common in Illinois groundwater (Figure 19-9). Methane occurs naturally from the microbial degradation of buried organic debris present in the glacial drift deposits throughout much of central and northeastern Illinois (Meents 1958, 1960; Coleman 1976). Many residents of Illinois have used this "drift gas" to run appliances or heat their homes (Meents 1960). Using isotope geochemistry, methane from glacial drift deposits can be distinguished from other sources, such as thermogenic methane associated with petroleum formation or generated in landfills (Coleman et al. 1977, 1988, 1995; Hackley et al. 1996). The ability to determine these differences is important when exploring possible environmental problems from methane-generating sources such as landfills.

Total Dissolved Solids

Total dissolved solids, or TDS, refers to the total mass

of all dissolved constituents (as ions) present in groundwater. The U.S. EPA's NSDWR puts a suggested limit of 500 mg/L on this parameter. The TDS can easily be approximated by using a specific conductance or electrical conductance meter to measure the electrical conductivity of water (its ability to conduct electricity). Conductivity has the following relationship with TDS (Hem 1986):

TDS = specific conductance × 0.59.

Distilled water, having almost no dissolved minerals, would have a specific conductance of near zero. Rainwater is very dilute with a low specific conductance of about 20 microsiemens per centimeter (μS/cm), and water with a large TDS load (such as seawater) has a very high value (close to 60,000 μS/cm in the case of seawater) (Table 19-2). The specific conductance of the 500 mg/L standard would be about 850 μS/cm.

ENVIRONMENTAL ISOTOPES

Isotopes are atoms of an element that have a different number of neutrons in the nucleus. Isotopes can be stable or radioactive. Because the number of protons and the electron configuration are the same as other atoms of that element, isotopes of a particular element behave similarly during chemical reactions. However, because the atomic weights are different, the isotopes of an element react at different rates, which results in different concentrations of isotopes in the coexisting phases of a compound or in the reaction products of chemical, physical, and biological processes. This natural partitioning process is very important in the field of stable isotope geochemistry and is quite useful for determining the source of water or certain dissolved constituents and for figuring out the geochemical processes that have occurred to give the present-day chemical composition of a certain groundwater. The use of environmental isotopes can help solve groundwater quality problems by establishing the source of contaminants (natural or human-induced). The isotopes can also be used to protect groundwater by helping to identify groundwater recharge areas and groundwater flow velocities. Elements with stable isotopes that are commonly used in groundwater studies include oxygen, hydrogen, carbon, sulfur, nitrogen, and, to a lesser degree, chlorine, strontium, helium, and beryllium.

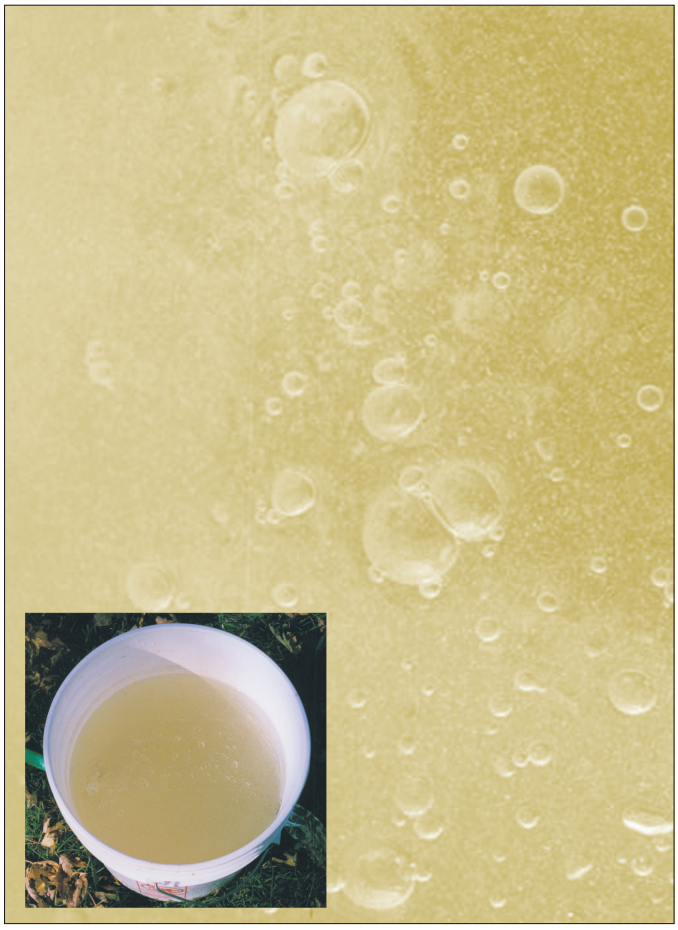

Figure 19-9 Gas (predominantly methane) bubbling out of groundwater pumped from the Mahomet aquifer in central Illinois. The largest bubbles were up to 1 inch (2.54 cm) in diameter. The presence of methane indicates reducing conditions within the aquifer. (Photographs by Samuel V. Panno.)

Radioactive isotopes have unstable nuclei and change into different atomic elements through spontaneous decay involving the emission of particles and energy. The rates of decay differ widely for the various radioactive isotopes, ranging from a fraction of a second to billions of years. The rate of decay is usually referred to as the half-life, the time needed for the concentration of the radioactive isotope to decrease by one-half. In hydrology, radioactive isotopes are typically used to determine the relative age of water and as tracers to help determine the source of water or of dissolved constituents in the water. Several radioactive isotopes are used in groundwater research; however, the most common are tritium (^{3}H), with a 12.3-year half-life, and carbon-14 (^{14}C), which has a 5,730-year half-life.

Two very good sources for information about isotope geochemistry applied to groundwater hydrology are Clark and Fritz (1997) and Kendall and McDonnell (1998). Examples of the use of isotope geochemistry applied to Illinois groundwater include the determination of origin of high-sulfate concentrations in deep aquifers of northern Illinois (Gilkeson et al. 1981), the processes controlling the enrichment of radium-226 and uranium-234 in the Cambrian and Ordovician aquifers of northern Illinois (Gilkeson et al. 1983), the origin of methane in glacial drift and Paleozoic bedrock (Coleman et al. 1988), detection of the impacts of landfill leachate and gases on local groundwater chemistry (Hackley et al. 1996, 1999), determination of sources of elevated nitrate concentrations (Panno et al. 2001, Hackley et

al. 2007, Roadcap et al. 2002, Hwang et al. 2003), the origin of the Illinois Basin brines and Mississippi Valley-type ore deposits (Clayton et al. 1966, Richardson et al. 1988, Stueber and Walter 1991), and the age of groundwater in a buried bedrock valley of central Illinois (Hackley 2002).

Although the concentrations of most radioactive isotopes measured in Illinois groundwater are low and do not detrimentally affect groundwater quality, dissolved radium from the deep Cambrian and Ordovician aquifers of northern Illinois is often present in relatively high concentrations. More than 300 wells in this area exceeded the U.S. EPA NPDWR for radium (Gilkeson et al. 1983). Radium-226 and radium-228 concentrations in groundwater ranged from 2.3 to 50.2 picocuries per liter (pCi/L); the U.S. EPA regulatory limit for the two radionuclides is 5.0 pCi/L (U.S. EPA 1991, 2009). The source of the radium in the aquifers is thought to be fine-grained materials such as the shale layers that form the bounds of the sandstone aquifers.

Conclusion

The quality of groundwater in Illinois changes with depth and location of the aquifer. Shallow surficial aquifers, such as glacially deposited sand and gravel or bedrock units near the land surface in the northern third of the state, contain relatively dilute groundwater compared with groundwater from deeper bedrock aquifers in the central and southern two-thirds of the state. Most of the aquifers in Illinois are made up of carbonate rock or contain considerable amounts of carbonate rock fragments, resulting in an almost ubiquitous problem with hard water. Many of the unconsolidated sand and gravel aquifers are deposited within fine-grained glacial tills and are confined aquifers that are under reducing conditions. The reducing conditions result in considerable amounts of dissolved iron and manganese and, in some cases, methane (drift gas). Most private wells in rural areas of Illinois use water softeners to extract iron and decrease the hardness of the groundwater. Groundwater pumped from wells in the central and southern parts of the state quickly become more saline as depths of wells increase and penetrate into the Pennsylvanian and deeper Paleozoic aquifers. Sodium and chloride concentrations tend to increase as depth increases.

Groundwater

Recharge and Groundwater Flow Within an Intracratonic Basin, Midwestern United States

by Samuel V. Panno[1], Zohreh Askari[2], Walton R. Kelly[3], Thomas M. Parris[4], and Keith C. Hackley[5]

Abstract

The conservative nature of chloride (Cl^-) in groundwater and the abundance of geochemical data from various sources (both published and unpublished) provided a means of developing, for the first time, a representation of the hydrogeology of the Illinois Basin on a basin-wide scale. The creation of Cl^- isocons superimposed on plan view maps of selected formations and on cross sections across the Illinois Basin yielded a conceptual model on a basin-wide scale of recharge into, groundwater flow within and through the Illinois Basin. The maps and cross sections reveal the infiltration and movement of freshwater into the basin and dilution of brines within various geologic strata occurring at basin margins and along geologic structures. Cross-formational movement of brines is also seen in the northern part of the basin. The maps and cross sections also show barriers to groundwater movement created by aquitards resulting in areas of apparent isolation/stagnation of concentrated brines within the basin. The distribution of Cl^- within the Illinois Basin suggests that the current chemical composition of groundwater and distribution of brines within the basin is dependent on five parameters: (1) presence of bedrock exposures along basin margins; (2) permeability of geologic strata and their distribution relative to one another; (3) presence or absence of major geologic structures; (4) intersection of major waterways with geologic structures, basin margins, and permeable bedrock exposures; and (5) isolation of brines within the basin due to aquitards, inhomogeneous permeability, and, in the case of the deepest part of the basin, brine density effects.

Introduction

The geochemical origin and the movement of brines within intracratonic sedimentary basins have been the subject of numerous studies for much of the latter half of the 20th century (e.g., Bethke et al. 1988; Hanor 1994). An understanding of these influences on the groundwater chemistry within the basin is important for water resource evaluation and natural resource exploitation. Moreover, reservoirs in intracratonic basins have been used for storage of natural gas, and the disposal of a variety of industrial, oil field, and other types of wastes (e.g., Bergstrom 1968). The magnitude of this disposal has increased considerably with injection of flow-back waters from unconventional oil and gas reservoirs and could increase with geologic carbon sequestration (Locke et al. 2013).

The Illinois Basin in the U.S. Midwest (Figure 1) is an anomaly among intracratonic basins because it contains no known halite-bearing evaporite sequences that could contribute to brine formation. The chemical composition and origin of brines in the Illinois Basin have been shown to be unique for Cambrian, Ordovician, Silurian–Devonian, and Mississippian–Pennsylvanian strata (Stueber et al. 1987; Walter et al. 1990; Stueber and Walter 1991, 1994; Panno et al. 2013). Groundwater movement within the Illinois Basin was studied by Cartwright (1970) using thermal anomalies in the southern half of Illinois and by Siegel (1989) using stable isotopes in northern Illinois. Both concluded that groundwater flows toward the center of the basin becoming more sluggish with depth, and discharges upward across confining units. Cartwright (1970) further suggested that upward movement of groundwater should occur along fractures associated with geologic structures.

Total dissolved solids (TDS) and chloride (Cl^-) concentrations of brines within intracratonic basins typically increase with depth (Domenico 1972). Within the Illinois Basin, Cl^- concentrations range from about 1 mg/L in shallow aquifers to over 200,000 mg/L for the deepest Paleozoic strata (Panno et al. 2013). Variable permeability and hydraulic gradients within Paleozoic

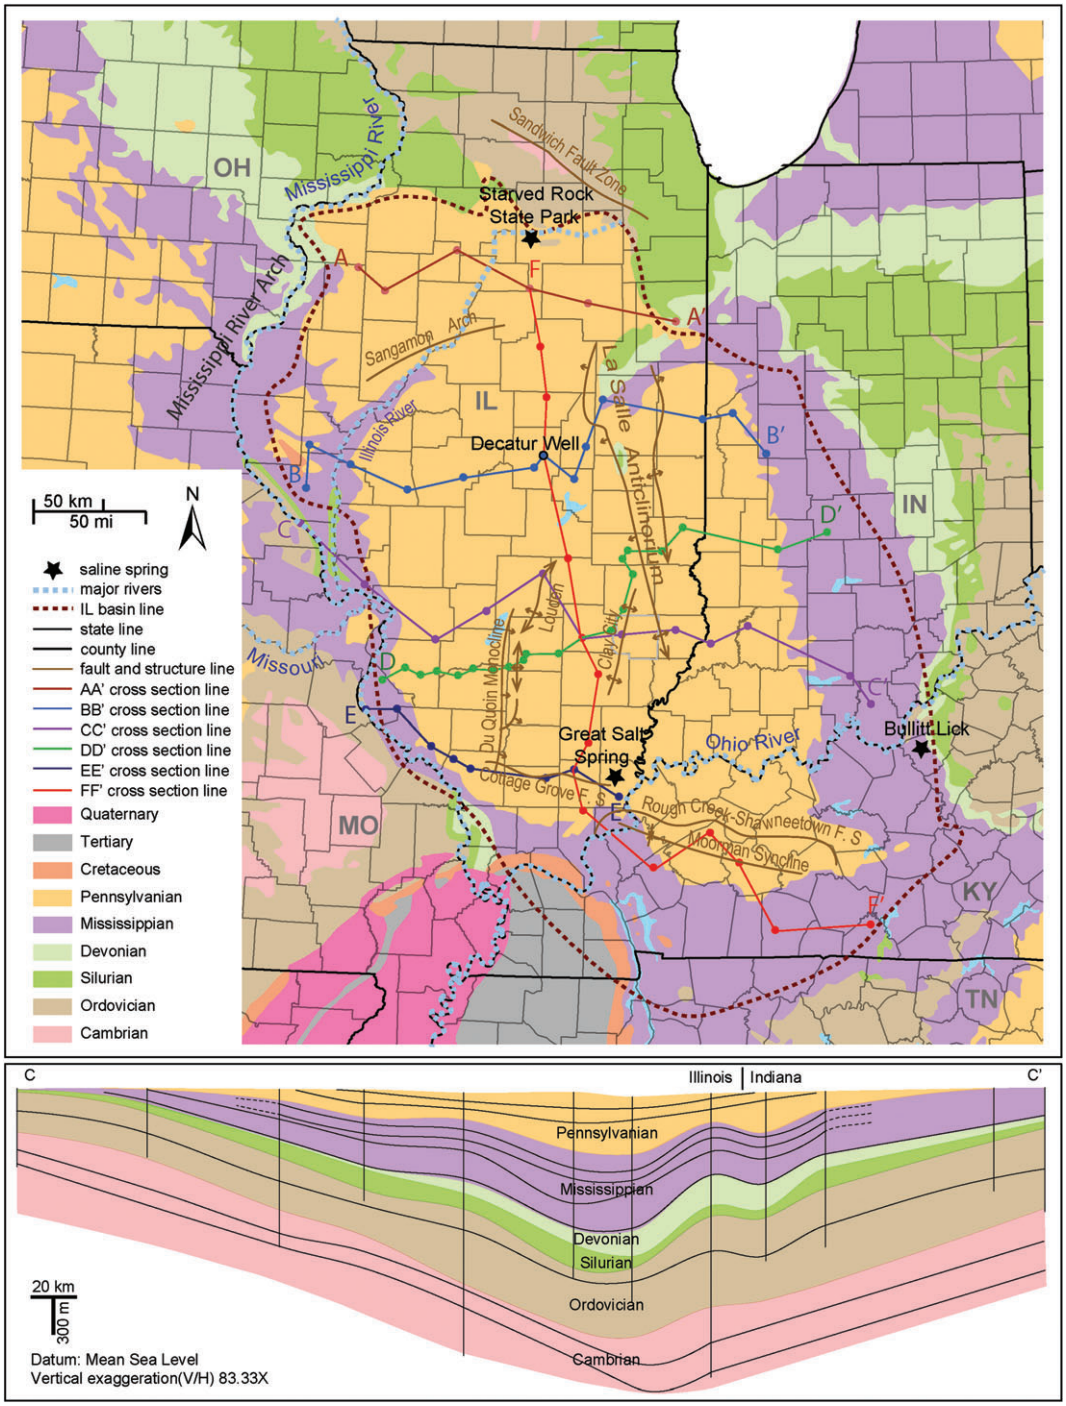

Figure 1. Cross section location map showing bedrock geology and structural features within the Illinois Basin. The bedrock geology was modified from Young (1992). East-west cross section C–C′ (at the bottom of the figure) shows the major strata, by age, of the basin.

strata, freshwater recharge at the margins of the basin and along zones of high permeability, and migration of brines through fractures associated with structural features all can cause departures from a monotonic increase in TDS and Cl^- concentrations with depth. Given the absence of halite-containing evaporites within the Illinois Basin, the conservative nature of Cl^- should allow it to act as a natural tracer revealing zones of recharge and preferential groundwater flow paths into, through, and out of the Illinois Basin (Figure 1). Chloride distribution should also indicate zones of low and high permeability, as well as zones of low flow, stagnation, or both. Mapping the distribution of Cl^- concentration in cross sections provides an efficient means of identifying dilution of basin brines within Paleozoic strata, mixing between aquifers, the isolating effects of aquitards, and potential flow paths along geologic structures (e.g., Panno et al. 1994).

Whereas, there has been a great deal of research on the Illinois Basin, previous studies have focused on selected formations and only portions of the basin. No basin-wide scale study has been done that would provide a comprehensive understanding of the hydrogeology of the Illinois Basin. Consequently, there is limited information regarding groundwater movement within and only speculation regarding discharge from the basin. The purpose of this investigation was to develop a conceptual model of recharge to, groundwater movement within, and discharge from the Illinois Basin on a basin-wide scale. To do this, we created plan-view maps of selected formations and detailed cross sections extending across the Illinois Basin and added Cl^- concentration data from oil and gas wells, municipal and private water wells, gas-injection wells, and published data. The Cl^- concentrations are represented with symbols and isocons on maps and cross sections that yield information regarding the current hydrogeologic state of the basin. This is important because recharge, groundwater movement within, and discharge from the basin can have a direct bearing on the transport of hydrocarbons, the feasibility of the sequestration of CO_2, and maintaining groundwater quality in those areas affected by basin brines and could provide insight into the source or flow paths of brines for the formation of Mississippi Valley-type ore deposits.

Geology and Hydrogeology of the Illinois Basin

The geology of the Illinois Basin is summarized from Collinson et al. (1988) and Kolata and Nelson (2010). Briefly, the Illinois Basin developed on Precambrian crystalline basement and now underlies most of the state of Illinois, western and southwestern Indiana, western Kentucky, and a portion of northwestern Tennessee (Figure 1). The basin is filled with Paleozoic marine sedimentary rocks ranging from Cambrian through Pennsylvanian that gently dip toward the center of the basin and extend to a depth of up to 9144 m along the Rough Creek Graben in western Kentucky (Goetz et al. 1992; Figure 1). The geometry, distribution, and interrelationships of the carbonate rocks, sandstones, and shales of the basin play a key role in recharge to and groundwater flow within the basin. Paleozoic sandstones and carbonate rocks whose groundwater is brackish to saline elsewhere in the basin, constitute productive aquifers in the northern-most part and along the eastern and western margins of the Illinois Basin, and shales constitute effective aquitards within the basin.

Cambrian and Ordovician aquifers are used extensively as a source of potable water in the northern third of Illinois (Larson and Herzog 2004). The Cambrian Mount Simon Sandstone is rarely used because it is only potable in the northern one-fifth of the state and has a moderately low permeability due to its well-cemented nature. Shale, siltstone, and dolomite of the overlying Eau Claire Formation act as a confining unit. The overlying Ironton-Galesville Sandstone is made up of a well-sorted and fine-grained sandstone, confined by overlying dolomites, shales and some sandstones, and provides a reliable potable water source. The Ordovician Glenwood-St. Peter Sandstone and overlying fractured and creviced Galena-Platteville Dolomite constitute major aquifers for northern Illinois. Because of their close proximity, these aquifers and are often combined into a single hydrogeologic unit referred to as the Cambrian-Ordovician aquifer. The St. Peter Sandstone is a relatively thick, well-sorted, fine-to medium-grained and loosely cemented sandstone of marine origin and belongs to the Ancell Group, which includes the overlying Glenwood Formation made up of sandstone, dolomite, and shale (Willman et al. 1975). In addition to being a prolific aquifer, the St. Peter Sandstone has long been known as a source of high-quality pure quartz sand in northern Illinois where it is exposed at the surface near, within, and north of Starved Rock State Park (Lamar 1928). The St. Peter Sandstone ranges from 1 to up to 275 m thick, averages between 30 and 100 m thick throughout the Illinois Basin (Willman et al. 1975), and is either exposed or shallowly buried in northern Illinois and at the northern margin of the basin. In this article, we focused on the water quality data from the St. Peter Sandstone. The Upper Ordovician Maquoketa Shale constitutes a confining unit between the underlying Cambrian-Ordovician aquifer and overlying Silurian strata.

Silurian strata consist of mostly fractured and creviced dolomite in the northern part of the basin and limestone in the southern part of the basin. Because of its karst nature, water yields range from small to very large. Devonian strata are predominantly limestone with some dolomite and shale; these strata are not present in the northern part of the basin because of erosion. These strata yield only small to moderate volumes of groundwater and are confined from the overlying Mississippian strata by the New Albany Shale (Larson and Herzog 2004).

Similarly, Mississippian strata are missing from the northern part of the basin because of erosion and are made up of limestone, with lesser amounts of dolomite, shale, siltstone, and sandstone. These strata are exposed on the margins of the Illinois Basin in western and southwestern Illinois and on the eastern margin in central Indiana, and are well known for their karst nature. Overlying Pennsylvanian strata are made up of predominantly shale with beds of sandstone, siltstone and limestone, and coal measures. These strata are thin to missing in the extreme northern part of the Illinois Basin due to erosion. Pennsylvanian strata typically constitute an aquitard, although some of its sandstone and limestone layers can yield small amounts of potable groundwater in the vicinity of outcrop areas. In much of Illinois and Indiana, Paleozoic rocks are capped by a thick layer of Pleistocene glacial drift that includes thick sand and gravel layers that are typically sandwiched between clay-rich tills. The sand and gravel deposits are used extensively in these states as freshwater aquifers; the Mahomet aquifer is a classic example of a glacial drift aquifer (e.g., Kempton et al. 1991).

Groundwater of the Illinois Basin ranges from extremely fresh $Ca\text{-}HCO_3^-$ type water at the near surface to concentrated mixed-cation-Cl^- brines at the deepest

17455584, 2018, 1, Downloaded from https://ngwa.onlinelibrary.wiley.com/doi/10.1111/gwat.12545 by TPS: NATIONAL GROUND WATER ASSOCIATION - NGWA - TPS ACCESS, Wiley Online Library on [28/09/2023]. part of the basin where Cl^- concentrations can be hundreds of grams per liter (Clayton et al. 1966). The salinity of the groundwater within the basin is typically stratified (Panno and Hackley 2010) with most shallow groundwater containing Na and Cl^- concentrations in sand and gravel aquifers between 1 and 15 mg/L for each ion (Panno et al. 2006). The sources of the Na-Ca-Cl-type brines of the Illinois Basin were studied by Stueber et al. (1987), Walter et al. (1990), Stueber and Walter (1991, 1994), Panno et al. (2013), and Labotka et al. (2015, 2016). These studies suggested, based on halide–halide and halide–cation ratios, and stable isotopes ($^{87}Sr/^{86}Sr$, δD and $\delta^{18}O$), that brines of the Illinois Basin originated as evaporated seawater and are composed of four geochemically distinct fluid regimes (Cambrian, Ordovician, Silurian–Devonian, and Mississippian–Pennsylvanian). Petroleum is found in Ordovician through Pennsylvanian rocks in the central and southern parts of the basin, and groundwater within these strata is highly saline. Because of the high salinity, few systematic hydrogeological studies have been conducted in these regions.

Methodology

Five east-west and one north-south cross section were constructed to illustrate the subsurface distribution of Cl^- in the Illinois Basin (Figure 1). The geologic data for the cross sections were compiled from geophysical logs from the Illinois State Geological Survey (ISGS) database and imported to GeoGraphix Discovery v5000 software (LMK Resources Inc., Houston, Texas) to create the cross sections and index maps. Boreholes that provided geologic data are represented as vertical lines in the cross sections; geologic structures were compiled from Nelson (1995).

The cross sections were populated with more than 600 Cl^- concentrations for groundwater samples from Cambrian through Pennsylvanian strata. Chloride concentration data are from Bartow et al. (1909), Meents (1952), Keller (1983), McIntosh et al. (2002), Panno et al. (2013), the Illinois State Water Survey (ISWS) Groundwater Quality Database (data available from ISWS on request), and the Kentucky Geological Survey (unpublished data). Well depths and screened intervals (or formation[s] from which groundwater was accessed) are available from these sources. Where brine data were acquired from oil fields, we used only samples collected before the onset of waterflood operations in oil fields to avoid possible contamination by mixing of brines or fresher waters from different stratigraphic units or dilution/contamination from drilling fluids. The Cl^- concentrations are represented with symbols, and by hand-contoured isocons, which represent locations of equal Cl^- concentrations. Adobe Illustrator CC 2015 (Adobe Systems, Incorporated, San Jose, California) was used for final editing and adding Cl^- concentration data for cross sections.

Chloride and TDS concentrations are highly correlated for these samples. The following equations developed by the authors of this article from data collected from fresh water aquifers, NaCl-enriched groundwater, and oil field brines in Illinois, were used to convert TDS concentrations to Cl^- concentrations (both in mg/L). Equations 1 and 2 were used for samples with TDS concentrations less than and greater than or equal to 5000 mg/L, respectively:

$$< 5000\,\text{mg/L} : Cl^- = 0.0022 \times TDS^{1.5328} \quad (R^2 = 0.895) \tag{1}$$

$$\geq 5000\,\text{mg/L} : \; Cl^- = 0.637 \times TDS \quad (R^2 = 0.989) \tag{2}$$

The relationship between TDS and Cl^- is supported by others working with a spectrum of water ranging from fresh to concentrated brines (Frape et al. 1984). For this article, the conversion was used for a direct comparison of Cl^- concentrations in cross sections and plan-view maps.

In addition to the cross sections, Cl^- isocon maps using simple interpolation were prepared for the Cambrian Mount Simon Sandstone (Figure 2) and the Ordovician St. Peter Sandstone (Figure 3). It is not clear, based on the sources of our data, whether the wells intersected both the Glenwood and St. Peter Sandstones or just the St. Peter Sandstone. Given their close proximity, and for our purposes we refer to the aquifer as the St. Peter Sandstone. The shaded counties contain one or more data points used in creating and contouring the St. Peter Sandstone map. A similar map, prepared for the Mount Simon Sandstone based on TDS data reported by Mehnert and Weberling, (2014; Figure 2), allowed comparison of Cl^- isocons with those of the St. Peter Sandstone (Figure 3). Not all cross sections and plan-view maps have the same density of data; consequently, some uncertainty/bias may be present in the interpretations. However, given the drilling activity in searching for fresh groundwater in the Illinois Basin, it is unlikely that formations containing potable groundwater would have gone undiscovered for more than a century.

Results and Discussion

Here we present, for the first time, plan view maps of selected formations and cross sections of the Illinois Basin containing Cl^- concentrations and isocons whose variability and patterns reflect the effects of freshwater recharge into and within a brine-dominated flow system. These patterns may be used as indicators of recharge, freshwater-brine mixing, cross-formational and flow-through movement of groundwater, and areas of brine stagnation within the basin.

Cambrian–Ordovician Aquifers

The aquifers of the Cambrian Mount Simon Sandstone, and the Ordovician Ironton-Galesville Sandstone, Glenwood-St. Peter Sandstone and Galena-Platteville Dolomite were referred to as the Cambrian-Ordovician Aquifer by Siegel and Mandel (1984) and Siegel (1989). However, they did not include the lowermost Mount

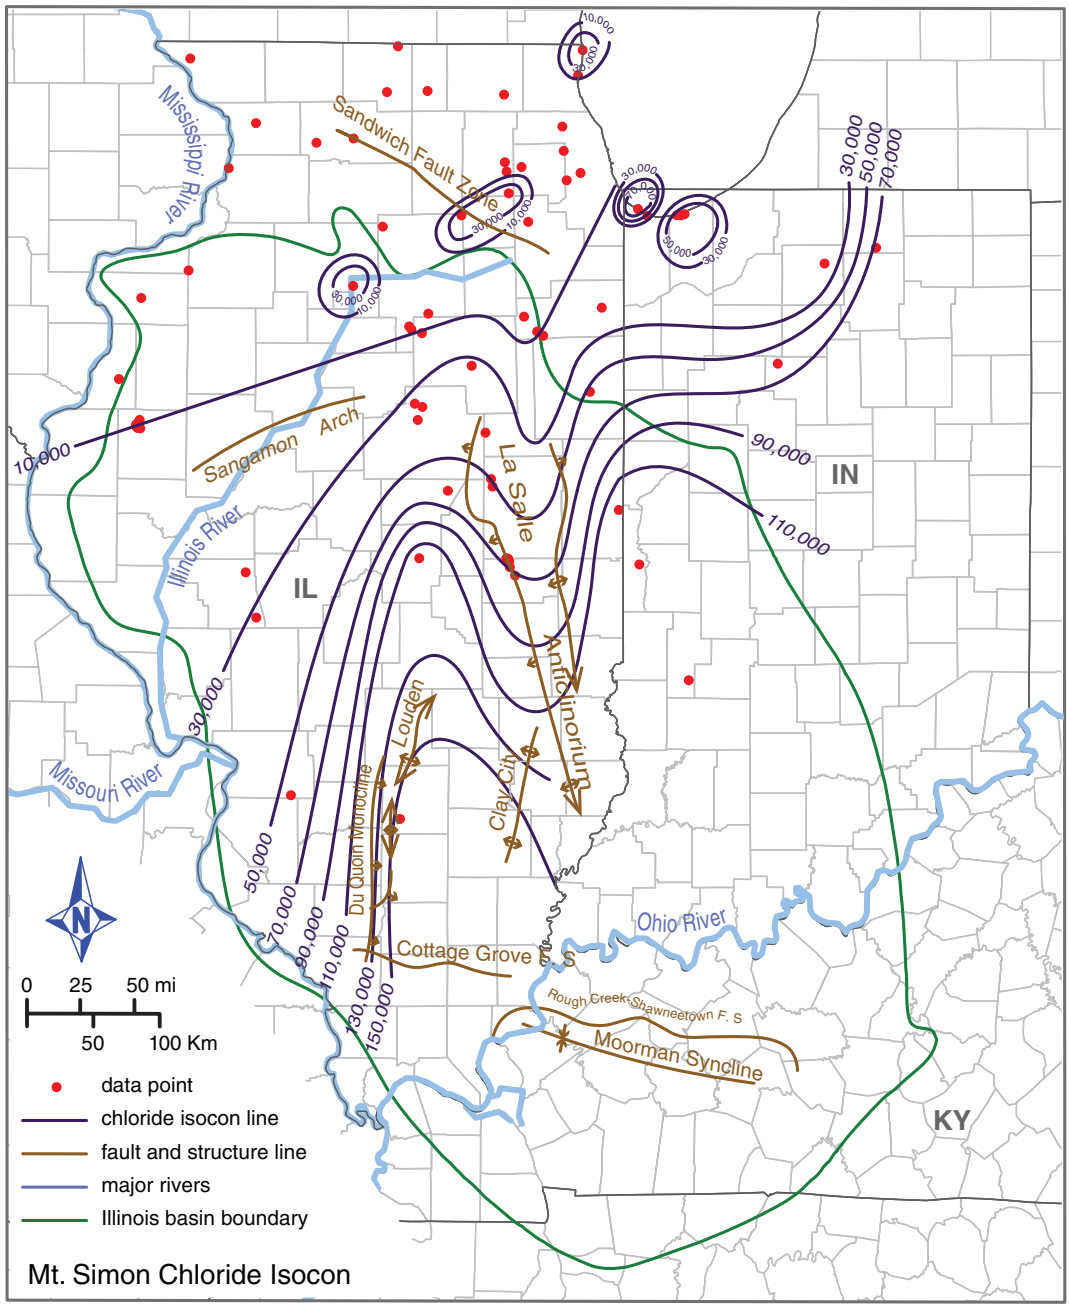

Figure 2. Chloride isocons in groundwater for the Mount Simon Sandstone. Water quality data (as TDS) are from Mehnert and Weberling (2014) and were converted to Cl^- concentrations using Equations 1 and 2.

Simon Formation because of the relatively high salinity of groundwater within this sandstone. These formations are used extensively in the northern third of Illinois for potable groundwater by municipalities and industries with wells that are often open to multiple aquifers (Larson and Herzog 2004).

Mount Simon Sandstone

The Mount Simon Sandstone represents the base of the Paleozoic sedimentary rock sequence that makes up the Illinois Basin. Unlike the St. Peter Sandstone, the Mount Simon Sandstone is rarely used as a freshwater resource because of its elevated TDS throughout the Illinois Basin. Mehnert and Weberling (2014) prepared a map of the distribution of TDS of brines within the Mount Simon Sandstone for much of the Illinois Basin. The data for this formation are from wells that are screened only within the Mount Simon Sandstone. We converted the TDS into Cl^- concentrations (for consistency within this investigation), contoured the data by hand, and added the Illinois River and pertinent geologic structures for interpretation purposes (Figure 2).

The Mount Simon isocon map shows preferential recharge from the northern, northwestern, and western boundaries of the Illinois Basin, and from north to south along the LaSalle Anticlinorium. The map also shows

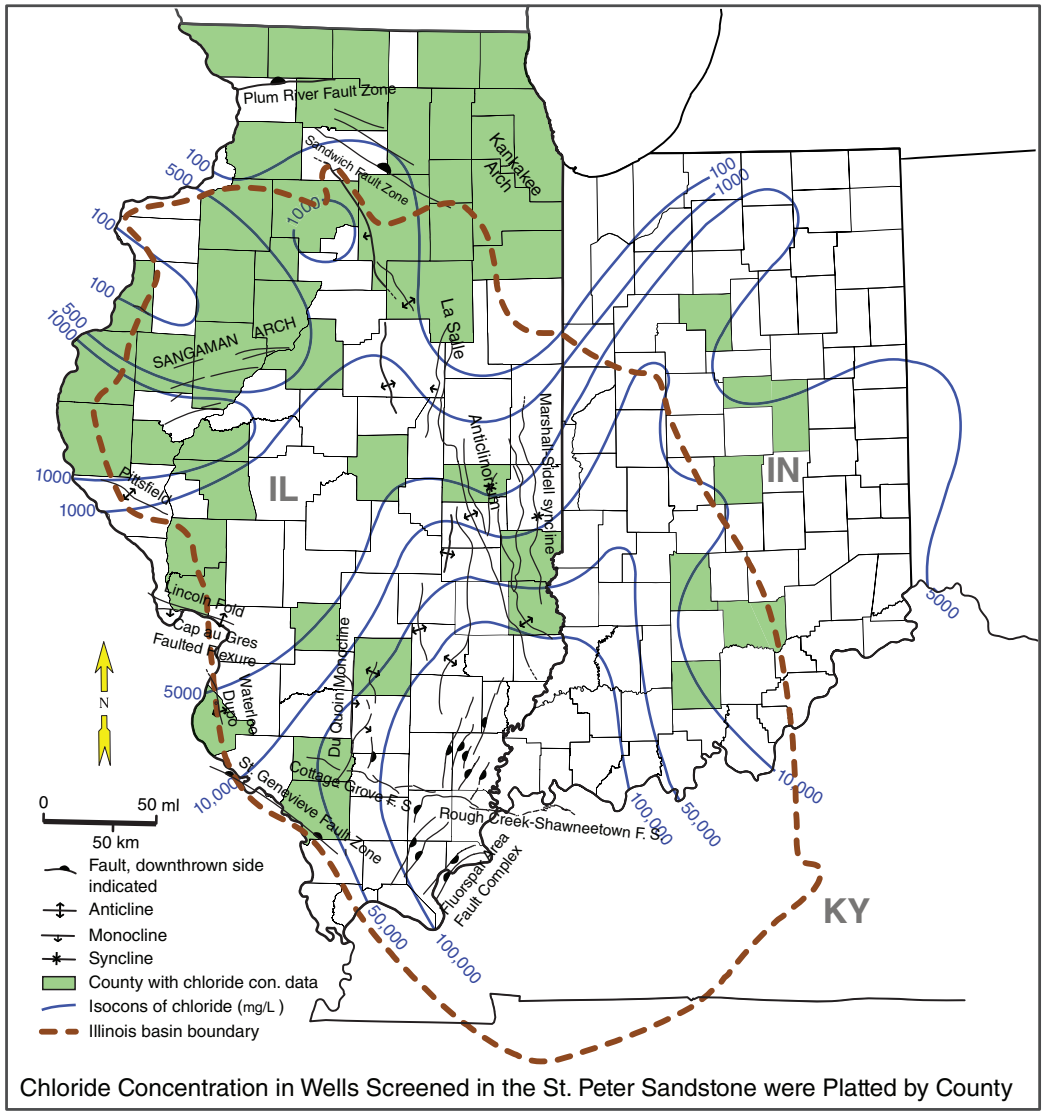

Figure 3. Chloride isocons in groundwater for the St. Peter Sandstone. Water quality data are from groundwater samples from wells screened in the St. Peter Sandstone. All concentrations are from published data and were plotted by county.

the presence of concentrated brines in the center of the basin in southern Illinois. Preferential recharge along the LaSalle Anticlinorium is of particular interest. The LaSalle Anticlinorium is a large geologic feature made up of numerous subparallel structures that collectively extend from southeastern Illinois to north-central Illinois and include anticlines, domes, monoclines, and synclines (Nelson 1995). Uplift of the LaSalle Anticlinorium occurred primarily during the late Paleozoic Era (Late Mississippian) but before the Pennsylvanian, and resumed after the Pennsylvanian. The anticlinorium was interpreted by Nelson (1995) to be the result of fault movement and displacement within the crystalline basement during the Late Paleozoic Era. Nelson (1995) suggests that the faults die out as they cut upward into the sedimentary rocks, and the structures of the LaSalle Anticlinorium become essentially drape folds. Recent seismic-reflection profiles by Kamp et al. (2016) suggest that the anticlinorium may be a fault system with strike-slip displacement.

The Mount Simon Cl^- isocon map (Figure 2) shows that salinity anomalies in the northern part of the basin and around the edge of Lake Michigan coincide with the Illinois River and the Sandwich Fault Zone. The saline anomaly farthest west and along the Illinois River (within and near Starved Rock State Park) contains nearly 40,000 mg/L of Cl^-. Just north and south of the anomaly, Cl^- concentrations are only 319 mg/L or less, and 7000 mg/L or less, respectively. This saline anomaly is coincident with the Illinois River and is probably associated with saline springs (Willman and Payne 1942) and relatively shallow saline wells (Panno, ISGS, unpublished data) of the Starved Rock State Park and surrounding area. The very low Cl/Br mass ratio of this groundwater (149 to 216; Panno, ISGS, unpublished data) suggests that the salinity originates from a mixture of brines from the underlying Cambrian and Ordovician strata, and perhaps crystalline basement brines (Table S1, Supporting Information). The upwelling of crystalline basement brines at

17455584, 2018, 1, Downloaded from https://ngwa.onlinelibrary.wiley.com/doi/10.1111/gwat.12545 by TPS: NATIONAL GROUND WATER ASSOCIATION - NGWA - TPS ACCESS, Wiley Online Library on [28/09/2023]. least into lower Cambrian strata is likely, based on work by Panno et al. (2013) and Labotka et al. (2015, 2016).

St. Peter Sandstone

The distribution of Cl^- on the isocon map for the St. Peter Sandstone suggests that recharge takes place along the northwestern (from Iowa) and central and northeastern parts (from northern Illinois) of the margins of the Illinois Basin (Figure 3). Recharge in these areas and groundwater flow into the Illinois Basin within this formation is consistent with groundwater flow directions for the northern and northeastern portion of the Illinois Basin identified by Siegel (1989) and Young (1992) based on predevelopment potentiometric surface data. Stable isotope data were determined from saline water samples from the St. Peter Sandstone collected from a well near Decatur, IL located about 160 km south of Starved Rock State Park (Figure 1), about 50 km south of Siegel's (1989) study area. The Decatur, Illinois, sample showed isotopically light (δD and δ^{18}O of −61.7 and −9.13, respectively) indicating a component of Pleistocene glacial meltwater (Panno and Fanta, unpublished report, Electronic Supplement). These data are consistent with those of samples collected from wells within the St. Peter Sandstone located in the vicinity of the Decatur well (Kelly, ISWS, and Panno, ISGS, unpublished data; Figure 1).

The Cl^- isocons also show that enhanced recharge is occurring horizontally along the LaSalle Anticlinorium (Figure 3) similar to that of the Mount Simon Sandstone (Figure 2). Dilation of fractures along faults and folds associated with the anticlinorium could provide preferential groundwater flow paths for groundwater (e.g., Bethke 1986). The Cl^- isocons of the St. Peter Sandstone (Figure 3) reveal that enhanced recharge is occurring horizontally along the LaSalle Anticlinorium (Figure 3) very similar to that of the Mount Simon Sandstone (Figure 2). We suggest, based on these isocon maps, that the LaSalle Anticlinorium provides structural controls on recharge and groundwater movement within the Illinois Basin and serves as a preferential flow path from north to south probably along fractures and faults associated with the anticlinorium. Stueber and Walter (1994) noted that the δ^{18}O of brines from the Ordovician Galena Formation had a meteoric-water signature for only those samples collected along the LaSalle Anticlinorium. These data support the concept of its role as a zone of enhanced anisotropic permeability with greater and/or more rapid recharge and groundwater movement along this structure within at least Cambrian and Ordovician strata. This structure also has been identified as the location of thermal anomalies and saline springs (Cartwright 1970; Panno et al. 1994; Panno, ISGS, unpublished data) suggesting the anticlinorium is a zone of enhanced permeability throughout the entire Paleozoic sequence. In addition, the LaSalle Anticlinorium has been described by Bethke (1986) as a structure that may have "funneled" ore-forming solutions from the southern part of the Illinois Basin to the host rocks of the Upper Mississippi Valley ore district to the north (Figure 1) in post-Pennsylvanian time. Finally, whereas Devonian rocks are exposed in isolated locations along the LaSalle Anticlinorium, it is unlikely that recharge via these "windows" through the Pennsylvanian strata is responsible for the preferential flow patterns in the St. Peter Sandstone or the Mount Simon Sandstone.

Cross Sections of the Illinois Basin

Chloride isocons on the cross sections (Figures 4–8 and S1) reveal patterns of recharge, stratification, paths of preferential groundwater flow, zones of near stagnation, and flow directions within and through the basin. The isocons often reveal strong contrasts in groundwater Cl^- concentrations in adjacent stratigraphic units, which suggests areas with limited to negligible vertical mixing and near stagnant brines. Some of the cross sections also show the effects of the LaSalle Anticlinorium on enhanced recharge into the basin. In addition, the isocons show that the shales of the Pennsylvanian strata, where present, provide a low flow boundary for recharge into the underlying strata. The cross sections are discussed in detail further.

The northernmost part of the Illinois Basin is characterized by exposures of Cambrian and Ordovician strata. Consequently, these strata are more easily recharged and groundwater in this area contains the lowest concentrations of Cl^- in the Illinois Basin (Figure 4). As a result, some of the lowest Cl^- values (e.g., all values are below that of average seawater of 19,800 mg/L; Table S1) are found in this part of the basin. Here, the shallowest bedrock (Pennsylvanian strata) contains Cl^- concentrations that are typically less than 100 mg/L, and concentrations barely exceed 20,000 mg/L in the deeper, typically briny, Mount Simon Sandstone. The isocons of A–A′ (Figure 4) indicate recharge of low Cl^- water to all Paleozoic formations along the northernmost margins of the Illinois Basin where the Ordovician St. Peter Sandstone is exposed at and near Starved Rock State Park. The low Cl^- concentrations in this area are consistent with findings by Siegel (1989, 1991) and Panno et al. (2013), who showed, using groundwater chemistry and stable isotopes, that Pleistocene recharge extended into the Illinois Basin from the north and west. McIntosh et al. (2002) showed a similar recharge into Devonian and Mississippian strata from the east. As cross section A–A′ (Figure 4) shows evidence of several isolated/narrow plumes of groundwater with elevated Cl^- concentrations, it is likely that there is an upward hydraulic gradient where deeper, saline groundwater is welling up to the surface. The widespread saline anomaly within and in the vicinity of Starved Rock State Park (Willman and Payne 1942; Panno, ISGS, unpublished data) is coincident with these plumes. The sporadic occurrence of saline wells, springs, and plumes of saline groundwater in this area suggest the upward movement of saline groundwater along faults and fractures.

Farther south, freshwater recharge is evident along the western margin of the basin and along the LaSalle Anticlinorium where Pennsylvanian shale is thin to absent (Figure 5). The greatest recharge appears to have been to

17455584, 2018, 1, Downloaded from https://ngwa.onlinelibrary.wiley.com/doi/10.1111/gwat.12545 by TPS: NATIONAL GROUND WATER ASSOCIATION - NGWA - TPS ACCESS, Wiley Online Library on [28/09/2023]. Figure 4. Cross section A–A′ extending east-west across northern Illinois. The most dilute groundwater in the Illinois Basin is found in the northern part of the basin because of the shallowness or exposure of the formations in this area, or both. Recharge is apparent from dilution effects from the west and east, and an upward movement of brines near the center of the cross section in the vicinity of the Illinois River.

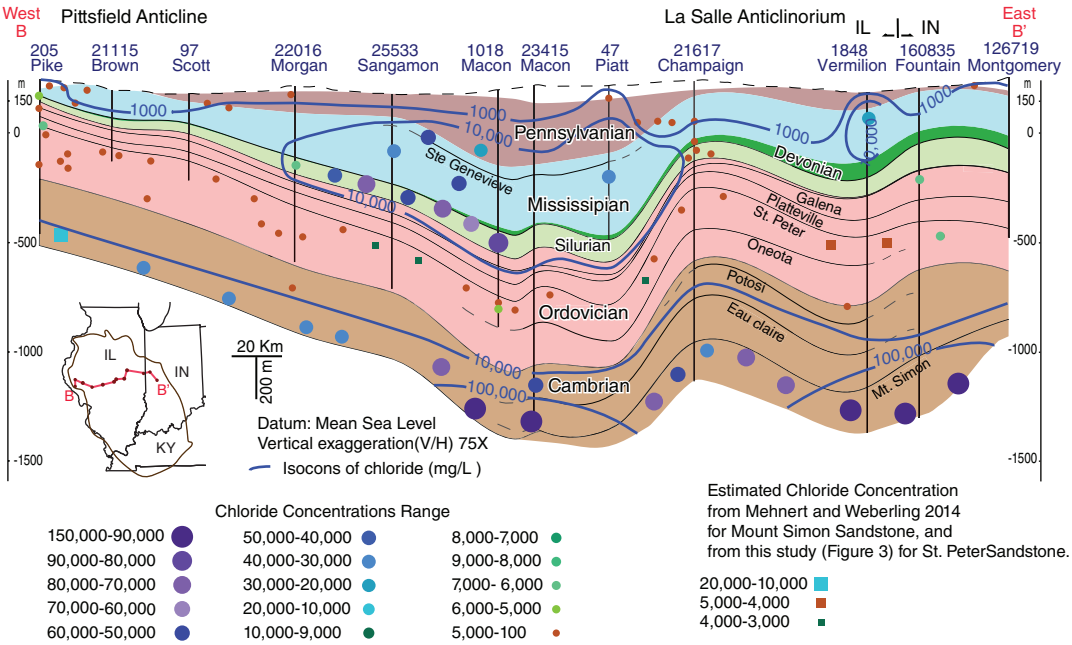

Figure 5. Cross section B–B′ extending east-west across central Illinois and central Indiana. The effects of freshwater recharge are apparent where Pennsylvanian strata are thin or absent and along the western and eastern margins of the basin and along the LaSalle Anticlinorium. Residual brines are present near the center of the cross section in Silurian–Devonian and Mississippian strata. The most concentrated brines are present near the center and far western part of the Cambrian strata.

Ordovician strata, primarily into the St. Peter Sandstone. Some of the lowest Cl^- concentrations are located along the LaSalle Anticlinorium. In the central region of cross section B–B′ (Figure 5), pools of dilute groundwater within the St. Peter Sandstone extend below pools of basin brines where Pennsylvanian strata are thickest. Greater concentrations of Cl^- lie within the Silurian, Mississippian, and Pennsylvanian strata above (many greater than 50,000 mg/L) and the Cambrian strata below (some greater than 100,000 mg/L). The greatest Cl^- concentrations are found within Cambrian strata on either side of the LaSalle Anticlinorium probably related to the effects of north to south fresh-water recharge within the Cambrian along the anticlinorium (Figure 2).

17455584, 2018, 1, Downloaded from https://ngwa.onlinelibrary.wiley.com/doi/10.1111/gwat.12545 by TPS: NATIONAL GROUND WATER ASSOCIATION - NGWA - TPS ACCESS, Wiley Online Library on [28/09/2023]. Figure 6. Cross section C–C′ extending east-west across southern Illinois and southern Indiana. The effects of freshwater recharge are most prominent at the western edge of the basin and in upper 200 m of Pennsylvanian strata. The most concentrated brines are present in the Cambrian Mount Simon Formation near the center of the basin.

Across the central portion of the Illinois Basin, cross section C–C′ reveals dilution of brines along zones of recharge at the western and, to a lesser extent, at the eastern edges of the basin where Pennsylvanian strata have been eroded (Figure 6). A relatively large plume of freshwater from the west has penetrated deep into the basin along Ordovician strata. The exposure of Ordovician, Silurian–Devonian, and Mississippian strata along the Mississippi River is a likely location for focused recharge, probably from glacial meltwaters during the Pleistocene Epoch. As the plume approaches the deepest part of the basin, it is bounded above by the Maquoketa Shale, below by the Eau Claire Formation, as well as above and below by brines with greater Cl^- concentrations. Dilution of brine within the Mount Simon Sandstone is also present from both the west and east, but to a lesser extent.

Freshwater recharge is indicated for much of the Pennsylvanian strata where Cl^- concentrations are less than 100 mg/L for the upper 50 to 100 m. Conversely, Cl^- concentrations in Mississippian through Silurian strata near the center of the basin exceed 50,000 mg/L where they are bounded above by thick Pennsylvanian strata and below by the New Albany Shale. Brines within these dominantly carbonate rock strata are diluted by freshwater recharge from both the west and east (Figure 6).

Just south of cross section C–C′, cross section D–D′ reveals similar conditions, but extends no deeper than Ordovician strata due to the paucity of geologic and geochemical data in this area (Figure 7). As with cross section C–C′, Cl^- concentrations suggest active recharge from the west and east where Pennsylvanian strata are thin or absent. Recharge from the east and west extends into Paleozoic strata from both sides of the basin. The eastern portion of the cross section within Indiana reveals greater recharge from the east within Silurian through Mississippian strata. This is supported by McIntosh et al. (2002) who found that the Silurian–Devonian strata provided a hydrologic pathway for recharging Pleistocene meltwater to depths up to 1 km across the eastern margin of the basin, and recharge from Mississippian strata, through underlying fractured New Albany Shale, and into Silurian–Devonian strata in the southeastern part of the Illinois Basin. Cross section D–D′ suggests recharge from the west is entering exposed Ordovician and Mississippian strata along the Mississippi River Arch (Figure 7).

Freshwater recharge is limited within the center of the basin where Pennsylvanian strata are thick (more than 600 m). Dilution of Cl^- concentrations of 1000 mg/L or less is consistent across Pennsylvanian strata to a depth of 60 to 120 m; however, limited data suggests that Cl^- concentrations rapidly increase, with depth, to greater than 10,000 mg/L within Pennsylvanian strata. Chloride concentrations within the center of cross section D–D′ (along the deepest part of the basin) reveal the presence of concentrated brines within all strata. Freshwater recharge from the north is apparent within the LaSalle Anticlinorium in the eastern half of the cross section and occurs within Upper Ordovician through Mississippian strata.

17455584, 2018, 1, Downloaded from https://ngwa.onlinelibrary.wiley.com/doi/10.1111/gwat.12545 by TPS: NATIONAL GROUND WATER ASSOCIATION - NGWA - TPS ACCESS, Wiley Online Library on [28/09/2023]. Figure 7. Cross section D–D′ extending east-west across southern Illinois and southern Indiana. Freshwater recharge affects the western and eastern margins of the basin, but not to the extent seen in cross sections farther north. Brines are also diluted along the LaSalle Anticlinorium (groundwater movement toward the reader). Again, the most concentrated brines are present in the Cambrian strata.

Farther south, cross section E–E′ does not extend beyond the Illinois-Indiana border and does not extend below Ordovician strata because of the paucity of geologic data (Figure S1). As with the cross sections C–C′ and D–D′, to the north, Cl^- concentrations show a plume of dilute water extending into the basin from the west. The absence of Pennsylvanian shale in the west has facilitated groundwater recharge where Ordovician through Mississippian strata are exposed along the Mississippi River Arch and in southwestern Illinois.

Constructed along the long axis of the Illinois Basin, cross section F–F′ reveals the effects of recharge, groundwater flow, and zones of stagnation within nearly the entire basin. It was used, in conjunction with the plan-view maps and east-west cross sections, as a conceptual model of recharge into, distribution of brines and brine-freshwater mixing within, and groundwater flow within and through the Illinois Basin. Based on the Cl^- concentrations and associated isocons, freshwater recharge is entering all Paleozoic formations including Cambrian strata in northern Illinois as seen in cross section A–A′ and B–B′ (Figures 4 and 5), and from the east and west (Figures 6, 7, and S1). Along the northern basin margin, Cl^- concentrations reveal a pool of dilute groundwater extending from Pennsylvanian strata at the surface downward into the Cambrian Mt. Simon Sandstone (Figure 8). The effects of freshwater recharge along the LaSalle Anticlinorium are seen in a short segment of the Mount Simon Formation about 200 km from the northern edge of the cross section. Here, Cl^- concentrations of Mount Simon brines are diluted below 100,000 mg/L. The overall distribution of isocons and Cl^- concentrations indicates groundwater flow from north to south through Ordovician strata with preferential recharge to and groundwater movement through the St. Peter Sandstone. The isocons also reveal a pattern of increasing Cl^- concentrations with distance from northern and western recharge areas about two thirds of the way to the southern end of the basin. Beyond the recharge zone to the north, thick Pennsylvanian strata protect brines within Silurian–Devonian and Mississippian strata from dilution by recharge; this is in contrast to the dilution of brines seen in these formations in the southern part of the basin where Pennsylvanian strata are thin to absent.

The separation of the 100,000 mg/L isocon within Cambrian strata in the northern third of cross section F–F′ is associated with dilution of brines along the LaSalle Anticlinorium. The deepest part of the basin contains the greatest concentration of Cl^- (and TDS) that extends from

17455584, 2018, 1, Downloaded from https://ngwa.onlinelibrary.wiley.com/doi/10.1111/gwat.12545 by TPS: NATIONAL GROUND WATER ASSOCIATION - NGWA - TPS ACCESS, Wiley Online Library on [28/09/2023]. Figure 8. Cross section F–F′ extending north-south from northern Illinois to southwestern Kentucky. This cross section reveals the effects of freshwater recharge in the northern part of the basin, where much of the Paleozoic strata are exposed or near surface. The greatest dilution is apparent in the St. Peter Sandstone aquifer, and the most concentrated brines are present in Cambrian strata and up into Ordovician strata at the center of the basin. Focused recharge deep into Ordovician strata is apparent in the vicinity of the Ohio River near the Rough Creek-Shawneetown Fault System, where Pennsylvania strata is thin to absent.

Cambrian strata up into Ordovician strata. Cartwright (1970) and Siegel (1989) suggested that discharge of concentrated brines in southern Illinois may be by upward migration across leaky confining units. The area in this cross section where the greatest Cl^- concentrations extend into Ordovician strata is immediately beneath the Great Salt Spring located near Equality, Illinois with saline springs on either side of the Saline River indicating points of discharge. However, the saline water of the Great Salt Spring appears to be characteristic of Pennsylvanian strata based on Cl/Br mass ratios and not derived from Cambrian and Ordovician strata (Panno, ISGS, unpublished data). The saline springs in this area may suggest an upward hydraulic gradient, perhaps with mixing of the brines prior to reaching the surface. In addition, it is possible that concentrated crystalline basement brines are upwelling into the original brines of the Cambrian Mount Simon Formation near the center of the basin as was observed in the Decatur well to the north by Panno et al. (2013) and Labotka et al. (2015, 2016).

The inferred pattern of north-to-south brine migration is interrupted in the southern part of the basin at or near the Ohio River (Figure 1). Here, recharge occurs where the Ohio River intersects the Rough Creek-Shawneetown Fault System. In this area, Pennsylvanian strata are thin or missing and Cl^- contours indicate the presence of a fresh-water plume, presumably from the Ohio River (perhaps including Pleistocene glacial meltwaters) recharging carbonate bedrock aquifers. Surface waters are probably recharging underlying aquifers as they flow through Mississippian and Silurian–Devonian strata, and into Ordovician strata. The Cl^- isocons further suggest that the freshwater recharge within Ordovician strata flows to the south-southeast into Kentucky toward the southern end of the Illinois Basin. The freshwater recharge is probably mixing with basin brines as it flows through Ordovician strata. We speculate that the resulting saline groundwater from the southeastern margin of the Illinois Basin may be discharging to the numerous salt licks found in northern and central Kentucky (e.g., Bullitt's Lick; Figure 1). These salt licks were used by Native Americans and frontiersmen as a source of salt and as hunting spots where herds of bison, deer, and elk would frequent the area and where bison "licked out deep trenches in the salt-impregnated clay" (McDowell 1956). Based on the Cl/Br mass ratio of Bullitt's Lick (189), one of many salt licks located just southeast of Louisville, Kentucky, the saline water is Cambrian-Ordovician in origin (Panno, ISGS, unpublished data), which is consistent with the inferred flow patterns and groundwater mixing within the Illinois Basin.

Conclusions

We develop, for the first time, a conceptual model of the hydrogeology of the Illinois Basin on a basin-wide scale. This model, based on Cl^- isocons on plan-view maps of selected formations and cross sections across the basin, reveal the infiltration and movement of freshwater recharge into the basin and dilution of brines within all of the Paleozoic strata, inter-formational interactions, and groundwater flow within and through the Illinois Basin. Pathways of greater permeability (e.g., highly conductive

17455584, 2018, 1, Downloaded from https://ngwa.onlinelibrary.wiley.com/doi/10.1111/gwat.12545 by TPS: NATIONAL GROUND WATER ASSOCIATION - NGWA - TPS ACCESS, Wiley Online Library on [28/09/2023]. lithologies and fractures associated with geologic structures) resulted in zones of dilute groundwater migrating through areas bounded on all sides by brines. Restrictions or barriers created by aquitards have created areas of near isolation/stagnation of concentrated brines within the basin. The Cl^- isocons suggest that the current chemical composition of groundwater and distribution of brines within the Illinois Basin is dependent on five parameters: (1) the presence of bedrock exposures along basin margins; (2) the permeability of geologic strata and their distribution relative to one another; (3) the presence or absence of major geologic structures; (4) the intersection of major rivers with geologic structures, basin margins, and permeable bedrock exposures; and (5) the isolation of brines within the basin resulting from aquitards, inhomogeneous permeability, and, in the case of the deepest part of the basin, brine density effects.

Cambrian Mount Simon Sandstone is bounded below by crystalline basement and above by the Eau Claire Formation and contains original brines (as determined by Labotka et al. 2016). Groundwater within the deepest part of the basin located in far southern Illinois may be under near stagnant conditions, or at least that part of the basin constitutes a zone of low flow within Cambrian and lower Ordovician strata. Based on previous work by McIntosh et al. (2002); Siegel (1989, 1991), and this study, groundwater flow through the basin appears to be from the northern, eastern, and western margins of the basin and dominantly through the Ordovician St. Peter Sandstone, and carbonate rocks of the Silurian–Devonian and Mississippian strata. Silurian–Devonian strata, consisting of mostly carbonate rocks, are bounded by the underlying Ordovician Maquoketa Shale and the overlying Devonian New Albany Shale. Similarly, the carbonate rocks of the Mississippian strata are bounded below and above by the New Albany Shale and the shale-dominated Pennsylvanian strata, respectively, where remnant brines remain. Our findings are consistent with Stueber and Walter (1994) who suggested that the remnant brines within the Silurian–Devonian and Mississippian strata are due to the bounding shale layers. We suggest that the inhomogeneous hydraulic characteristics of the Silurian–Devonian and Mississippian strata (i.e., dual porosity) probably help maintain brine compositions within these strata.

Pennsylvanian strata, where present, act as a confining unit to protect brines of the underlying Mississippian strata from freshwater recharge. Where Pennsylvanian strata are thin or absent, brines of the Mississippian strata have been diluted to various degrees, and, in some cases, to potable groundwater. Exposures of formations near basin margins allow recharge from meteoric water and, in the past, glacial meltwaters. Where the Mississippi River intersects bedrock exposures along the Mississippi River Arch (western margin of the Illinois Basin), enhanced recharge is likely responsible for freshwater plumes that extend deep into the basin from the west. The intersection of major rivers with major geologic structures is responsible for relatively rapid fresh-water recharge and movement of groundwater through the Illinois Basin. Evidence of Pleistocene meltwater recharge is observed along the LaSalle Anticlinorium where associated faults and fractures have created a zone of enhanced anisotropic permeability. Glacial meltwaters appear to have flushed out much of the brines within the St. Peter Sandstone within the northern part of the Illinois Basin during the Pleistocene based on data by Siegel (1989, 1991) and this study. Subsequently, deep-seated brines welled up along fault and fracture planes and created saline springs and the sporadic occurrence of saline wells near the Illinois River.

Chloride isocons within the Cambrian Mount Simon Sandstone and the St. Peter Sandstone reveal a marked dilution along the LaSalle Anticlinorium that extends into southern Illinois. This pattern of dilution also was observed in younger formations along the anticlinorium in the cross sections. In far southern Illinois, the intersection of the Rough Creek–Shawneetown Fault System (a major fault zone across the southern part of the basin) and the Ohio River has resulted in enhanced recharge deep into the Illinois Basin extending from surficial Mississippian strata, through Devonian and Silurian strata, and continuing to near the base of Ordovician strata. Within Ordovician strata, we speculate that the freshwater plume joins groundwater flowing through Ordovician strata via the St. Peter Sandstone and continues south into Kentucky where it discharges to numerous salt licks and saline springs near and south of Louisville and perhaps into northern Tennessee. These observations are consistent with an overall north to south flow of groundwater within the Illinois Basin and discharge along its southern boundaries.

Acknowledgments

The authors thank Chris Korose (ISGS) for his assistance with the geology/cross section location map. This paper was greatly improved through the comments and suggestions of Randy Locke, Dana Labotka (ISGS), Executive Editor Kristine Uhlman, and an anonymous reviewer, and editing by Susan Krusmark (ISGS). Re: Newton Power Plant Primary Ash Pond; IEPA ID # W0798070001-01

Dear Mr. LeCrone:

In accordance with Title 35 of the Illinois Administrative Code (35 I.A.C.) Section (§) 845.610(b)(3)(D), Illinois Power Generating Company (IPGC) is submitting groundwater monitoring data for the Quarter 2 2023 sampling event at the Newton Power Plant Primary Ash Pond, identified by Illinois Environmental Protection Agency (IEPA) ID No. W0798070001-01. This data is being submitted and placed in the facility's operating record as required by 35 I.A.C. § 845.800(d)(15) within 60 days of receiving final laboratory analytical data. Results were compared with the groundwater protection standards (GWPSs) described in 35 I.A.C. § 845.600 to determine exceedances of the GWPS.

The date of this submittal is considered to be the date that exceedances of the GWPS were detected. This notification of exceedances of the GWPSs in 35 I.A.C. § 845.600 will be placed in the facility's operating record within 30 days as required by 35 I.A.C. § 845.800(d)(16). As allowed in 35 I.A.C. § 845.650(e), an alternate source demonstration (ASD) will be evaluated for the detected exceedances of the GWPS and, if successfully completed, the ASD will be submitted to IEPA within 60 days of this transmittal.

Sincerely,

Phil Morris, PE
Senior Director, Environmental

35 I.A.C. § 845.610(B)(3)(D)
GROUNDWATER MONITORING DATA AND DETECTED EXCEEDANCES
QUARTER 2 2023
PRIMARY ASH POND, NEWTON POWER PLANT, NEWTON, ILLINOIS

August 7, 2023

Samples were collected between April 25 and April 28, 2023 and analyzed for the parameters listed in Title 35 of the Illinois Administrative Code (35 I.A.C) Section (§) 845.600(a), calcium, and turbidity. Final laboratory analytical data were received on June 8, 2023.

The monitoring well locations are included in **Figure 1**. **Attachment A** summarizes the groundwater elevation data for the Quarter 2 2023 sampling event. **Table 1** is a summary of the field parameters and analytical results. **Attachment B** contains the associated laboratory analytical reports and field data sheets for the Quarter 2 2023 sampling event.

Statistical procedures used to evaluate groundwater results are provided in Appendix A of the Groundwater Monitoring Plan[1] provided in the operating permit application. In accordance with 35 I.A.C. § 845.610(b)(3)(B), the Quarter 2 2023 groundwater monitoring data were evaluated for statistically significant levels (SSLs) over background levels for the constituents listed in 35 I.A.C. § 845.600. **Attachment C** shows the statistically derived values compared to background levels.

In accordance with 35 I.A.C. § 845.610(b)(3)(C), the statistically derived values identified as Statistical Results in **Table 2** were compared with the groundwater protection standards (GWPSs) described in 35 I.A.C. § 845.600 to determine exceedances of the GWPS, as shown in **Table 2**. The date of this submittal is considered to be the date that the exceedances of the GPWS were detected.

As allowed in 35 I.A.C. § 845.650(e), an alternate source demonstration (ASD) will be evaluated for the detected exceedances of the GWPS and, if successfully completed, the ASD will be submitted to Illinois Environmental Protection Agency (IEPA) within 60 days of this transmittal.

APW18	Compliance	E001	04/25/2023	pH (field)	7.8	SU

Notes:
C = Celsius
cm = centimeter
mg/L = milligrams per liter
mV = millivolts
NTU = Nephelometric Turbidity Units
pCi/L = picocuries per liter
SU = Standard Units
J = The result is an estimated quantity. The associated numerical value is the approximate concentration of the analyte in the sample.
J+ = The result is an estimated quantity, but the result may be biased high.
U = The analyte was analyzed for, but was not detected above the level of the adjusted detection limit or quantitation limit, as appropriate.

TABLE 2.
COMPARISON OF STATISTICAL RESULTS TO GWPS - QUARTER 2, 2023
845 QUARTERLY REPORT
NEWTON POWER PLANT
PRIMARY ASH POND
NEWTON, IL

Notes:
Determined: An exceedance was determined upon without resampling
HSU = hydrostratigraphic unit:

- UA = Uppermost Aquifer
- UD = Upper Drift

mg/L = milligrams per liter
ND = non-detect
pCi/L = picocuries per liter
SU = standard units
Sample Count = number of samples from Sampled Date Range used to calculate the Statistical Result
Statistical Calculation = method used to calculate the statistical result:

- All ND - Last = All results were below the reporting limit, and the last determined reporting limit is shown
- CB around T-S line = Confidence band around Thiel-Sen line
- CB around linear reg = Confidence band around linear regression
- CI around geomean = Confidence interval around the geometric mean
- CI around mean = Confidence interval around the mean
- CI around median = Confidence interval around the median
- Most recent sample = Result for the most recently collected sample used due to insufficient data

Statistical Result = calculated in accordance with Statistical Analysis Plan using constituent concentrations observed at monitoring well during all sampling events within the specified date range
For pH, the values presented are the lower / upper limits
GWPS = Groundwater Protection Standard
GWPS Source:

- Standard = standard specified in 35 I.A.C. § 845.600(a)(1)
- Background = background concentration (see cover page for additional information)

Terry Hanratty
Vistra - Newton
Newton Energy Center 6725 N. 500th St
Newton, IL 62448

Dear Terry Hanratty:

Please find enclosed the analytical results for the sample(s) the laboratory received. All testing is performed according to our current TNI accreditations unless otherwise noted. This report cannot be reproduced, except in full, without the written permission of Pace Analytical Services, LLC.

If you have any questions regarding your report, please contact your project manager. Quality and timely data is of the utmost importance to us.

Pace Analytical Services appreciates the opportunity to provide you with analytical expertise. We are always trying to improve our customer service and we welcome you to contact the General Manager, Lisa Grant, with any feedback you have about your experience with our laboratory at 309-683-1764 or lisa.grant@pacelabs.com.

Sincerely,

Gail Schindler
Project Manager

SAMPLE RECEIPT CHECK LIST

Items not applicable will be marked as in compliance

Work Order GD04461

YES	Samples received within temperature compliance when applicable
YES	COC present upon sample receipt
YES	COC completed & legible
YES	Sampler name & signature present
YES	Unique sample IDs assigned
YES	Sample collection location recorded
YES	Date & time collected recorded on COC
YES	Relinquished by client signature on COC
YES	COC & labels match
YES	Sample labels are legible
YES	Appropriate bottle(s) received
YES	Sufficient sample volume received
YES	Sample containers received undamaged
YES	Zero headspace, <6 mm present in VOA vials
NO	Trip blank(s) received
YES	All non-field analyses received within holding times
YES	Short hold time analysis
YES	Current PDC COC submitted
NO	Case narrative provided

NOTES

Specifications regarding method revisions, method modifications, and calculations used for analysis are available upon request. Please contact your project manager.

* Not a TNI accredited analyte

Certifications

CHI - McHenry, IL - 4314-A W. Crystal Lake Road, McHenry, IL 60050
TNI Accreditation for Drinking Water and Wastewater Fields of Testing through IL EPA Accreditation No. 100279
Illinois Department of Public Health Bacterial Analysis in Drinking Water Approved Laboratory Registry No. 17556

PIA - Peoria, IL - 2231 W. Altorfer Drive, Peoria, IL 61615
TNI Accreditation for Drinking Water, Wastewater, Solid and Hazardous Material Fields of Testing through IL EPA Accreditation No. 100230
Illinois Department of Public Health Bacterial Analysis in Drinking Water Approved Laboratory Registry No. 17553
Drinking Water Certifications/Accreditations: Iowa (240); Kansas (E-10338); Missouri (870)
Wastewater Certifications/Accreditations: Arkansas (88-0677); Iowa (240); Kansas (E-10338)
Solid and Hazardous Material Certifications/Accreditations: Arkansas (88-0677); Iowa (240); Kansas (E-10338)

SPMO - Springfield, MO - 1805 W Sunset Street, Springfield, MO 65807
USEPA DMR-QA Program

STL - Hazelwood, MO - 944 Anglum Rd, Hazelwood, MO 63042
TNI Accreditation for Wastewater, Solid and Hazardous Material Fields of Testing through KS KDHE Certification No. E-10389
TNI Accreditation for Wastewater, Solid and Hazardous Material Fields of Testing through IL EPA Accreditation No. - 200080
Illinois Department of Public Health Bacterial Analysis in Drinking Water Approved Laboratory, Registry No. 171050
Missouri Department of Natural Resources - Certificate of Approval for Microbiological Laboratory Service - No. 1050

Qualifiers

H	Test performed after the expiration of the appropriate regulatory/advisory maximum allowable hold time.
M	Analyte failed to meet the required acceptance criteria for duplicate analysis.
Q4	The matrix spike recovery result is unusable since the analyte concentration in the sample is greater than four times the spike level. The associated blank spike was acceptable.

Terry Hanratty
Vistra - Newton
Newton Energy Center 6725 N. 500th St
Newton, IL 62448

Dear Terry Hanratty:

Please find enclosed the analytical results for the sample(s) the laboratory received. All testing is performed according to our current TNI accreditations unless otherwise noted. This report cannot be reproduced, except in full, without the written permission of Pace Analytical Services, LLC.

If you have any questions regarding your report, please contact your project manager. Quality and timely data is of the utmost importance to us.

Pace Analytical Services appreciates the opportunity to provide you with analytical expertise. We are always trying to improve our customer service and we welcome you to contact the General Manager, Lisa Grant, with any feedback you have about your experience with our laboratory at 309-683-1764 or lisa.grant@pacelabs.com.

Sincerely,

Gail Schindler

SAMPLE RECEIPT CHECK LIST

Items not applicable will be marked as in compliance

Work Order GD04486

YES	Samples received within temperature compliance when applicable
YES	COC present upon sample receipt
YES	COC completed & legible
YES	Sampler name & signature present
YES	Unique sample IDs assigned
YES	Sample collection location recorded
YES	Date & time collected recorded on COC
YES	Relinquished by client signature on COC
YES	COC & labels match
YES	Sample labels are legible
YES	Appropriate bottle(s) received
YES	Sufficient sample volume received
YES	Sample containers received undamaged
NO	Zero headspace, <6 mm present in VOA vials
NO	Trip blank(s) received
YES	All non-field analyses received within holding times
NO	Short hold time analysis
YES	Current PDC COC submitted
NO	Case narrative provided

ANALYTICAL REPORT

June 01, 2023

Pace IR - Peoria, IL

Sample Delivery Group:	L1611854
Samples Received:	05/03/2023
Project Number:	GD04486
Description:	Vistra-Newton
Site:	001
Report To:	Gail Schindler 2231 W. Altorfer Drive Peoria, IL 61615

Entire Report Reviewed By:

Haley Torrence
Project Manager

Results relate only to the items tested or calibrated and are reported as rounded values. This test report shall not be reproduced, except in full, without written approval of the laboratory. Where applicable, sampling conducted by Pace Analytical National is performed per guidance provided in laboratory standard operating procedures ENV-SOP-MTJL-0067 and ENV-SOP-MTJL-0068. Where sampling conducted by the customer, results relate to the accuracy of the information provided, and as the samples are received.

CASE NARRATIVE

All sample aliquots were received at the correct temperature, in the proper containers, with the appropriate preservatives, and within method specified holding times, unless qualified or notated within the report. Where applicable, all MDL (LOD) and RDL (LOQ) values reported for environmental samples have been corrected for the dilution factor used in the analysis. All radiochemical sample results for solids are reported on a dry weight basis with the exception of tritium, carbon-14 and radon, unless wet weight was requested by the client. All Method and Batch Quality Control are within established criteria except where addressed in this case narrative, a non-conformance form or properly qualified within the sample results. By my digital signature below, I affirm to the best of my knowledge, all problems/anomalies observed by the laboratory as having the potential to affect the quality of the data have been identified by the laboratory, and no information or data have been knowingly withheld that would affect the quality of the data.

GLOSSARY OF TERMS

Guide to Reading and Understanding Your Laboratory Report

The information below is designed to better explain the various terms used in your report of analytical results from the Laboratory. This is not intended as a comprehensive explanation, and if you have additional questions please contact your project representative.

Results Disclaimer - Information that may be provided by the customer, and contained within this report, include Permit Limits, Project Name, Sample ID, Sample Matrix, Sample Preservation, Field Blanks, Field Spikes, Field Duplicates, On-Site Data, Sampling Collection Dates/Times, and Sampling Location. Results relate to the accuracy of this information provided, and as the samples are received.

Abbreviations and Definitions

MDA	Minimum Detectable Activity.
Rec.	Recovery.
RER	Replicate Error Ratio.
RPD	Relative Percent Difference.
SDG	Sample Delivery Group.
(T)	Tracer - A radioisotope of known concentration added to a solution of chemically equivalent radioisotopes at a known concentration to assist in monitoring the yield of the chemical separation.
Analyte	The name of the particular compound or analysis performed. Some Analyses and Methods will have multiple analytes reported.
Dilution	If the sample matrix contains an interfering material, the sample preparation volume or weight values differ from the standard, or if concentrations of analytes in the sample are higher than the highest limit of concentration that the laboratory can accurately report, the sample may be diluted for analysis. If a value different than 1 is used in this field, the result reported has already been corrected for this factor.
Limits	These are the target % recovery ranges or % difference value that the laboratory has historically determined as normal for the method and analyte being reported. Successful QC Sample analysis will target all analytes recovered or duplicated within these ranges.
Original Sample	The non-spiked sample in the prep batch used to determine the Relative Percent Difference (RPD) from a quality control sample. The Original Sample may not be included within the reported SDG.
Qualifier	This column provides a letter and/or number designation that corresponds to additional information concerning the result reported. If a Qualifier is present, a definition per Qualifier is provided within the Glossary and Definitions page and potentially a discussion of possible implications of the Qualifier in the Case Narrative if applicable.
Result	The actual analytical final result (corrected for any sample specific characteristics) reported for your sample. If there was no measurable result returned for a specific analyte, the result in this column may state “ND” (Not Detected) or “BDL” (Below Detectable Levels). The information in the results column should always be accompanied by either an MDL (Method Detection Limit) or RDL (Reporting Detection Limit) that defines the lowest value that the laboratory could detect or report for this analyte.
Uncertainty (Radiochemistry)	Confidence level of 2 sigma.
Case Narrative (Cn)	A brief discussion about the included sample results, including a discussion of any non-conformances to protocol observed either at sample receipt by the laboratory from the field or during the analytical process. If present, there will be a section in the Case Narrative to discuss the meaning of any data qualifiers used in the report.
Quality Control Summary (Qc)	This section of the report includes the results of the laboratory quality control analyses required by procedure or analytical methods to assist in evaluating the validity of the results reported for your samples. These analyses are not being performed on your samples typically, but on laboratory generated material.
Sample Chain of Custody (Sc)	This is the document created in the field when your samples were initially collected. This is used to verify the time and date of collection, the person collecting the samples, and the analyses that the laboratory is requested to perform. This chain of custody also documents all persons (excluding commercial shippers) that have had control or possession of the samples from the time of collection until delivery to the laboratory for analysis.
Sample Results (Sr)	This section of your report will provide the results of all testing performed on your samples. These results are provided by sample ID and are separated by the analyses performed on each sample. The header line of each analysis section for each sample will provide the name and method number for the analysis reported.
Sample Summary (Ss)	This section of the Analytical Report defines the specific analyses performed for each sample ID, including the dates and times of preparation and/or analysis.

Qualifier	Description
J	The identification of the analyte is acceptable; the reported value is an estimate.
U	Below Detectable Limits: Indicates that the analyte was not detected.

CASE NARRATIVE

All sample aliquots were received at the correct temperature, in the proper containers, with the appropriate preservatives, and within method specified holding times, unless qualified or notated within the report. Where applicable, all MDL (LOD) and RDL (LOQ) values reported for environmental samples have been corrected for the dilution factor used in the analysis. All radiochemical sample results for solids are reported on a dry weight basis with the exception of tritium, carbon-14 and radon, unless wet weight was requested by the client. All Method and Batch Quality Control are within established criteria except where addressed in this case narrative, a non-conformance form or properly qualified within the sample results. By my digital signature below, I affirm to the best of my knowledge, all problems/anomalies observed by the laboratory as having the potential to affect the quality of the data have been identified by the laboratory, and no information or data have been knowingly withheld that would affect the quality of the data.

GLOSSARY OF TERMS

Guide to Reading and Understanding Your Laboratory Report

The information below is designed to better explain the various terms used in your report of analytical results from the Laboratory. This is not intended as a comprehensive explanation, and if you have additional questions please contact your project representative.

Results Disclaimer - Information that may be provided by the customer, and contained within this report, include Permit Limits, Project Name, Sample ID, Sample Matrix, Sample Preservation, Field Blanks, Field Spikes, Field Duplicates, On-Site Data, Sampling Collection Dates/Times, and Sampling Location. Results relate to the accuracy of this information provided, and as the samples are received.

Abbreviations and Definitions

MDA	Minimum Detectable Activity.
Rec.	Recovery.
RER	Replicate Error Ratio.
RPD	Relative Percent Difference.
SDG	Sample Delivery Group.
(T)	Tracer - A radioisotope of known concentration added to a solution of chemically equivalent radioisotopes at a known concentration to assist in monitoring the yield of the chemical separation.
Analyte	The name of the particular compound or analysis performed. Some Analyses and Methods will have multiple analytes reported.
Dilution	If the sample matrix contains an interfering material, the sample preparation volume or weight values differ from the standard, or if concentrations of analytes in the sample are higher than the highest limit of concentration that the laboratory can accurately report, the sample may be diluted for analysis. If a value different than 1 is used in this field, the result reported has already been corrected for this factor.
Limits	These are the target % recovery ranges or % difference value that the laboratory has historically determined as normal for the method and analyte being reported. Successful QC Sample analysis will target all analytes recovered or duplicated within these ranges.
Original Sample	The non-spiked sample in the prep batch used to determine the Relative Percent Difference (RPD) from a quality control sample. The Original Sample may not be included within the reported SDG.
Qualifier	This column provides a letter and/or number designation that corresponds to additional information concerning the result reported. If a Qualifier is present, a definition per Qualifier is provided within the Glossary and Definitions page and potentially a discussion of possible implications of the Qualifier in the Case Narrative if applicable.
Result	The actual analytical final result (corrected for any sample specific characteristics) reported for your sample. If there was no measurable result returned for a specific analyte, the result in this column may state “ND” (Not Detected) or “BDL” (Below Detectable Levels). The information in the results column should always be accompanied by either an MDL (Method Detection Limit) or RDL (Reporting Detection Limit) that defines the lowest value that the laboratory could detect or report for this analyte.
Uncertainty (Radiochemistry)	Confidence level of 2 sigma.
Case Narrative (Cn)	A brief discussion about the included sample results, including a discussion of any non-conformances to protocol observed either at sample receipt by the laboratory from the field or during the analytical process. If present, there will be a section in the Case Narrative to discuss the meaning of any data qualifiers used in the report.
Quality Control Summary (Qc)	This section of the report includes the results of the laboratory quality control analyses required by procedure or analytical methods to assist in evaluating the validity of the results reported for your samples. These analyses are not being performed on your samples typically, but on laboratory generated material.
Sample Chain of Custody (Sc)	This is the document created in the field when your samples were initially collected. This is used to verify the time and date of collection, the person collecting the samples, and the analyses that the laboratory is requested to perform. This chain of custody also documents all persons (excluding commercial shippers) that have had control or possession of the samples from the time of collection until delivery to the laboratory for analysis.
Sample Results (Sr)	This section of your report will provide the results of all testing performed on your samples. These results are provided by sample ID and are separated by the analyses performed on each sample. The header line of each analysis section for each sample will provide the name and method number for the analysis reported.
Sample Summary (Ss)	This section of the Analytical Report defines the specific analyses performed for each sample ID, including the dates and times of preparation and/or analysis.

Qualifier	Description
C1	Tracer recovery limits have been exceeded; values are outside upper control limits.
J	The identification of the analyte is acceptable; the reported value is an estimate.
J6	The sample matrix interfered with the ability to make any accurate determination; spike value is low.
U	Below Detectable Limits: Indicates that the analyte was not detected.

CASE NARRATIVE

All sample aliquots were received at the correct temperature, in the proper containers, with the appropriate preservatives, and within method specified holding times, unless qualified or notated within the report. Where applicable, all MDL (LOD) and RDL (LOQ) values reported for environmental samples have been corrected for the dilution factor used in the analysis. All radiochemical sample results for solids are reported on a dry weight basis with the exception of tritium, carbon-14 and radon, unless wet weight was requested by the client. All Method and Batch Quality Control are within established criteria except where addressed in this case narrative, a non-conformance form or properly qualified within the sample results. By my digital signature below, I affirm to the best of my knowledge, all problems/anomalies observed by the laboratory as having the potential to affect the quality of the data have been identified by the laboratory, and no information or data have been knowingly withheld that would affect the quality of the data.

Haley Torrence

GLOSSARY OF TERMS

Guide to Reading and Understanding Your Laboratory Report

The information below is designed to better explain the various terms used in your report of analytical results from the Laboratory. This is not intended as a comprehensive explanation, and if you have additional questions please contact your project representative.

Results Disclaimer - Information that may be provided by the customer, and contained within this report, include Permit Limits, Project Name, Sample ID, Sample Matrix, Sample Preservation, Field Blanks, Field Spikes, Field Duplicates, On-Site Data, Sampling Collection Dates/Times, and Sampling Location. Results relate to the accuracy of this information provided, and as the samples are received.

Abbreviations and Definitions

MDA	Minimum Detectable Activity.
Rec.	Recovery.
RER	Replicate Error Ratio.
RPD	Relative Percent Difference.
SDG	Sample Delivery Group.
(T)	Tracer - A radioisotope of known concentration added to a solution of chemically equivalent radioisotopes at a known concentration to assist in monitoring the yield of the chemical separation.
Analyte	The name of the particular compound or analysis performed. Some Analyses and Methods will have multiple analytes reported.
Dilution	If the sample matrix contains an interfering material, the sample preparation volume or weight values differ from the standard, or if concentrations of analytes in the sample are higher than the highest limit of concentration that the laboratory can accurately report, the sample may be diluted for analysis. If a value different than 1 is used in this field, the result reported has already been corrected for this factor.
Limits	These are the target % recovery ranges or % difference value that the laboratory has historically determined as normal for the method and analyte being reported. Successful QC Sample analysis will target all analytes recovered or duplicated within these ranges.
Original Sample	The non-spiked sample in the prep batch used to determine the Relative Percent Difference (RPD) from a quality control sample. The Original Sample may not be included within the reported SDG.
Qualifier	This column provides a letter and/or number designation that corresponds to additional information concerning the result reported. If a Qualifier is present, a definition per Qualifier is provided within the Glossary and Definitions page and potentially a discussion of possible implications of the Qualifier in the Case Narrative if applicable.
Result	The actual analytical final result (corrected for any sample specific characteristics) reported for your sample. If there was no measurable result returned for a specific analyte, the result in this column may state “ND” (Not Detected) or “BDL” (Below Detectable Levels). The information in the results column should always be accompanied by either an MDL (Method Detection Limit) or RDL (Reporting Detection Limit) that defines the lowest value that the laboratory could detect or report for this analyte.
Uncertainty (Radiochemistry)	Confidence level of 2 sigma.
Case Narrative (Cn)	A brief discussion about the included sample results, including a discussion of any non-conformances to protocol observed either at sample receipt by the laboratory from the field or during the analytical process. If present, there will be a section in the Case Narrative to discuss the meaning of any data qualifiers used in the report.
Quality Control Summary (Qc)	This section of the report includes the results of the laboratory quality control analyses required by procedure or analytical methods to assist in evaluating the validity of the results reported for your samples. These analyses are not being performed on your samples typically, but on laboratory generated material.
Sample Chain of Custody (Sc)	This is the document created in the field when your samples were initially collected. This is used to verify the time and date of collection, the person collecting the samples, and the analyses that the laboratory is requested to perform. This chain of custody also documents all persons (excluding commercial shippers) that have had control or possession of the samples from the time of collection until delivery to the laboratory for analysis.
Sample Results (Sr)	This section of your report will provide the results of all testing performed on your samples. These results are provided by sample ID and are separated by the analyses performed on each sample. The header line of each analysis section for each sample will provide the name and method number for the analysis reported.
Sample Summary (Ss)	This section of the Analytical Report defines the specific analyses performed for each sample ID, including the dates and times of preparation and/or analysis.

Qualifier	Description
J	The identification of the analyte is acceptable; the reported value is an estimate.
U	Below Detectable Limits: Indicates that the analyte was not detected.

Results relate only to the items tested or calibrated and are reported as rounded values. This test report shall not be reproduced, except in full, without written approval of the laboratory. Where applicable, sampling conducted by Pace Analytical National is performed per guidance provided in laboratory standard operating procedures ENV-SOP-MTJL-0067 and ENV-SOP-MTJL-0068. Where sampling conducted by the customer, results relate to the accuracy of the information provided, and as the samples are received.

CASE NARRATIVE

All sample aliquots were received at the correct temperature, in the proper containers, with the appropriate preservatives, and within method specified holding times, unless qualified or notated within the report. Where applicable, all MDL (LOD) and RDL (LOQ) values reported for environmental samples have been corrected for the dilution factor used in the analysis. All radiochemical sample results for solids are reported on a dry weight basis with the exception of tritium, carbon-14 and radon, unless wet weight was requested by the client. All Method and Batch Quality Control are within established criteria except where addressed in this case narrative, a non-conformance form or properly qualified within the sample results. By my digital signature below, I affirm to the best of my knowledge, all problems/anomalies observed by the laboratory as having the potential to affect the quality of the data have been identified by the laboratory, and no information or data have been knowingly withheld that would affect the quality of the data.

GLOSSARY OF TERMS

Guide to Reading and Understanding Your Laboratory Report

The information below is designed to better explain the various terms used in your report of analytical results from the Laboratory. This is not intended as a comprehensive explanation, and if you have additional questions please contact your project representative.

Results Disclaimer - Information that may be provided by the customer, and contained within this report, include Permit Limits, Project Name, Sample ID, Sample Matrix, Sample Preservation, Field Blanks, Field Spikes, Field Duplicates, On-Site Data, Sampling Collection Dates/Times, and Sampling Location. Results relate to the accuracy of this information provided, and as the samples are received.

Abbreviations and Definitions

MDA	Minimum Detectable Activity.
Rec.	Recovery.
RER	Replicate Error Ratio.
RPD	Relative Percent Difference.
SDG	Sample Delivery Group.
(T)	Tracer - A radioisotope of known concentration added to a solution of chemically equivalent radioisotopes at a known concentration to assist in monitoring the yield of the chemical separation.
Analyte	The name of the particular compound or analysis performed. Some Analyses and Methods will have multiple analytes reported.
Dilution	If the sample matrix contains an interfering material, the sample preparation volume or weight values differ from the standard, or if concentrations of analytes in the sample are higher than the highest limit of concentration that the laboratory can accurately report, the sample may be diluted for analysis. If a value different than 1 is used in this field, the result reported has already been corrected for this factor.
Limits	These are the target % recovery ranges or % difference value that the laboratory has historically determined as normal for the method and analyte being reported. Successful QC Sample analysis will target all analytes recovered or duplicated within these ranges.
Original Sample	The non-spiked sample in the prep batch used to determine the Relative Percent Difference (RPD) from a quality control sample. The Original Sample may not be included within the reported SDG.
Qualifier	This column provides a letter and/or number designation that corresponds to additional information concerning the result reported. If a Qualifier is present, a definition per Qualifier is provided within the Glossary and Definitions page and potentially a discussion of possible implications of the Qualifier in the Case Narrative if applicable.
Result	The actual analytical final result (corrected for any sample specific characteristics) reported for your sample. If there was no measurable result returned for a specific analyte, the result in this column may state “ND” (Not Detected) or “BDL” (Below Detectable Levels). The information in the results column should always be accompanied by either an MDL (Method Detection Limit) or RDL (Reporting Detection Limit) that defines the lowest value that the laboratory could detect or report for this analyte.
Uncertainty (Radiochemistry)	Confidence level of 2 sigma.
Case Narrative (Cn)	A brief discussion about the included sample results, including a discussion of any non-conformances to protocol observed either at sample receipt by the laboratory from the field or during the analytical process. If present, there will be a section in the Case Narrative to discuss the meaning of any data qualifiers used in the report.
Quality Control Summary (Qc)	This section of the report includes the results of the laboratory quality control analyses required by procedure or analytical methods to assist in evaluating the validity of the results reported for your samples. These analyses are not being performed on your samples typically, but on laboratory generated material.
Sample Chain of Custody (Sc)	This is the document created in the field when your samples were initially collected. This is used to verify the time and date of collection, the person collecting the samples, and the analyses that the laboratory is requested to perform. This chain of custody also documents all persons (excluding commercial shippers) that have had control or possession of the samples from the time of collection until delivery to the laboratory for analysis.
Sample Results (Sr)	This section of your report will provide the results of all testing performed on your samples. These results are provided by sample ID and are separated by the analyses performed on each sample. The header line of each analysis section for each sample will provide the name and method number for the analysis reported.
Sample Summary (Ss)	This section of the Analytical Report defines the specific analyses performed for each sample ID, including the dates and times of preparation and/or analysis.

Qualifier	Description
C1	Tracer recovery limits have been exceeded; values are outside upper control limits.
J	The identification of the analyte is acceptable; the reported value is an estimate.
J6	The sample matrix interfered with the ability to make any accurate determination; spike value is low.
U	Below Detectable Limits: Indicates that the analyte was not detected.

Notes:
Lower Confidence Limit (LCL) or Upper Confidence Limit (UCL) exceeded the statistical background value
HSU = hydrostratigraphic unit:

UA = Uppermost Aquifer

UD = Upper Drift

mg/L = milligrams per liter
ND = non-detect
pCi/L = picocuries per liter
SU = standard units
Sample Count = number of samples from Sampled Date Range used to calculate the Statistical Result
Statistical Calculation = method used to calculate the statistical result:

All ND - Last = All results were below the reporting limit, and the last determined reporting limit is shown

CB around T-S line = Confidence band around Thiel-Sen line

CB around linear reg = Confidence band around linear regression

CI around geomean = Confidence interval around the geometric mean

CI around mean = Confidence interval around the mean

CI around median = Confidence interval around the median

Most recent sample = Result for the most recently collected sample used due to insufficient data

Statistical Result = calculated in accordance with Statistical Analysis Plan using constituent concentrations observed at monitoring well during all sampling events within the specified date range
For pH, the values presented are the lower / upper limits of the background determination

AVAILABILITY OF BOOKS AND MAPS OF THE U.S. GEOLOGICAL SURVEY

Instructions on ordering publications of the U.S. Geological Survey, along with prices of the last offerings, are given in the current-year issues of the monthly catalog "New Publications of the U.S. Geological Survey." Prices of available U.S. Geological Survey publications released prior to the current year are listed in the most recent annual "Price and Availability List." Publications that are listed in various U.S. Geological Survey catalogs (**see back inside cover**) but not listed in the most recent annual "Price and Availability List" are no longer available.

Prices of reports released to the open files are given in the listing "U.S. Geological Survey Open-File Reports," updated monthly, which is for sale in microfiche from the U.S. Geological Survey, Books and Open-File Reports Section, Federal Center, Box 25425, Denver, CO 80225. Reports released through the NTIS may be obtained by writing to the National Technical Information Service, U.S. Department of Commerce, Springfield, VA 22161; please include NTIS report number with inquiry.

Order U.S. Geological Survey publications **by mail** or **over the counter** from the offices given below.

BY MAIL

Books

Professional Papers, Bulletins, Water-Supply Papers, Techniques of Water-Resources Investigations, Circulars, publications of general interest (such as leaflets, pamphlets, booklets), single copies of Earthquakes & Volcanoes, Preliminary Determination of Epicenters, and some miscellaneous reports, including some of the foregoing series that have gone out of print at the Superintendent of Documents, are obtainable by mail from

U.S. Geological Survey, Books and Open-File Reports
Federal Center, Box 25425
Denver, CO 80225

Subscriptions to periodicals (Earthquakes & Volcanoes and Preliminary Determination of Epicenters) can be obtained ONLY from the

Superintendent of Documents
Government Printing Office
Washington, D.C. 20402

(Check or money order must be payable to Superintendent of Documents.)

Maps

For maps, address mail orders to

U.S. Geological Survey, Map Distribution
Federal Center, Box 25286
Denver, CO 80225

Residents of Alaska may order maps from

Alaska Distribution Section, U.S. Geological Survey,
New Federal Building - Box 12
101 Twelfth Ave., Fairbanks, AK 99701

OVER THE COUNTER

Books

Books of the U.S. Geological Survey are available over the counter at the following Geological Survey Public Inquiries Offices, all of which are authorized agents of the Superintendent of Documents:

- **WASHINGTON, D.C.**--Main Interior Bldg., 2600 corridor, 18th and C Sts., NW.
- **DENVER, Colorado**--Federal Bldg., Rm. 169, 1961 Stout St.
- **LOS ANGELES, California**--Federal Bldg., Rm. 7638, 300 N. Los Angeles St.

FOREWORD

THE REGIONAL AQUIFER-SYSTEM ANALYSIS PROGRAM

The Regional Aquifer-System Analysis (RASA) Program was started in 1978 following a congressional mandate to develop quantitative appraisals of the major ground-water systems of the United States. The RASA Program represents a systematic effort to study a number of the Nation's most important aquifer systems, which in aggregate underlie much of the country and which represent an important component of the Nation's total water supply. In general, the boundaries of these studies are identified by the hydrologic extent of each system and accordingly transcend the political subdivisions to which investigations have often arbitrarily been limited in the past. The broad objective for each study is to assemble geologic, hydrologic, and geochemical information, to analyze and develop an understanding of the system, and to develop predictive capabilities that will contribute to the effective management of the system. The use of computer simulation is an important element of the RASA studies, both to develop an understanding of the natural, undisturbed hydrologic system and the changes brought about in it by human activities, and to provide a means of predicting the regional effects of future pumping or other stresses.

The final interpretive results of the RASA Program are presented in a series of U.S. Geological Survey Professional Papers that describe the geology, hydrology, and geochemistry of each regional aquifer system. Each study within the RASA Program is assigned a single Professional Paper number, and where the volume of interpretive material warrants, separate topical chapters that consider the principal elements of the investigation may be published. The series of RASA interpretive reports begins with Professional Paper 1400 and thereafter will continue in numerical sequence as the interpretive products of subsequent studies become available.

ENGLISH-TO-METRIC UNITS CONVERSION FACTORS AND ABBREVIATIONS

For readers who prefer to use metric (International System) units rather than the inch-pound units used in this report, conversion factors are listed below.

Multiply inch-pound unit	*By*	*To obtain metric unit*
	Length	
foot (ft)	0.3048	meter (m)
mile (mi)	1.609	kilometer (km)
	Area	
square mile (mi^2)	2.590	square kilometer (km^2)
	Volume	
cubic foot (ft^3)	0.02832	cubic meter (m^3)
	Flow	
foot per second (ft/s)	0.3048	meter per second (m/s)
foot per year (ft/yr)	0.3048	meter per year (m/yr)
cubic foot per square mile per year [$(ft^3/mi^2)/yr$]	0.01093	cubic meter per square kilometer per year [$(m^3/km^2)/yr$]
	Temperature	
degree Fahrenheit (°F)	0.5556 (°F−32)	degree Celsius (°C)

Sea level: In this report "sea level" refers to the National Geodetic Vertical Datum of 1929 (NGVD of 1929)—a geodetic datum derived from a general adjustment of the first-order level nets of both the United States and Canada, formerly called "Sea Level Datum of 1929."

SYMBOLS AND DEFINITIONS

δ	Isotopic composition expressed as permil differences in the measured isotopic ratios of sample and standard.
$\delta^{13}C$	Standard expression of the ratio of the ^{13}C ion with respect to the ^{12}C ion.
δD	Standard expression of the ratio of the ^{2}H ion (deuterium) with respect to the ^{1}H ion.
$\delta^{18}O$	Standard expression of the ratio of the ^{18}O ion with respect to the ^{16}O ion.
$\delta^{34}S$	Standard expression of the ratio of the ^{34}S ion with respect to the ^{32}S ion.
$\mu g/L$	Micrograms per liter.
Eh	Oxidation potential, log activity of e^1.
e^1	Electron.
(g)	Gaseous.
meq/L	Milliequivalents per liter.
mg/L	Milligrams per liter.
P_{CO_2}	Partial pressure of carbon dioxide.
PDB	PeeDee belemnite ^{13}C isotopic standard.
pCi/L	Picocuries per liter.
pH	Negative log activity of H^+.
ppm	Parts per million.
SI	Saturation index.
SMOW	Standard Mean Ocean Water ^{18}O and ^{2}H isotopic standard.
(s)	Solid.

GEOCHEMISTRY OF THE CAMBRIAN-ORDOVICIAN AQUIFER SYSTEM IN THE NORTHERN MIDWEST, UNITED STATES

By D.I. SIEGEL

ABSTRACT

Distributions of solutes in aquifers of Cambrian and Ordovician age were studied in Minnesota, Wisconsin, Iowa, Illinois, northwestern Indiana, and northern Missouri to determine the sources of solutes and the probable chemical mechanisms that control regional variations in water quality. This work is part of the Northern Midwest Regional Aquifer-System Analysis project, whose objective is to describe and model the regional hydrogeology of the Cambrian-Ordovician aquifer system in the study region. The data base used included more than 3,000 ground-water-quality analyses from all major aquifers, but especially from the St. Peter, Jordan, and Mount Simon Sandstones and their equivalents. Regional variations in the water chemistry of glacial drift and other sedimentary units that overlie the Cambrian-Ordovician aquifer system in recharge areas in Minnesota, Iowa, Wisconsin, and Illinois were also studied, but to a lesser degree.

The most important chemical variation in the aquifer is the change in water type from calcium-sodium-sulfate-bicarbonate water to sodium-calcium-sulfate-bicarbonate and sodium-chloride waters along the longest regional flow path from northwestern Iowa to the Illinois basin. Sodium predominance downgradient from the recharge area is probably related to mechanisms of ion exchange and shale-membrane filtration near the Illinois and Forest City basins.

The most striking aspect of the distribution of dissolved solids and carbon isotopic content of bicarbonate is the increase in concentration and isotopic enrichment from southwestern Wisconsin, southern Minnesota, and northwestern Illinois south toward Missouri. This trend is perpendicular to the present hydraulic gradient that trends from northwestern Iowa southeastward to the Illinois basin. The distribution of dissolved solids defines a "plume" of dilute water having a dissolved-solids concentration of about 500 milligrams per liter, compared with surrounding concentrations more than twice as large. Distribution of the isotopic content of oxygen ($\delta^{18}O$) and hydrogen (δD) in water closely parallels that of dissolved solids and shows covariance similar to modern meteoric water. The isotopic contents are more depleted (lighter) toward the south, perpendicular to the direction of current hydraulic gradients. The degree of depletion, compared with the isotopic content of modern recharge water, indicates that the plume and a significant fraction of the ground water in Iowa, northern Missouri, and possibly central Illinois may have originated as recharge during Pleistocene time.

Distributions of dissolved trace constituents in the aquifers probably are related to the proximity to mineralogic sources as well as chemical and hydraulic mechanisms. For example, concentrations of some constituents, such as cadmium and arsenic, are largest in the vicinity of the Dakota Formation in northwestern Iowa. Other constituents, such as beryllium and vanadium, have larger concentrations near the edge of the Forest City basin in southwestern Iowa and northwestern Missouri. Strontium and fluoride concentrations generally increase from north to south, which suggests the input of these trace constituents during the recharge events. However, concentrations of bromide, radium-226, and lithium show distribution patterns similar to the "plume" defined by dissolved solids and isotopes of water, suggesting dilution of concentrations of trace constituents by Pleistocene recharge. Concentrations of other constituents are partly controlled by aquifer temperature, such as silica in south-central Iowa, and solubility controls, such as barium in northeastern Illinois. Additional information on the chemical and mineralogical composition of the aquifer matrix and the isotopically lightest ground water is needed to evaluate the hypothesis of Pleistocene mixing before more quantitative studies can be done to evaluate the different proposed mechanisms that have controlled and modified the water chemistry over time. This study, however, indicates that the ground water in the region is thousands of years old. The study also indicates that the major chemical trends in the aquifers probably are related as much to paleohydrogeologic flow systems during Pleistocene time as to the present flow system, which may postdate the retreat of the last ice sheet about 12,000 years ago.

INTRODUCTION

Sandstone and dolomite strata of Cambrian and Ordovician age make up much of the sedimentary rocks overlying the Precambrian basement in the northern Midwest and form the major aquifer system of that area. In October 1978, the U.S. Geological Survey began a regional assessment of the Cambrian-Ordovician aquifer system in that area (Steinhilber and Young, 1979) as part of its national Regional Aquifer-System Analysis (RASA) program (Bennett, 1979). The major goals of the RASA program are to (1) gain an understanding of the hydrogeologic system in each region, including the nature of the hydrogeologic units, ground-water flow system, and chemical quality of the water, and (2) describe the regional interaction of components of the system, especially as affected by large-scale withdrawal of ground water. The latter goal is accomplished by constructing digital-computer models that simulate the ground-water flow system.

Manuscript approved for publication November 15, 1985.

PURPOSE AND SCOPE

This report describes the hydrologic and geochemical mechanisms that cause regional differences in groundwater quality in the northern Midwest. Other regional reports on the aquifer system are being published as chapters of U.S. Geological Survey Professional Paper 1405. They include chapter A, a summary of the Northern Midwest RASA (H.L. Young, U.S. Geological Survey, written commun., 1988), chapter B, which describes the regional hydrogeology and water quality (Young, in press), chapter C, which describes a regional three-dimensional ground-water model of the study area (Mandle and Kontis, in press), and chapter E, which describes a detailed three-dimensional ground-water flow model of the Chicago-Milwaukee area (H.L. Young and A.J. MacKenzie, U.S. Geological Survey, written commun., 1988).

The study covers about 161,000 mi^2 in northern Illinois, northwestern Indiana, Iowa, southeastern Minnesota, northern Missouri, and Wisconsin (fig. 1). The border of the study area delimits either the natural physical or hydrologic boundaries of the aquifer system or places where the aquifers are not used because of poor water quality. The northern boundary, from northwestern Iowa to northeastern Wisconsin, delineates the erosional edge of Cambrian rocks overlying crystalline basement rocks of Precambrian age. The Missouri River is a discharge line and forms the western and southwestern boundary. Beyond the eastern and southeastern boundary in Michigan, Illinois, and Indiana, water in the aquifer is too highly mineralized to be used. As a first approximation, the brine-saltwater interface at about 30,000 mg/L is assumed to be a minimal-flow boundary.

The primary subject of the study is the Cambrian- and Ordovician-age rocks that form the dominant aquifer system in the study area. However, because some wells developed in the Cambrian-Ordovician aquifer system are also open to the overlying carbonate rocks of the Silurian-Devonian aquifer, the latter, although only a minor aquifer regionally, is included in the study.

ACKNOWLEDGMENTS

I express my appreciation to many U.S. Geological Survey colleagues for their assistance in this study. Special thanks go to E.C. Alexander, Jr., and H.E. Wright, Jr., University of Minnesota, and to E.G. Perry, Jr., Northern Illinois University, for discussions on Pleistocene geology and environmental isotope geochemistry in the study area, and to the many geologists in State agencies with whom I had helpful conversations.

HYDROGEOLOGIC SETTING

The regional hydrogeology of the Cambrian-Ordovician aquifer system in the northern Midwest is summarized in Professional Paper 1405-B. The following is a brief regional synopsis of the structural, lithologic, and hydrologic features of the geologic formations in the study area and a description of the vertical discretization of geologic units into layers used in the regional flow model. Detailed accounts of the geology and hydrology of each of the States in the study area can be found in publications of State agencies and the U.S. Geological Survey referenced in Professional Paper 1405-B. The nomenclature used in this report was established for the Northern Midwest RASA (see Professional Paper 1405-B) and does not necessarily coincide with that previously accepted by the U.S. Geological Survey. It follows usage prevalent in the majority of the study area, or usage of a particular State, where appropriate.

The consolidated sedimentary rocks in the northern Midwest consist of sandstone, carbonate, and shale sequences that range in age from Precambrian to Cretaceous (fig. 2). They overlie the eroded surface of the Precambrian basement complex, which consists of crystalline igneous and metamorphic rocks. This basement complex forms the North American craton, the more permanent nucleus of the continent. The widespread sedimentary rocks were deposited in the midcontinental interior by a series of transgressions and regressions of the epeiric Sauk and Tippicanoe seas (King, 1959) as the craton subsided. Irregular subsidence resulted in the formation of the Illinois, Michigan, and Forest City basins, beginning in Early Cambrian time. The major structurally high areas, the Kankakee, Transcontinental, and Wisconsin arches, also began developing during Cambrian time (fig. 2). Cambrian and Ordovician rocks presently crop out or subcrop beneath Pleistocene drift and Holocene sediments in southeastern Minnesota, northeastern Iowa, northern Illinois, and southern Wisconsin. A band of Silurian and Devonian rocks subcrop beneath glacial drift along the trend of the Kankakee arch between Michigan and Illinois, along the eastern part of Wisconsin, and in northeastern Iowa (fig. 2). Mississippian and younger rocks border the major sedimentary basins and are present southwest and east of the Silurian rocks.

The Cambrian and Ordovician rocks in the northern Midwest have long been divided into rock-stratigraphic units on the basis of lithology and lateral continuity. For this study, the units were grouped into five aquifer layers and four confining layers on the basis of their hydrologic properties. Figure 3 is a generalized geologic

FIGURE 1.—Location and general features of the Northern Midwest Regional Aquifer-System Analysis area.

section from Missouri to Wisconsin, which shows this hydrogeologic grouping. The first and deepest hydrogeologic unit, the Mount Simon aquifer (aquifer layer 1), is composed mainly of the Mount Simon Sandstone and its equivalents. This basal sandstone rests on the Precambrian basement complex in much of the study area, but on older Precambrian red clastic rocks in Minnesota and western Wisconsin. The latter are included in aquifer layer 1. The Mount Simon Sandstone is a marine, fine- to coarse-grained conglomeratic sandstone and ranges in thickness from less than 100 ft in Minnesota and Wisconsin to more than 2,500 ft in the northern part of the Illinois basin. In the northern part of the area it is overlain by shale, dolomitic sandstone, siltstone, and dolomite of the Eau Claire Formation, which constitutes a regional confining unit. The Eau Claire is predominantly a fine-grained sandstone in Wisconsin but has varying amounts of shale. The Eau

DESCRIPTION OF UNITS (aquifers shown in blue)

- Q — Pleistocene deposits
- P — Pennsylvanian rocks
- M — Mississippian rocks
- DS — Devonian and Silurian rocks
- Om — Maquoketa Shale
- Okp — Kimmswick, Decorah, and Plattin Formations
- Ogp — Galena Dolomite, Decorah and Platteville Formations
- Osg — St. Peter Sandstone; Smithville Formation; Powell, Cotter, and Jefferson City Dolomites; Roubidoux Formation; Gasconade Dolomite
- Osp — St. Peter Sandstone, Prairie du Chien Group
- Ce — Eminence Dolomite
- Cj — Jordan Sandstone
- Csf — St. Lawrence Formation, Potosi Dolomite, Franconia Formation
- Cst — St. Lawrence Formation, Tunnel City Group in Iowa and Wisconsin
- Cpd — Potosi and Derby-Doerun Dolomites, Davis Formation
- Cb — Bonneterre Formation
- Cl — Lamotte Sandstone
- Cem — Elk Mound Group, undifferentiated—Where differentiated, consists of Ironton and Galesville Sandstone Members of the Wonewoc Sandstone, Eau Claire Formation, Mount Simon Sandstone in Iowa and Wisconsin
- Cig — Ironton and Galesville Sandstones
- Cw — Wonewoc Sandstone in Iowa and Wisconsin
- Cec — Eau Claire Formation
- Cms — Mount Simon Sandstone
- pC — Precambrian crystalline rocks

FIGURE 3.—Geologic section from Missouri to Wisconsin. (Modified from Young, in press.)

Claire is not strongly confining in much of Wisconsin and is hydrologically connected with the underlying Mount Simon Sandstone and the overlying Ironton and Galesville Sandstones, except toward the south where the upper part becomes more shaly. To the south in Missouri, the Eau Claire grades into dolomite of the Bonneterre Formation. In northern Illinois, the lower part of the Eau Claire, the Elmhurst Sandstone Member, is included in aquifer layer 1, which is locally termed the "basal sandstone aquifer." In south-central Minnesota, the Eau Claire Formation consists, in part, of glauconitic "greensands."

Aquifer layer 2, the Ironton-Galesville aquifer, is the combined Ironton and Galesville Sandstones and, in Iowa and Wisconsin, the equivalent Wonewoc Formation. It is generally less than 100 ft thick but exceeds 200 ft in the Illinois basin. It consists of calcareous to dolomitic sandstone in Minnesota, Wisconsin, and northern Illinois. The aquifer layer is absent in southern Illinois and is thin or absent and grades into carbonate rocks of the lower part of the Davis Formation in southwestern Iowa and Missouri. Shaly sandstones of the Franconia Formation and limestone and dolomite of the St. Lawrence Formation overlie and confine the Ironton-Galesville aquifer in the north. The southern equivalent of the St. Lawrence-Franconia confining unit is the upper Davis Formation through Potosi Dolomite interval.

The composition of the third aquifer layer varies with its geographic location. In most of the study area it consists of, from oldest to youngest, the Jordan Sandstone, the overlying Prairie du Chien Group, and the St. Peter Sandstone. In Missouri, the Gasconade Dolomite-Smithville Formation sequence is a general equivalent and replaces the Prairie du Chien Group. Also, the Jordan Sandstone is replaced by the Eminence Dolomite in Missouri and all but the extreme northwestern part of Illinois. These formations are generally in hydrologic connection. They are treated as a single unit because fractures commonly penetrate through the Prairie du Chien Group.

The Jordan Sandstone is a coarse- to medium-grained orthoquartzite to dolomitic sandstone in Minnesota, Wisconsin, and Iowa, grading into sandy dolomite and dolomite in southern Iowa, northern Missouri, and all but the extreme northwestern part of Illinois. The Prairie du Chien Group consists of fossiliferous dolomite and limestone interbedded with thin, discontinuous beds of sandstone, siltstone, and shale. Aquifer layers 1 and 3 generally range from 200 to 600 ft in thickness in the northern half of the study area but thicken to more than 1,500 ft in the Illinois basin. The St. Peter Sandstone is a laterally persistent clean and friable orthoquartzite, generally 100 to 200 ft thick except locally in northern Illinois, where thickness exceeds 700 ft upon pre-St. Peter karstic topography.

The Maquoketa Shale forms a very effective confining unit above aquifer layer 3 over much of the study area. The Maquoketa consists of thick pyritic shales except in western Iowa and Minnesota, where the shales grade into interbedded dolomitic limestones and shaly dolomites that provide a hydraulic connection with overlying and underlying carbonates. The shaly dolomites, which make up the Galena Dolomite and Decorah and Platteville Formations or equivalents, are generally of low permeability where overlain by the Maquoketa and are included as part of the confining unit. The base of the confining unit is the Glenwood Formation, which consists generally of shale and silty, shaly sandstone. Extensive phosphatic beds are present within the Maquoketa in Iowa. The Cambrian-Ordovician aquifer system is further confined by thick sequences of younger Paleozoic rocks south of the outcrop of the Maquoketa Shale.

Aquifer layer 4 consists of the carbonate rocks of the Silurian through Middle Devonian and is termed the Silurian-Devonian aquifer for this study. The rocks are dominantly thick- to thinly bedded dolomites, limestones, and shales that are hydraulically connected by fractures. Where not eroded, they generally range in thickness from 200 to 500 ft, but they are more than 1,000 ft thick in the Illinois basin. The excellent confinement of the Maquoketa Shale, which separates aquifer layer 4 from aquifer layer 3, limits the potential of water in aquifer layer 4 to affect the chemistry of water in the Cambrian-Ordovician aquifer system. However, the opposite may be true where the Maquoketa is mainly a fractured carbonate. The very thick sequence of younger consolidated rocks from the Upper Devonian through the Pennsylvanian contains little aquifer material and, for the purposes of this study, is considered to be a confining unit between aquifer layers 4 and 5. In Iowa, the Mississippian is classified as a separate aquifer (Horick and Steinhilber, 1973).

Aquifer layer 5 consists of the combined Holocene surficial deposits, Pleistocene glacial drift, or Cretaceous rocks that form the land surface over most of the study area. This layer directly overlies the units of the Cambrian-Ordovician aquifer system in much of the Cambrian-Ordovician outcrop areas in Minnesota, Iowa, Wisconsin, and Illinois. Most drift is calcareous because of carbonate minerals derived from the glacial erosion of Paleozoic limestones and dolomites in Manitoba and Michigan and within the study area. Except for the Driftless Area of southwestern Wisconsin and adjacent small areas in Illinois and Iowa, the entire study area was glaciated during the Pleistocene. Cretaceous rocks that overlie the Cambrian and Ordovician rocks in western Minnesota and Iowa consist of varicolored marine shales, siltstones, and lignitic sandstones of the Dakota Formation, which commonly contains disseminated pyrite in its basal part.

The ground-water reservoir is recharged by infiltration of precipitation through the soil into the underlying rock. Because glacial deposits are the surficial rocks in most of the northern Midwest, they receive most of the initial recharge. Aquifer layers 1 through 4 also are recharged by infiltration of precipitation where they crop out at the land surface, such as in the Driftless

Area. These aquifers also receive recharge by vertical seepage across confining beds, where they subcrop beneath aquifer layer 5 and where they are penetrated by buried bedrock valleys eroded by glacial meltwater streams during Pleistocene time. Both field observation and steady-state simulation of the ground-water flow system (Mandle and Kontis, in press) indicate that vertical head gradients in the Cambrian-Ordovician aquifers (aquifer layers 1 through 3) are generally upward where overlain by the Maquoketa Shale in Iowa, Illinois, and Wisconsin (fig. 4). Vertical head gradients are downward in the Cambrian-Ordovician outcrop areas in much of south-central Minnesota, south-central Wisconsin, and northern Iowa.

Ground water flows from topographically high recharge areas to low discharge areas. Most of the ground water in aquifer layer 5 moves within local flow systems of a few miles in length and discharges to small first- and second-order tributaries of the major rivers. Ground-water movement in the unconfined parts of the Cambrian-Ordovician aquifer system is similar, but the flow systems are larger and discharge is toward the major river valleys. Figure 5 is a representation of the original predevelopment potentiometric surface of aquifer layer 3, for which the most data are available, and is generally representative of the predevelopment potentiometric heads in the lower aquifer layers. The more localized flow systems in the unconfined areas are shown by the topographic control and steeper gradient of the contours there. In the confined areas, ground water moves toward the Illinois and Michigan basins but can discharge only as upward leakage across confining units. Thus the rate of lateral flow into the basins is greatly decreased. The longest flow paths in the aquifer system (more than 300 mi) extend from recharge areas in northwestern Iowa to the center of the Illinois basin (fig. 5). Shorter flow paths (less than 50 mi) in the northern part of the area extend from recharge areas: in central Minnesota to the Minnesota River; in central Wisconsin, central Minnesota, northeastern Iowa, and northwestern Illinois to the Mississippi River; and in eastern Wisconsin and northeastern Illinois toward Lake Michigan. Penetration of aquifer layers by the Mississippi River valley during the Pleistocene causes the flow system in the northern part of the study area to have shorter flow paths. This effect of the Mississippi River is most pronounced in aquifer layers 3 and 4 and is less pronounced in layers 1 and 2. For example, flow in layer 3 discharges to the Mississippi River as far south as about 50 mi south of the Wisconsin-Illinois State line, but the direct influence of the river on aquifer layer 1 extends only as far as the Minnesota-Iowa State line. Aquifer layer 4 discharges toward the Mississippi River downstream from northeastern Iowa.

GEOCHEMISTRY

METHODS OF INVESTIGATION

The interpretation of regional ground-water quality is based on a synthesis of more than 3,000 chemical analyses of ground water available from the U.S. Geological Survey WATSTORE (Water Data Storage and Retrieval System) data base, publications of State and Federal agencies, and scientific journals. Published descriptions of the water chemistry of parts of the Cambrian-Ordovician aquifer system were reviewed, particularly in the following references (grouped by State): Minnesota—Winter (1974), Norvitch and others (1973), and Maderak (1965); Wisconsin—Kammerer (1981), Holt and Skinner (1973), and Ryling (1961); Iowa—Horick and Steinhilber (1978); Missouri—Feder (1979) and Gann and others (1971, 1973); and Illinois—Larson (1963), Gibb and O'Hearn (1980), and Schicht and others (1976). Description and analyses of brines in Cambrian-Ordovician aquifer units were obtained from Meents and others (1952), Graf and others (1965, 1966), Bond (1972), and the files of the Indiana and Michigan Geological Surveys and the Illinois State Water Survey.

Mean concentrations are used where multiple analyses are available. In general, analyses that did not balance electrochemically within 5 percent were deleted from the data base. Some partial analyses of brines include data for only dissolved solids and chloride, but these analyses were used to complete the areal distribution of dissolved solids along the southeastern boundary of the study area. Thus, the lines of equal concentration there should be considered approximate.

One hundred and sixty-four ground-water samples were collected for the study during the period 1980–82 to determine the concentrations of trace constituents and radiochemical species as well as stable isotope ratios. Seventy-five samples were collected to determine the isotopic composition of oxygen and hydrogen in the ground water and of carbon in bicarbonate. The isotopic composition of sulfur in sulfate was determined for selected samples. Field pH, alkalinity, and temperature of the water were measured at critical sample locations along ground-water flow paths to enable calculation of chemical species at equilibrium. Analyses were made using methods described in American Public Health Association (1980) and Skougstad and others (1979). Isotopic composition of water, carbon in inorganic carbon, and sulfur in sulfate was determined by standard methods. By convention, the isotopic variations are expressed as $\pm \delta$ values in parts per thousand (permil) differences in the measured isotopic ratios in a sample and in appropriate standards: Standard Mean Ocean Water (SMOW) for oxygen ($\delta^{18}O$) and

hydrogen (δD) in water, Canyon Diablo troilite for sulfur (δ^{34}S), and PeeDee belemnite (PDB standard) for carbon (δ^{13}C). Results of the analyses for the study are given in tables 1, 2, and 3 (at the end of the report). Figure 6 shows the locations of the wells in aquifer layers 1, 3, and 5 sampled for this study and the locations of selected wells in aquifer layers 1 and 3 with WATSTORE and published analyses. Data distribution for aquifer layer 5 was dense throughout the recharge areas of Wisconsin, Minnesota, Iowa, and Illinois; consequently, the locations of only new data for this aquifer layer are shown in figure 6. In subsequent figures that show areal distribution of solutes, only locations of data collected during this study are plotted.

Maps showing the areal distribution of solutes were derived from a composite of data from aquifer layers 1 and 3, for which there is significant regional coverage. It is recognized that because the lithologies of these layers are different, the chemistry may be different. However, the composited data are used as a first approximation in describing the regional chemical patterns for the following reasons:

1. The chemical quality of ground water in aquifer layers 1 and 3 is essentially the same in outcrop areas in Minnesota, Wisconsin, Illinois, and Iowa.
2. In the major confined areas in Iowa, Missouri, Illinois, and eastern Wisconsin, all but a few data points are from aquifer layer 3 (fig. 6).

The maps of areal solute distribution in this report, therefore, represent mainly aquifer layer 3 in the confined part of the aquifer and aquifer layers 1, 2, and 3 in outcrop areas. Where data distribution was dense, maps of concentrations of dissolved solids and particular ions were prepared, in part, by data-management techniques described by Kontis and Mandle (1980).

The detailed evaluation of the water quality of the Cambrian-Ordovician aquifer system was restricted to aquifer layers 3 and 5, for which the areal distribution of data was considered sufficient to evaluate regional trends and variations in concentrations of major dissolved constituents. In most of Wisconsin and north-central Illinois, aquifer layers 1, 2, and 3 are unconfined and are hydraulically connected; thus water quality in those aquifer layers is probably similar. All statistical calculations were made using computer methods of the Statistical Analysis System (SAS Institute, Inc., 1979).

DISSOLVED SOLIDS

The chemical quality of the water in the Cambrian-Ordovician aquifer system varies widely from recharge areas to discharge areas. Dissolved-solids concentrations range from less than 200 mg/L in the outcrop areas in Wisconsin and southeastern Minnesota to more than 200,000 mg/L in the Illinois basin. The 500-mg/L line of equal dissolved solids (isopleth) in figure 7 roughly outlines the extent of the predominantly unconfined flow systems in the northern half of the study area. The 500-mg/L line also is approximately parallel to the outcrop pattern of the Maquoketa Shale in Illinois and Wisconsin, the major confining unit between the Cambrian-Ordovician aquifer system and the overlying units. Dissolved solids generally increase in the direction of the hydraulic gradient.

In Iowa, the 500-mg/L line shows a plume-shaped zone of fresher water trending from the northeast to the south-southwest across the Maquoketa Shale outcrop (figs. 2, 7). In both Iowa and Missouri, the gradient toward increasing dissolved solids (fig. 7) varies but is generally perpendicular to the direction of the hydraulic gradient shown in figure 5. For example, along the flow path that is approximately coincident with geochemical section A–A' (fig. 6), dissolved solids decrease from 2,400 mg/L at well 59 (Hibbing, Iowa) to 440 mg/L at well 144 (Altoona, Iowa) in the south-central part of the State. Dissolved solids increase southeast of Altoona to more than 100,000 mg/L in the Illinois basin (fig. 7). Dissolved solids normally increase along the hydraulic gradient because as the residence time of water in the aquifer increases, the water has a longer period of interaction with the rock minerals (Chebotarev, 1955; Back and Hanshaw, 1965). The discordance of increasing dissolved-solids distribution with the hydraulic gradient in the central part of the study area is an abnormal occurrence and poses a major geochemical anomaly that is examined and discussed in a later section, "Hypothetical Geochemical Models."

CHEMICAL CLASSIFICATION

Water chemistry in the aquifer system was classified by calculating percentages of equivalents per liter for major cations and anions. Maps were prepared showing the areal distribution of water types according to the method described by Back (1966). These maps were used to relate water chemistry to lithologic changes in aquifers and to evaluate possible geochemical and hydrologic processes that control the evolution of water chemistry along and across the hydraulic gradients.

A wide range of water types is present in the Cambrian-Ordovician aquifer system. Water recharged to the system through aquifer layer 5 ranges from a Ca-Mg-HCO_3 type in the northern part of the area to a Ca-Na-SO_4-HCO_3 type in northwestern Iowa and southwestern Minnesota (fig. 8). Dissolved solids in aquifer layer 5 range from less than 300 to more than 2,000 mg/L in Minnesota, Wisconsin, and northwestern Iowa.

Water chemistry in the Cambrian-Ordovician aquifer system in recharge areas in Minnesota, Wisconsin, Illinois, and Iowa is very similar to that in the overlying

FIGURE 9.—Hydrochemical facies of ground water in aquifer layers 1 and 3.

aquifer layer 5. Water in both aquifer layers 1 and 3 in the northern part of the study area is a Ca-Mg-HCO_3 type, but water in northwestern Iowa and southwestern Minnesota is a Ca-Na-SO_4-HCO_3 type (fig. 9).

The most pronounced geochemical changes occur in the confined parts of the aquifer system. Along flow paths confined by the Maquoketa Shale from eastern Wisconsin east toward the Michigan basin, water chemistry changes from Ca-Mg-HCO_3 to Ca-Na-SO_4 and Na-Cl-SO_4 waters, a transition to the Ca-SO_4 and Ca-Cl_2 types of brines in the Michigan basin (fig. 9). From northern Illinois to central Illinois also, the water changes from a Ca-Mg-HCO_3 type to a Na-Cl type similar to the brines in the Illinois basin.

The largest variability in water chemistry occurs along confined flow paths in the aquifer system from northwestern Iowa to central Illinois. Water type evolves along the hydraulic gradient to the Illinois basin from the Ca-Na-SO_4-HCO_3 water that typically is present in the Dakota Formation and overlying drift of aquifer layer 5 to Na-Ca-SO_4-HCO_3, Na-anion (no dominant anion), and Na-Cl water. This change occurs in aquifer layer 3 even though the dissolved-solids concentration decreases along the central part of the flow path. South of the Na-Ca-SO_4-HCO_3 facies in south-central Iowa, the water is of either the Na-Cl or the Na-anion type.

Few generalizations can be made about variations in water types in aquifer layers 1 and 2 or with depth in individual aquifer layers because of the scant data on the areal distribution of the major solutes in aquifer layers 1, 2, and 4. Saline water is present in aquifer layer 1 at several locations along the Mississippi River valley. Chemical data from municipal wells in aquifer layer 1 at Red Wing, Minn. (fig. 1), indicate that the water type changes from Ca-Mg-HCO_3 to Na-Cl at depth (table 4). This change in water quality with depth can occur with increases of dissolved solids from less than 500 to several thousand milligrams per liter (Hall and others, 1911; Thiel, 1944). A similar increase in dissolved solids and change in water type in aquifer layer 1 occurs near Lake Michigan, where high salinity makes aquifer layer 1 nonpotable in some places. Samples collected from aquifer layer 1 in a deep test well drilled for this study at Zion, Ill. (fig. 1), illustrate the increase in salinity with depth (table 4). This increase in salinity is also found in aquifer layer 1 within the Illinois basin in central Illinois and eastern Indiana (Meents and others, 1952; R.J. Shedlock, U.S. Geological Survey, written commun., 1983). These data plus scant data from wells in south-central Iowa (fig. 6) suggest that the Na-Cl water type in Iowa in aquifer layer 1 may be present much farther up the hydraulic gradient than in aquifer layer 3.

GEOCHEMICAL PROCESSES

CALCIUM-MAGNESIUM-BICARBONATE WATER TYPE

The major geochemical and hydrologic processes that cause the changes in dissolved-solids concentrations and water types in the Cambrian-Ordovician aquifer system can be evaluated at different levels of complexity. Qualitatively, the Ca-Mg-HCO_3 water in all layers probably reflects the dissolution of calcite ($CaCO_3$) and dolomite [$CaMg(CO_3)_2$] in the aquifer matrix and overlying drift. The chemical reactions involved in the dissolution of carbonate minerals are a combination of hydrolysis and dissociation. The major source of acidity in the northern part of the study area is probably carbon dioxide in the atmosphere and soil. The pertinent reactions for the dissolution of calcite by carbonic acid may be expressed by

$$CO_{2(g)}+H_2O=H_2CO_3, \quad (1)$$

$$H_2CO_3=H^++HCO_3^-, \quad (2)$$

$$HCO_3^{-1}=H^++CO_3^{2-}, \quad (3)$$

and

$$(Ca_{1-x}Mg_x)CO_{3(s)}+2H^+=(1-x)Ca^{2+}+xMg^{2+}+2HCO_3^-. \quad (4)$$

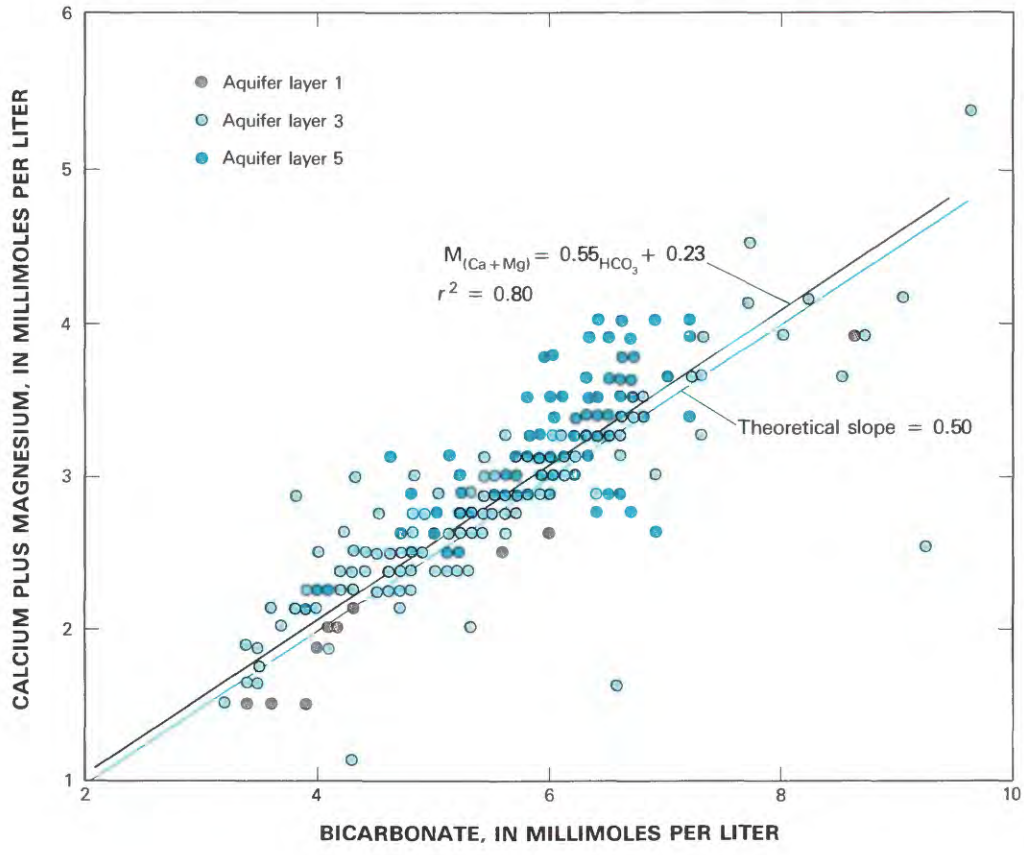

FIGURE 10.—Correlation of calcium plus magnesium and bicarbonate in ground water from the Ca-Mg-HCO_3 facies in aquifer layers 1, 3, and 5 in the northern outcrop area of the Cambrian-Ordovician aquifer system.

Combining equations 1 through 4 and neglecting CO_3^{2-} because of the near-neutral pH conditions in the aquifer,

$$(Ca_{1-x}Mg_x)CO_{3(s)} + H_2O + CO_{2(g)} = (1-x)Ca^{2+} + xMg^{2+} + 2HCO_3^- . \quad (5)$$

Little information exists on the mole fractions of calcium and magnesium in the major carbonate minerals in either the Cambrian-Ordovician aquifer system or the overlying units in aquifer layer 5. A large number of rock analyses of carbonate units from Minnesota obtained from the Cambrian-Ordovician aquifer system are available—for example, Prokopovich and Schwartz (1956), Thiel and Stauffer (1947), and Stauffer (1950)—and show that there is both wide vertical and wide areal variability in the CaO and MgO content of the aquifer carbonate rocks and confining units. It is likely that there is a similar variability in calcium and magnesium content of the carbonate rocks elsewhere in the study area.

However, if dissolved calcium, magnesium, and bicarbonate in the ground water result mainly from the dissolution of carbonate minerals according to equation 5, then the molar proportions of $(Ca^{2+}+Mg^{2+})$ to HCO_3^- should be linear with a slope of 0.5. Calcium and magnesium are summed because of variability of the mole fractions within the carbonate minerals. The line of regression (fig. 10) of $(Ca^{2+}+Mg^{2+})$ versus HCO_3^- for ground-water samples in aquifer layers 1, 3, and 5 in the northern outcrop area of the Cambrian-Ordovician aquifer system in Minnesota, Wisconsin, and northeastern Iowa has a slope of 0.55. The coefficient of correlation (r^2) is 0.80, which indicates a good fit between the carbonate-dissolution model and field data.

The state of equilibrium between ground water and carbonate minerals can be tested by use of saturation indices (*SI*), expressed as

$$SI_{\text{mineral}} = \log \frac{IAP}{K_{sp}}, \quad (6)$$

where *IAP* is the ion-activity product calculated from analytical data and K_{sp} is the solubility product, an

equilibrium constant for ions in a saturated solution in contact with excess solid phases.

A saturation index of 0.0 indicates that *IAP* and K_{sp} are equal and that thermodynamic equilibrium of the solution exists with the solid phase in question; a negative or positive index indicates undersaturation and oversaturation, respectively. Saturation indices for calcite and dolomite in selected water samples from aquifer layer 3 in Iowa and northeastern Missouri were determined by use of WATEQF, a U.S. Geological Survey water chemical-equilibrium calculation program (Truesdell and Jones, 1974; Plummer and others, 1976). Saturation indices calculated for calcite and dolomite range generally from about 0.0 to +0.6 and from −0.2 to +1.0, respectively (fig. 11), for wells in Iowa and northeastern Missouri.

The accuracy of the saturation index for determining equilibrium between solution and carbonate minerals depends largely on the accuracy of field measurements of pH and alkalinity. The most accurate method of measuring pH is by using a flow-through cell or bath until pH is constant for at least 15 minutes (Thorstenson and others, 1979). Precision by this method can be within 0.05 pH unit. Unfortunately, during this study the general accuracy of field pH measurements may have been within only ±0.1 pH unit. Accurate field measurements of alkalinity should be done by potentiometric titration to inflection points rather than to specified end points (Barnes, 1964), which was the method used during this study. The combined errors in pH measurements and alkalinity determinations could result in errors in saturation indices for carbonate dissolution reactions within a range of 20 percent. Within these error limits, ground water in the Cambrian-Ordovician aquifer system seems to be nearly saturated or oversaturated with respect to calcite and dolomite (fig. 11).

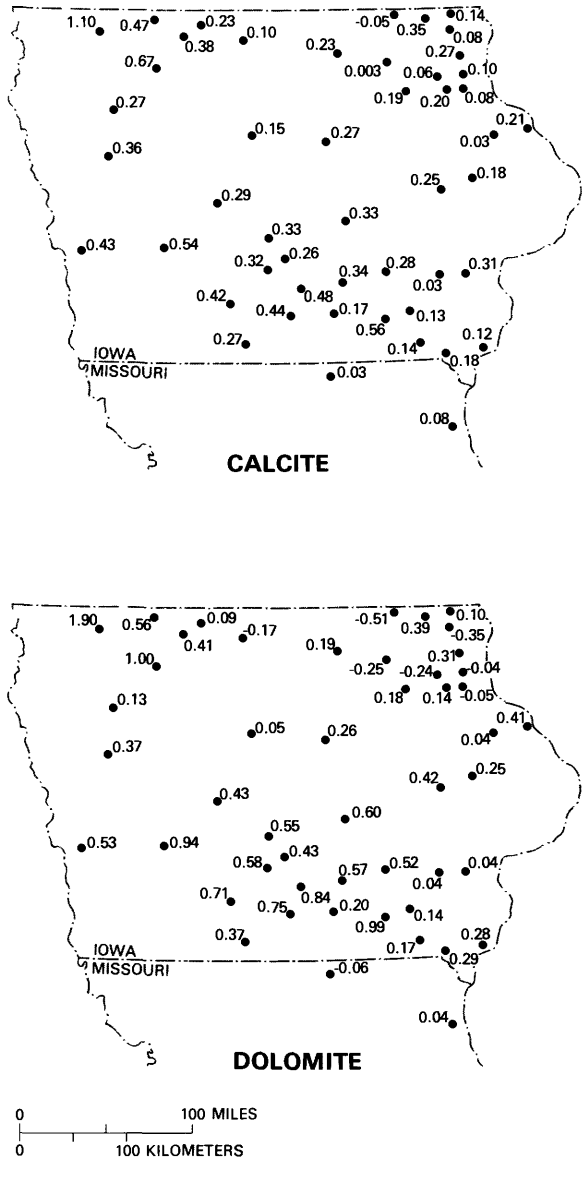

FIGURE 11.—Saturation indices for calcite and dolomite in water from selected wells in aquifer layer 3 in Iowa and northeastern Missouri.

CALCIUM-SODIUM-SULFATE-BICARBONATE WATER TYPE

Ca-Na-SO_4-HCO_3 water is common in the drift and the Dakota Formation (table 5) and is present in all aquifer layers that subcrop beneath the Dakota Formation. For instance, samples of water collected at "nests" of vertically spaced observation wells (piezometers) in aquifer layers 1, 2, and 3 in southwestern Minnesota are all of the Ca-Na-SO_4-HCO_3 type (table 6). The relative chemical uniformity of water in aquifer layers 1, 2, and 3 observed in the piezometers in southwestern Minnesota is an important factor in evaluating chemical and hydrologic mechanisms that affect changes in chemistry southeastward along the major direction of groundwater flow in Iowa. Water-quality data are scant for aquifer layers 1, 2, and 4. If the chemistry of water recharging these aquifer layers is similar to the chemistry of the ground water in aquifer layer 3, one can probably assume that the major geochemical mechanisms that control the water chemistry in all aquifer layers in the recharge areas are generally similar.

The origin of Ca-Na-SO_4-HCO_3 water in the Dakota Formation, the Quaternary drift, and the Cambrian-

Ordovician aquifer system in northwestern Iowa and southwestern Minnesota is related to both the oxidation of pyrite and the dissolution of carbonate minerals. Oxidation of pyrite produces sulfuric acid that dissociates to sulfate and hydrogen ions as follows:

$$FeS_{2(s)} + 7/2 O_{2(g)} + H_2O = Fe^{2+} + 2SO_4^{2-} + 2H^+. \quad (7)$$

Depending on the Eh (redox potential) and pH of the water, the resultant ferrous iron may then be oxidized to ferric iron,

$$Fe^{2+} + 1/4 O_2 + H^+ = Fe^{3+} + 1/2 H_2O, \quad (8)$$

which hydrolyzes to form insoluble iron oxides or hydroxide, for example,

$$Fe^{3+} + 3H_2O = Fe(OH)_{3(s)} + 3H^+. \quad (9)$$

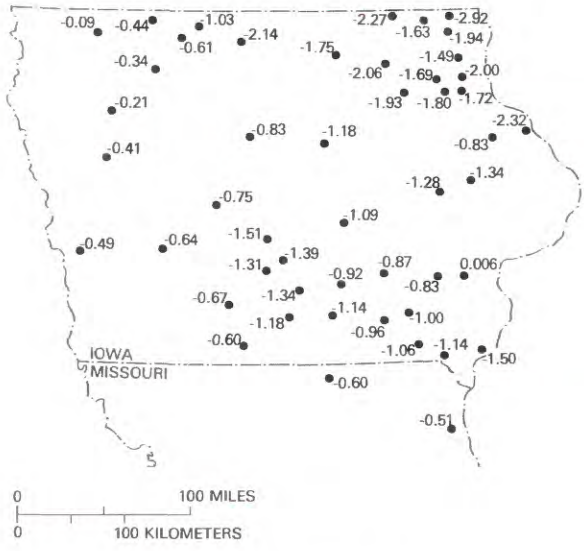
Acidity produced in the oxidation process may be neutralized by carbonate minerals (eq. 5) that are found as part of the matrix in the Dakota Formation and the underlying aquifer units.

Sulfate in the Dakota Formation and other aquifers in northwestern Iowa and southwestern Minnesota has also been attributed to possible dissolution of either gypsum ($CaSO_4 \cdot 2H_2O$) or anhydrite ($CaSO_4$) (Winter, 1974; Munter and others, 1983). No petrographic evidence of primary evaporite minerals has been noted in the literature, however. Dissolution of gypsum proceeds rapidy compared with dissolution of carbonates and other common minerals in the aquifer matrix. The hydraulic conductivity of the Dakota Formation is generally low owing to bedded shale and siltstone. Therefore, the residence time of ground water in the Dakota probably is long. This is supported by the carbon-14 dates for water in the Dakota ranging from 22,000 to more than 35,000 years B.P. (before present) (D.L. Iles, South Dakota Geological Survey, written commun., 1982). Because of this long residence time, ground water in the Dakota Formation should be in equilibrium with gypsum, if gypsum is present, as should the ground water in aquifer layer 3, where the ground water is recharged from the Dakota. However, negative saturation indices for gypsum in ground water in aquifer layer 3 in northwestern Iowa (fig. 12) show the water to be undersaturated with respect to gypsum, and this indi-



EXPLANATION

-0.75 • WELL LOCATION—Number is saturation index, *SI* (see text for discussion)

FIGURE 12.—Saturation indices for gypsum in water from selected wells in aquifer layer 3 in Iowa and northeastern Missouri.

rectly indicates that there is not enough gypsum in the Dakota Formation to be the source of sulfate, as suggested by other investigators.

Data on the isotopic composition of sulfur in sulfate is another way to test independently whether the sulfur is from the oxidation of pyrite (FeS_2) or the dissolution of gypsum or anhydrite. Negative $\delta^{34}S$ values typically indicate that the source of sulfur is weathered sulfide from shales, whereas positive values generally indicate an evaporitic mineral source (Holser and Kaplan, 1966; Hitchon and Krouse, 1972; Hoefs, 1980).

The $\delta^{34}S$ in sulfate from the Cambrian-Ordovician aquifer system and the Dakota Formation in northwestern Iowa (fig. 13) ranges from −10.8 to −1.0 permil (parts per thousand, written o/oo), considerably lighter than $\delta^{34}S$ associated with marine evaporites in the Cretaceous Period (Claypool and others, 1980). $\delta^{34}S$ of pyrite and other disseminated sulfide minerals in shales tends to be less than +10 o/oo, the lower limit for evaporitic sulfate (Holser and Kaplan, 1966). These values are similar to isotopic sulfur ratios in streams that drain basins underlain by marine Cretaceous rock, roughly similar to the Dakota Formation, in the MacKenzie River Basin of Canada (Hitchon and Krouse, 1972). The values of $\delta^{34}S$ indicate that the original source of sulfur was probably pyrite in the Dakota Formation.

The isotopic composition of the sulfur in sulfate reflects the isotopic composition of the sulfur in the original pyrite and depends on many factors. Sulfur isotopes approach equilibrium at earth temperatures and pressures very slowly (Pearson and Rightmire, 1980). Most differences in sulfur isotope content in aqueous sulfur compounds are caused by kinetic fractionation accompanying inorganic or bacterial reduction or by oxidation of sulfur compounds (Kaplan and Rittenburg, 1964; Goldhaber and Kaplan, 1974). Hydrogen sulfide degassing is a common problem in many wells in the Dakota Formation; this indicates that reducing conditions do exist locally in the formation (U.S. Geolgical Survey, unpub. data; Burkart, 1984). In southwestern Minnesota, methane is also common in both drift and the underlying Cambrian-Ordovician aquifer system (Coleman, 1978, 1979).

$\delta^{34}S$ in sulfate in aquifer layer 3 is enriched downgradient from the northwestern recharge area in central Iowa but is still less than +10 o/oo (fig. 13). The $\delta^{34}S$ enrichment may be related to the preferential bacterial reduction and consequent loss of sulfur-32 in H_2S or metal sulfide precipitates. Although sulfide in solution is present in the aquifer system in central Iowa (fig. 14), data are insufficient to document the presence of such possible bacteriological mediation of the reduction process. The low concentrations of sulfide may reflect precipitation of pyrite or other metal sulfides. Calculations from the WATEQF program show that sulfide-bearing solutions are supersaturated with respect to pyrite.

Some input of sulfur to the aquifer system could have been from the oxidation of pyrite in the Maquoketa Shale along the outcrop area in northeastern Iowa. However, the scant data on the isotopic content of sulfur in sulfate in central Iowa (fig. 13) show $\delta^{34}S$ greater than +5 o/oo, which is considerably heavier than that of the sulfur in sulfate derived from either the oxidation of pyrite in northwestern Iowa or from the Maquoketa Shale in northeastern Iowa.

Elsewhere in the aquifer system, $\delta^{34}S$ in sulfate may indicate a sulfur source from evaporite minerals. East of the Maquoketa confining unit in northern Illinois, $\delta^{34}S$ in sulfate in oxidized water is about +20 o/oo and is too enriched to be derived solely from the oxidation of sulfide minerals (Perry and others, 1982). Gilkeson and others (1981) proposed that some of the sulfate may have been placed in the aquifer system during Pleistocene glaciations and may be related to Michigan basin evaporites. Hydraulic gradients in Illinois, at least during the Wisconsin ice advances, could have been from east to west, reversed from current hydraulic gradients, because of the pressure head from the weight of the ice sheets that periodically covered the Lake Michigan

basin (Gilkeson and others, 1981; Filley and Parizek, 1983; Siegel and Mandle, 1983). The influence of Pleistocene glaciations on the water chemistry of the Cambrian-Ordovician aquifer system was profound and is discussed in a later section, "Isotopic Composition of Water and Pleistocene Recharge Model."

SODIUM-MIXED ANION WATER TYPE

The evolution of Ca-Na-SO_4-HCO_3 water to Na-Ca-SO_4-HCO_3 and Na-Cl water is well illustrated in figure 15, a plot of analyses in terms of equivalent weights on the trilinear diagram of Piper (1944). Data from wells along geochemical sections A–A' and B–B' indicate a trend toward sodium predominance on the cation plot, and toward chloride predominance on the anion plot. The increase in sodium and the decrease in calcium and magnesium along the flow path could be the result of several processes.

Sodium could be contributed by dissolution of sodium-bearing silicate or evaporite minerals in the aquifer system. However, no petrographic evidence exists to indicate the presence of halite (NaCl) in the aquifer system, and the dissolution rate of sodic plagioclase ($NaAlSi_3O_8$) is much too slow to account for the concentrations of sodium found in central Iowa.

The inverse relationship between concentrations of sodium and alkaline-earth metals could also be explained by ion exchange, which has been identified in many aquifer systems elsewhere (for example, Foster, 1950; Krothe and Parizek, 1979; Thorstenson and others, 1979; Krothe and Bergeron, 1981; Chapelle and Knobel, 1983). Exchange would follow the generalized reaction

$$M^{2+} + Na_2\text{-Clay} = 2Na^+ + M\text{-Clay}, \qquad (10)$$

where M^{2+} is $Ca^{2+} + Mg^{2+}$ or other alkaline-earth metals.

Micaceous clays such as illite and glauconite are more common in the Cambrian-Ordovician aquifer system than are mixed-layered clays such as montmorillonite and smectite, which are usually associated with cation exchange. Major clay minerals in the Ordovician Decorah Formation and Glenwood Formation, which are part of the Maquoketa confining unit that separates aquifer layer 3 from aquifer layer 4, are kaolinite and illite (Parham and Austin, 1967, 1969). However, distinctive beds of potassium montmorillonite have been identified in the Decorah Formation and other Ordovician formations throughout the study area (Mossler and Hayes, 1966). Although the presence of montmorillonite in Ordovician and Cambrian rocks suggests that significant cation-exchange capacity may be present in the aquifers, such exchange probably cannot completely account for the linear plot of the cations (fig. 15). If cation exchange were the dominant mechanism, the plot would trend more parallel to the calcium-sodium axis rather than toward the sodium apex (Piper, 1944), unless exchange of calcium and magnesium for sodium occurred at rates that would maintain similar Ca:Mg molar ratios along the flow path. Covariance of the molality of sodium to molality of (Ca+Mg) has a low coefficient of correlation (r^2) of 0.3 and a slope of +2.1. If ion exchange were a major process, r^2 would be closer to unity and the slope would be close to −2 (Chapelle, 1983). Given the areal variability and probable scarcity of clays having high cation-exchange capacity for calcium and magnesium in the aquifer system, it is unlikely that much ion exchange occurs except in recharge areas underlain by clayey till and the Dakota Formation.

Mixtures of two waters will also plot on straight lines if all solutes remain in solution and do not increase or decrease as a result of chemical reactions. The linearity of the cation plot (fig. 15) may indicate simple mixing of Na-mixed anion water with Ca-Na-mixed anion water, but the curvilinear fit of the anion data indicates sources and sinks along the flow path with respect to bicarbonate and sulfate.

Although cation trends on the trilinear diagrams could indicate mixing of two types of water, sodium and chloride concentrations along the major southeastward direction of ground-water flow across Iowa probably

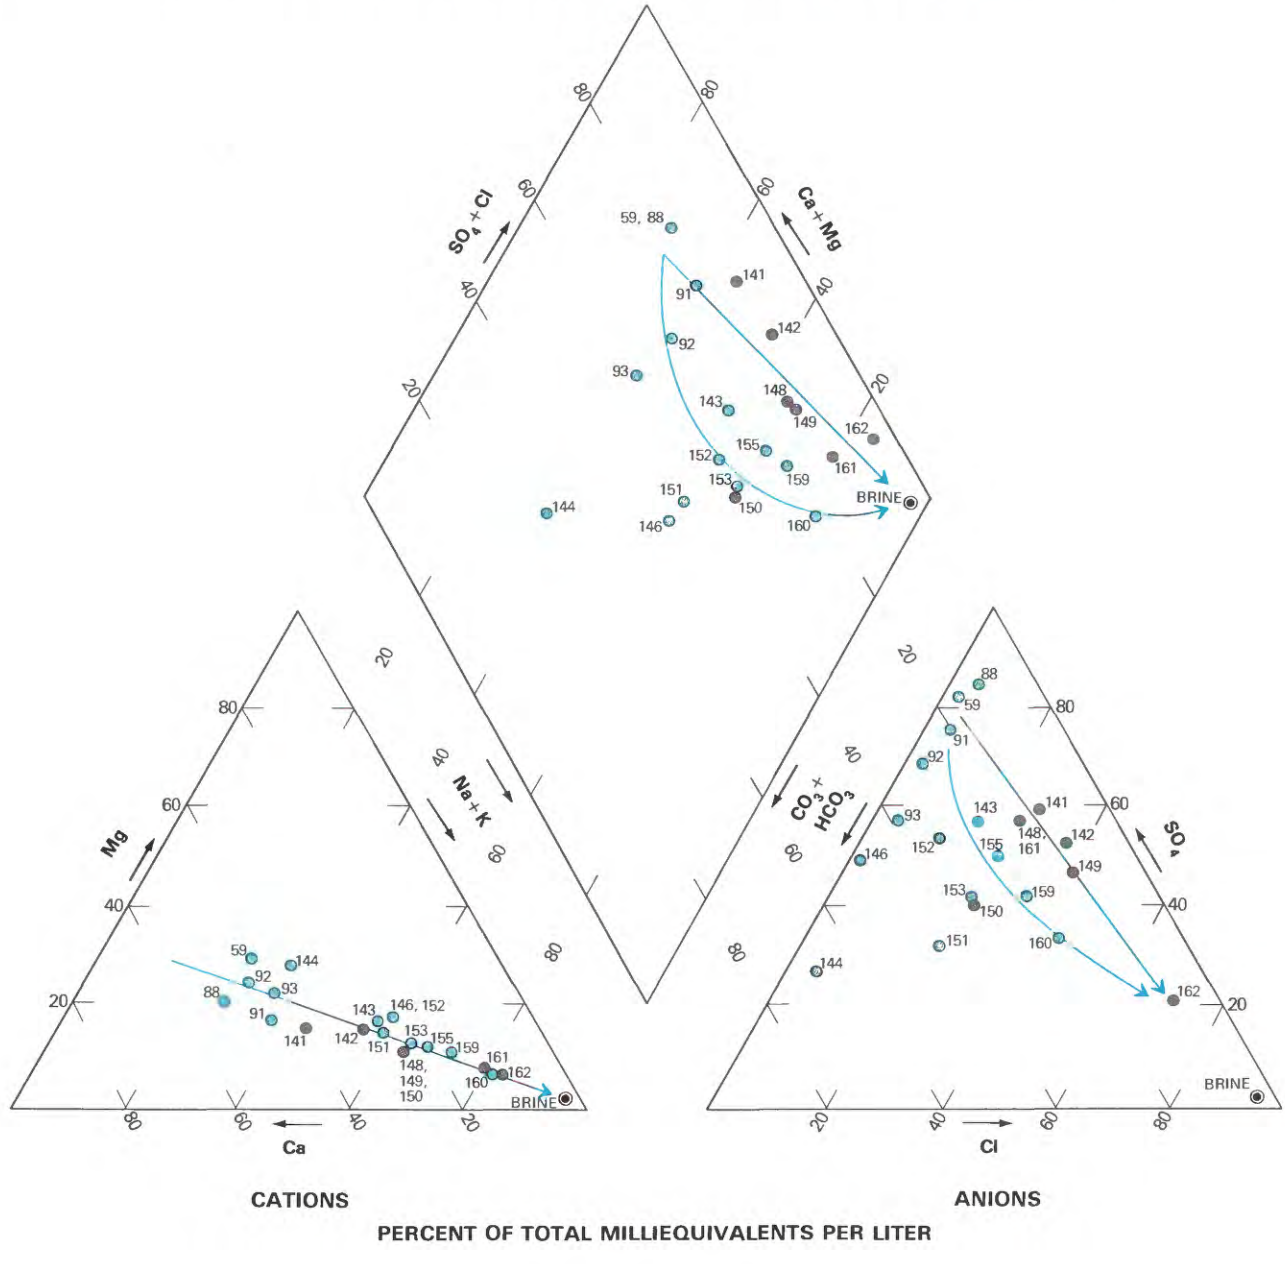

FIGURE 15.—Trilinear diagram of water chemistry along geochemical sections *A-A′* and *B-B′*.

reflect a gradual mineralization of the waters as they approach the Na-Cl brines of the Illinois basin. The origin of the brines is related to reverse chemical osmosis and membrane filtration (Graf and others, 1965; Clayton and others, 1966; Hanshaw and Coplen, 1973; Graf, 1982). The combined effects of these processes that concentrate sodium and chloride probably extend upgradient in the Cambrian-Ordovician aquifer system outside the Illinois basin proper. For example, chloride concentrations increase to more than 100 mg/L in southern Iowa, halfway down the regional flow paths from northwestern and western Iowa to southeastern Iowa (fig. 16). The overall trend toward more chloride-rich waters occurs even in central Iowa within the plume of low-dissolved-solids water, where concentrations of chloride are several times greater than to the northeast (figs. 7, 16). Figures 17 and 18 show concentrations of major constituents along geochemical sections A–A' and B–B'. Concentrations of chloride and sodium begin to increase from south-central Iowa down the major flow paths to the southeast toward the Illinois basin.

The trilinear plot of anions (fig. 15) shows that, although chloride is less than 10 percent, sulfate decreases from about 80 percent at the recharge area in western Iowa to about 55 percent near the Mississippi River. Bicarbonate plus carbonate increases from less than 20 percent to more than 40 percent. The apparent inverse relationship between equivalents of these constituents suggests that sulfate is possibly being reduced to sulfide along the hydraulic gradient, probably with an associated loss of oxygen, in the presence of a reducing agent such as organic material.

If the reducing agent is organic material, the following reactions are possible:

$$15CH_2O+2Fe_2O_3+8SO_4^{2-}+H_2CO_3 = 4FeS_2+16HCO_3^-+8H_2O \quad (11)$$

or

$$SO_4^{2-}+2CH_2O+2H^+ = H_2S+2CO_2+2H_2O. \quad (12)$$

Hematite (Fe_2O_3) and ferric oxyhydroxide [FeO(OH)] are common in the Cambrian-Ordovician aquifer system. Organic material is less common, but bacteriogenic decomposition of organic material occurs within the overlying Dakota Formation. Thus, recharge from the Dakota Formation and possible reduction of organic material in shales associated with aquifer layer 3 could produce bacteriogenic methane in water. Methane concentrations of as much as 15 ppm in aquifer layer 3 and 7 ppm in aquifer layers 2 and 1 were identified in southwestern Minnesota (Coleman, 1978; Minnesota Department of Natural Resources, written commun., 1981).

The equivalent weight of sulfate lost should approximately equal that of bicarbonate gained if the reactions are a reasonable explanation for the observed chemical changes (eqs. 11, 12). A plot of equivalents of sulfate against bicarbonate for sections A–A' and B–B' shows the contrary (fig. 19); as sulfate decreases, bicarbonate remains the same, at about 5 meq/L. Furthermore, saturation indices indicate that the ground water is oversaturated or is nearly in equilibrium with calcite and dolomite (fig. 11). Bicarbonate concentrations remain constant even in the vicinity of the dilute plume in central Iowa. If the dilute plume is caused by dilution of ground water with recharge water of low dissolved-solids content, the uniform bicarbonate concentrations and saturation indices would suggest that ground water has reequilibrated with carbonate minerals in the aquifer since the dilution episode or episodes. The mechanism, timing, and amount of such recharge can be explained hypothetically by glacial advances during the Pleistocene and are discussed later in the section "Isotopic Composition of Water and Pleistocene Recharge Model."

TRACE AND MINOR CONSTITUENTS

The areal distribution of many trace constituents in the aquifer system is related approximately to the availability of the constituents in the source rocks. Although specific data on the trace-element content of the aquifer matrix is lacking, compilation of the average distribution of elements in major rock types (Turekian and Wedepohl, 1961; Drever, 1982) indicates that higher concentrations of many transition metals are found in shales rather than in carbonate rocks or sandstones. Concentrations of the alkaline earth strontium and of halogens, such as bromine and fluorine, are more variable with respect to rock type.

The areal distribution of the transitional metals cadmium and arsenic in the aquifer system may be related to the proximity of the argillaceous Dakota Formation. Concentrations of these metals are generally less than 5 μg/L, except where the aquifer subcrops beneath the Dakota Formation in northwestern Iowa and southwestern Minnesota (fig. 20). Scant data suggest that selenium concentrations are less than 5 μg/L except at one location beneath the Dakota Formation. Cadmium concentrations may also increase to more than 5 μg/L in southeastern Iowa and northeastern Missouri on the edge of the Illinois basin. Concentrations of iron and manganese increase where the aquifer is overlain by the Dakota Formation and by drift derived from the Dakota (fig. 21). For example, concentrations of iron

and manganese exceed 1,000 μg/L and 100 μg/L, respectively, in northwestern Iowa. Concentrations of iron, manganese, copper, lead, and cobalt increase in southwestern Iowa near the margin of the Forest City basin (figs. 21, 22). Concentrations of cadmium and copper are more than 5 and 20 μg/L, respectively, in southeastern Iowa near the western flank of the Illinois basin (figs. 20, 22).

The controls on the concentrations of these and other trace metals are complicated and are related as much to complexation of metals by organic and inorganic ligands, sorption of metals onto solids, and oxidation-reduction potential of the water as to the metal content of the source rock (Garrels and Christ, 1965; Stumm and Morgan, 1981; Eichenberger and Chen, 1982; Hem, 1985). The influence of these processes on the trace-metal content of the water cannot be evaluated at the present time because the detection limits of the analyses for the metals were at reconnaissance levels and because information on the composition of dissolved organic carbon in the water and regional mineralogical and trace-metal composition of the aquifer matrix are

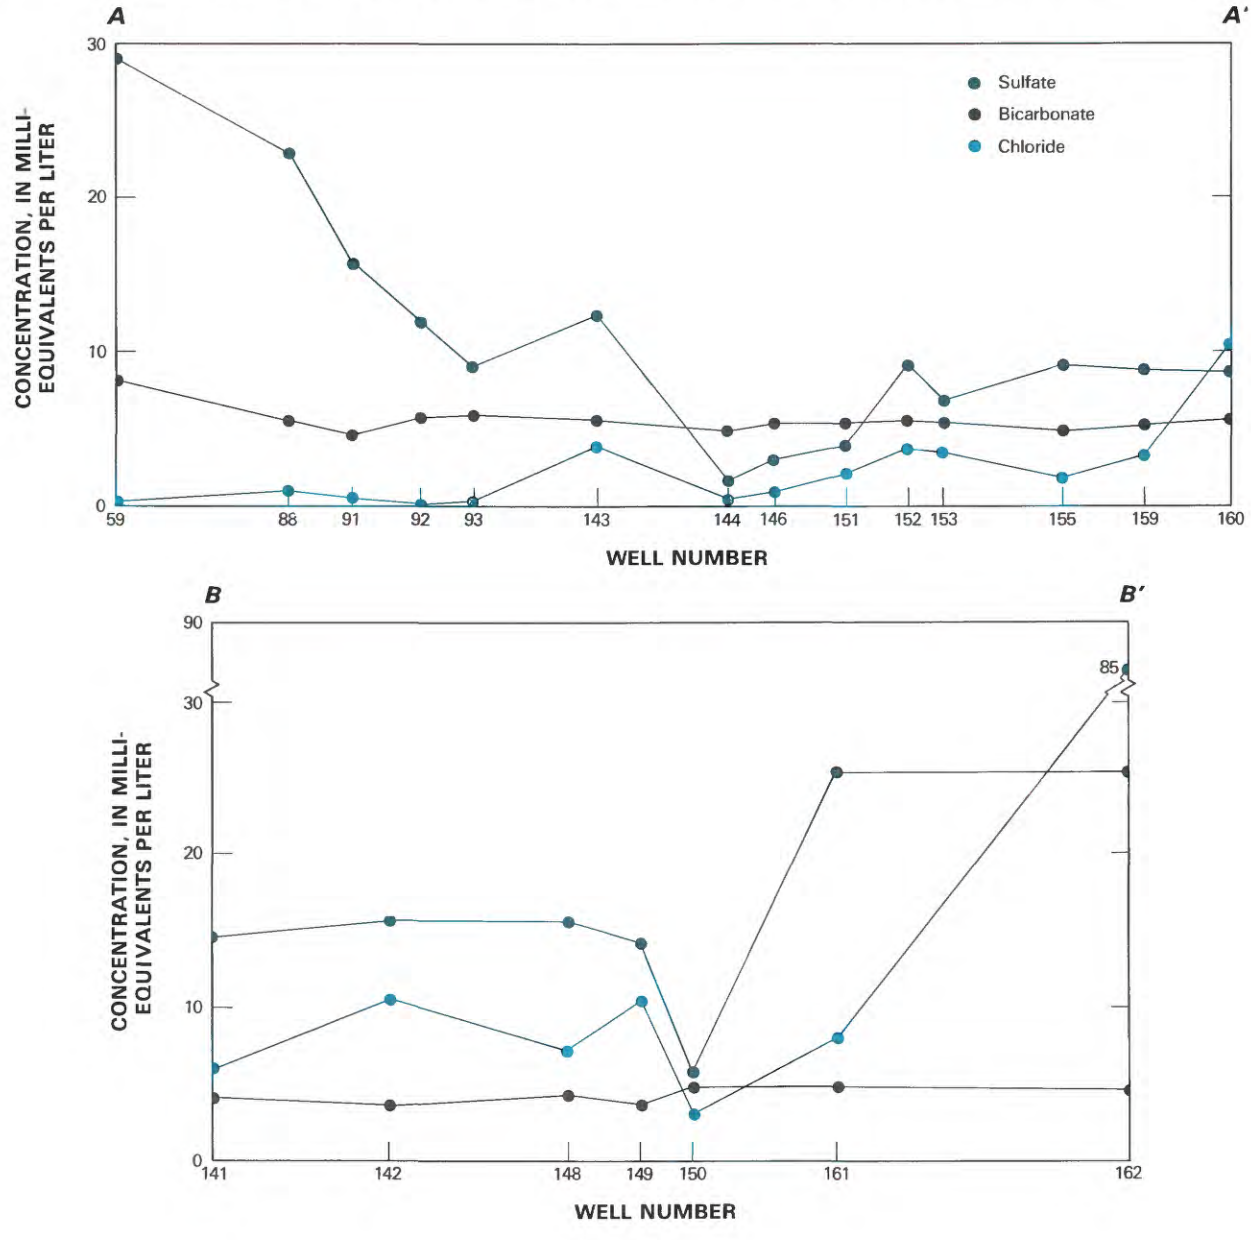

FIGURE 18.—Concentrations of major anions in water from wells in aquifer layers 1 and 3 along geochemical sections *A-A'* and *B-B'*. (Location of wells shown in fig. 6.)

lacking. Some trace metals, such as iron, can be reduced by bacteria at the pH values prevalent in the aquifer. Reducing conditions, identified by measurable dissolved sulfide, are present throughout the aquifer where it is confined by the Maquoketa Shale (fig. 14) and locally in the Dakota Formation (Burkart, 1984), and they probably are a major control on trace-metal concentrations in western Iowa.

The relationship between some trace-metal concentrations in ground water and proximity to the Forest City basin may be indicated by concentrations of beryllium and molybdenum of more than 1 and 10 μg/L, respectively, in southwestern Iowa (fig. 23). Concentrations of these and other metals may increase near the Illinois basin. However, no trace-metal data for water from the Cambrian-Ordovician aquifer system are available for that area. Several wells in northeastern and north-central Iowa inexplicably have molybdenum concentrations of more than 10 μg/L.

Some trace constituents that have relatively similar average concentrations in different sedimentary rock types show increases in concentration in ground water

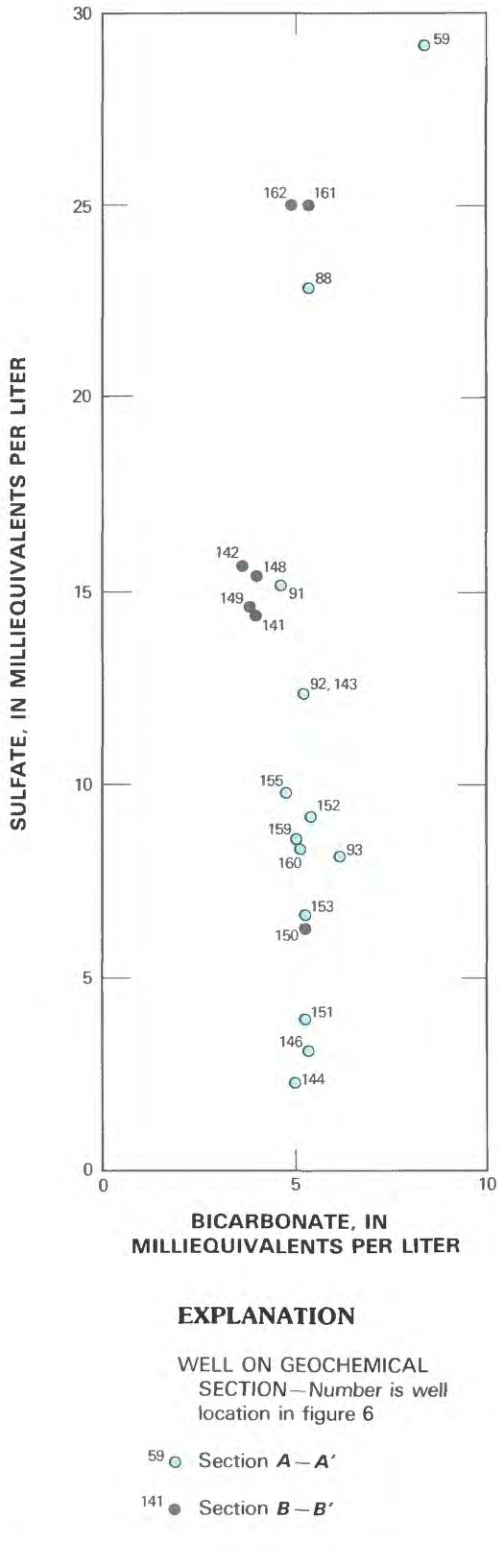

FIGURE 19.—Sulfate-bicarbonate relationship along geochemical sections *A-A′* and *B-B′*.

southwestward across Iowa and eastward across Wisconsin. For example, fluoride concentrations increase from less than 1 to more than 2 mg/L, lithium from less than 10 to more than 400 μg/L, boron from less than 200 to more than 2,000 μg/L, and strontium from less than 1,000 to more than 6,000 μg/L across Iowa (figs. 24–27). Strontium concentrations exceed 1,000 μg/L in eastern Wisconsin where dissolved solids generally exceed 500 mg/L (Nichols and McNall, 1957; Kammerer, 1981). Boron concentrations exceed 5,000 μg/L near the western edge of the Illinois basin (fig. 26).

There is no identifiable plume of dilute concentration of trace constituents in Iowa (as there is for dissolved solids), with the exception of bromide (fig. 28) and possibly lithium (fig. 25). Bromide concentrations in the aquifer are generally less than 0.5 mg/L except near the western edge of the Illinois basin, where concentrations approach 10 mg/L. In central and southern Iowa, a broad zone of bromide concentration of less than 0.5 mg/L is surrounded by areas of bromide concentrations of greater than 1.0 mg/L (fig. 28). This distribution roughly matches the dilution shown by the dissolved-solids distribution (fig. 7). Bromide is a conservative, relatively nonreactive constituent and therefore is a good indicator of hydrological processes that involve mixing of different water types. The lack of similar dilution plumes in the distribution of strontium, fluoride, and boron suggests that chemical processes other than mixing have controlled the distribution of these trace constituents, thus masking the reacharge plume(s).

Concentrations of barium in the ground water are related both to source and to geochemical processes. Gilkeson and others (1981) showed that barium concentrations or more than 1 mg/L in northeastern Illinois are due to a zone of reducing conditions in the confined Cambrian-Ordovician aquifer system. Sulfate ion is reduced to sulfide, thereby allowing concentrations of barium to increase until the solubility limit of barite ($BaSO_4$) is reached. Concentrations exceeding 100 μg/L in the northwestern part of the study area are probably due to barium contained in shales of the Dakota Formation (fig. 29). Concentrations also exceed 100 μg/L in the northeastern corner of Iowa near the Mississippi River. The cause of the higher barium concentrations in Iowa is unknown. Higher barium concentrations also are present in the aquifer in southeastern Wisconsin along the strike of the Maquoketa Shale, apparently an extension of the conditions in northeastern Illinois. Additional work is needed to determine whether the solubility of barite controls the high barium concentrations in these waters.

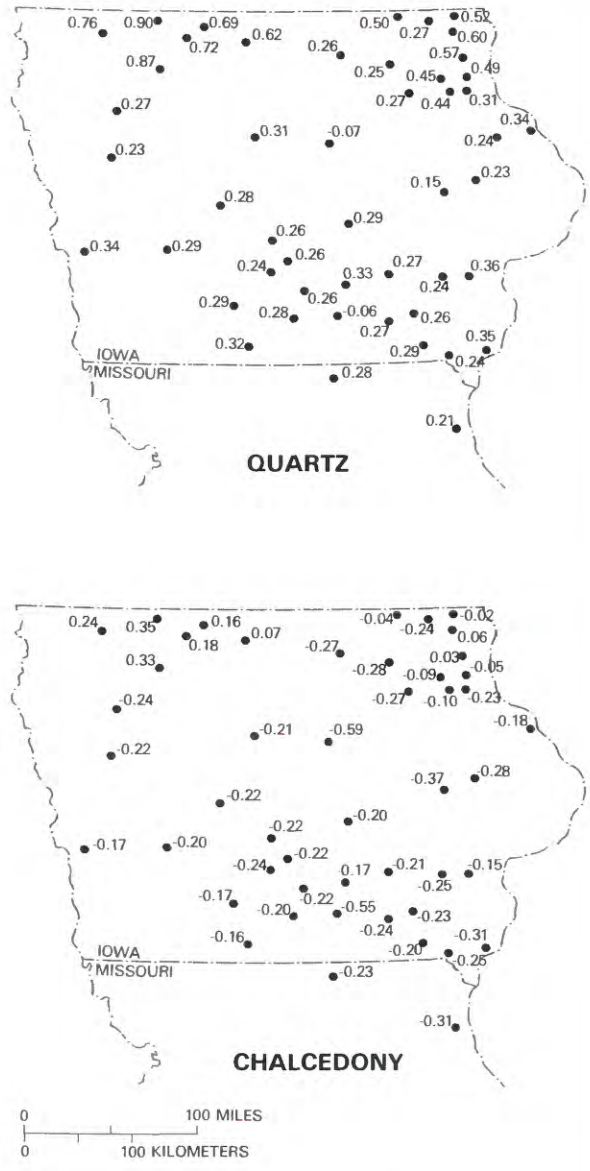

FIGURE 31.—Saturation indices for quartz and chalcedony in water from selected wells in aquifer layer 3 in Iowa and northeastern Missouri.

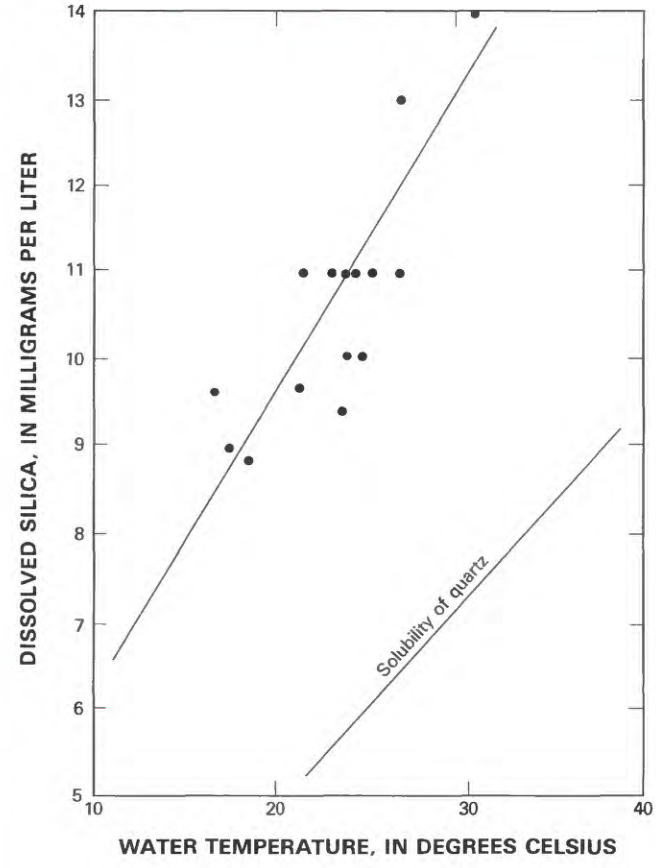

FIGURE 32.—Comparison of dissolved silica concentration and the solubility of quartz with water temperature in southwestern and southern Iowa and northeastern Missouri.

Concentrations of silica in the aquifer system range from less than 8 to more than 20 mg/L (fig. 30). The differences in silica content are related to the solubility of silicate phases in the aquifer matrix. Saturation indices show oversaturation of quartz and undersaturation of chalcedony (fig. 31); this is a typical occurrence in many waters. The solubility of silica in surface and ground water is related to solid-phase products of aluminosilicate mineral dissolution, but no aluminum data are available to test the thermodynamic models of such dissolution in a formal sense.

Concentrations of silica greater than 20 mg/L are present in the recharge area in northwestern Iowa, where the Dakota Formation and the overlying drift contain siliceous shales. Concentrations decrease downgradient to less than 10 mg/L in central Iowa, increase to more than 10 mg/L in south-central Iowa, and then decrease to less than 10 mg/L in southeastern Iowa. The distribution patterns of silica and temperature are very similar, showing the direct relationship of silica solubility to water temperature. However, the data in figure 32 indicate that the relationship of quartz solubility with temperature is not the control on dissolved silica (Helgeson, 1969). This suggests that silica phases other than quartz are contributing silica to the ground water.

FIGURE 33.—Distribution of dissolved uranium and radium-226 in aquifer layers 1 and 3.

The distribution of uranium and radium-226 in the aquifer system shows the effects of the dilution plume in Iowa (fig. 33) on the concentration of these constituents. Uranium exceeds 1 μg/L in northwestern and southeastern Iowa but is less than 1 μg/L in central and southern Iowa and in northern Missouri in the vicinity of the plume of low dissolved solids. The 5-pCi/L line of radium-226 activity clearly defines the shape of the plume. Activity increases to more than 15 pCi/L southward near the Iowa-Missouri border, but the scant available data show a decrease to 5 pCi/L in northern Missouri.

High radium activities have been identified in Iowa (Brown and Morris, 1959; Lucas, 1960, 1985; Morris and Klinsky, 1962; Horick and Steinhilber, 1978; Cochran and Hahne, 1979), eastern Wisconsin (Lucas, 1960, 1985; Hahn, 1984), and northeastern Illinois (Lucas and Ilcewicz, 1958; Krause, 1959, 1960; Larson and Weatherford, 1960; Lucas, 1960, 1985; Emrich and Lucas, 1963; Kristoff and others, 1975; Gilkeson and Cowart, 1982; Gilkeson and others, 1983).

The sources of the high radium concentrations in the ground water are probably related to uranium-238 and thorium-232 in the aquifer matrix. These radioisotopes decay to radium-226 and 228, respectively. In Illinois, Gilkeson and others (1978) used radium-226 and radium-228 concentrations in 33 samples of Cambrian and Ordovician rocks to estimate the equivalent amounts of uranium-238 and thorium-232, assuming equilibrium between the parent-daughter nuclides. Calculated average uranium-238 concentrations ranged from about 1 ppm in sandstone to about 3 ppm in shale. Direct determinations of uranium-238 indicated that uranium-238 and radium-226 are in equilibrium or near equilibrium in the Cambrian-Ordovician rocks.

The activity of radium-226 and concentrations of uranium in solution may not be directly correlated, however, because of restraints on the solubility of uranium in different redox (reduction-oxidation) environments. Uranium is mobile in oxidizing environments and immobile in reducing environments (Hostetler and Garrels, 1962; Langmuir, 1978). Gilkeson and Cowart (1982) observed a decrease in total uranium concentrations from a few tenths μg/L to less than 0.01 μg/L across a reduction front along a flow path in the Cambrian-Ordovician aquifer system in northeastern Illinois. Downgradient from the reduction front, however, uranium increased to more than 0.3 μg/L under oxidizing conditions. The decrease in uranium in the central part of Iowa also could be due partly to more reducing conditions along the major flow paths. The increase in uranium in southeastern Iowa, however, probably is not caused by increased uranium solubility in oxidizing conditions, because other chemical constituents, such as dissolved sulfide, indicate probable reducing conditions.

Radium-226 activity can be increased in the ground water along a reducing front because of decay of uranium in the water and uranium previously precipitated in the aquifer matrix. The decrease in uranium in Iowa is not accompanied by an increase in radium-226 from northeast to southwest. Therefore, concentrations of uranium and radium-226 in central Iowa seem to be related more to the dilution events than to geochemical processes in the aquifer system.

The activity ratio of $^{234}U/^{238}U$ generally increases across a reducing front because of alpha-recoil transfer (Kronfeld and others, 1975; Cowart and Osmond, 1977). No such increase in the activity ratio is apparent from the data in central Iowa. However, to relate redox relationships to uranium and radium in ground water, more detailed sampling is necessary at a closer spacing than for the reconnaissance purposes of this study. Defining sources and sinks for radium and uranium in the study area would require more detailed information on the concentrations and isotopic variability of these constituents and thorium in aquifer matrices and ground water. For example, in a more detailed study, Gilkeson and Cowart (1982) determined $^{234}U/^{238}U$ alpha-activity ratios in ground water from the aquifer system along a flow path from the unconfined to confined system in northeastern Illinois. Where the aquifer is confined by the Maquoketa Shale, ratios exceed 20, but in the unconfined area, ratios are generally less than 5. The disequilibrium in the confined area is pronounced, and Gilkeson and Cowart (1982) suggest that dissolved uranium was emplaced in the aquifer during Pleistocene glaciation when flow directions may have been different from those of today. Uranium-234 could then have been leached from glacial till and the Maquoketa Shale. However, the observed disequilibrium still is problematical, because the role of geochemical and radiogenic mechanisms in enriching the isotopic ratio is not fully understood (Gilkeson and others, 1978).

Similar disequilibria are found in selected samples of water from aquifer layer 3 in Iowa. $^{234}U/^{238}U$ activity ratios determined from a few selected water samples showed disequilibrium and range from 2.3 to 14.1 with no discernible pattern (fig. 33). For example, the ratio is 9.1 for water in the northwest recharge area associated with the Dakota Formation as well as for water in the central dilute plume area. The scant data suggest that the ratio in Iowa increases generally toward the south, but additional data are needed to verify the trend.

A water sample from a 2,673-ft-deep test well drilled during this study at Green Island in extreme eastern Iowa is of particular interest. The sample from the interval 1,741 to 2,673 ft in the Mount Simon Sand-

stone had the extraordinarily high ratio of 100 (fig. 33). This may be the largest known uranium disequilibrium in an aquifer system. Gilkeson and Cowart (1982) indicate that the highest reported ratio prior to their work was 12.3. They measured activity ratios as high as 28.6 in the Cambrian-Ordovician aquifer system in northeastern Illinois and activity ratios "greater than 40" in the aquifer system in other parts of Illinois.

Gilkson and Cowart (1982) hypothesize that such extreme disequilibrium may be related to influx of uranium-234-enriched uranium derived from fine-grained materials during the emplacement of glacial meltwater during the Pleistocene. The uranium-234-enriched ground water could be further enriched by isotopic fractionation caused by precipitation of the uranium in the reducing zone downgradient from the meltwater recharge front. Unfortunately, the scant areal distribution of the uranium isotope data for this study is not sufficient to evaluate this hypothesis further, and the causes of the isotopic enrichment are still unknown.

ISOTOPIC COMPOSITION OF WATER AND PLEISTOCENE RECHARGE MODEL

The direction of the dilute plume, from northeastern Iowa to south-southwestern Iowa, suggests a flow system having recharge areas in southeastern Minnesota and northeastern Iowa and discharge areas in Missouri or farther south. The study region was glaciated numerous times during the Pleistocene Epoch. Work by Boellstorff (1976, 1980) indicates that at least Nebraska and Iowa were glaciated as long ago as 2.5 m.y. (million years) and that the classic Nebraskan-Kansan sequence of glaciation—now referred to as Pre-Illinoian (Richmond and Fullerton, 1986)—occurred 1.0 to 0.4 m.y. ago. At least five ice advances occurred in Iowa and Nebraska during this time. No similar sequence of glaciation has been identified in Wisconsin and Illinois to date, but evidence of such glaciation could be obscured by glaciation during Illinoian and Wisconsin time, from about 100,000 to 12,000 yr B.P. (years before present).

The extent of major glaciations (fig. 34) has been estimated from the stratigraphic relationships among glacial deposits (Flint, 1972). Pre-Illinoian advances extended almost to the Missouri River and covered much of the study area. Later advances during Illinoian time covered most of Illinois and parts of Wisconsin. During Wisconsin time, numerous ice lobes advanced into Wisconsin, Minnesota, Iowa, and Illinois.

Theoretical reconstructions of the temperature distribution in continental Pleistocene glaciers have indicated that a pressure-melting zone probably was extensive in the basal part of the ablation zone. The zone may have extended upgradient for a few hundred miles from frozen ice margins (Hooke, 1977; Sugden, 1977; Moran and others, 1980). Glacial movement in these unfrozen areas involved basal sliding (Weertman, 1957, 1961, 1964; Clayton and Moran, 1974). Landforms such as drumlins, tunnel valleys, and streamlined ridges are field evidence for basal melting (Wright, 1973; Clayton and Moran, 1974; Moran and others, 1980) where meltwater under high hydrostatic head could have recharged the Cambrian-Ordovician aquifer system in outcrop areas.

The isotopic composition of oxygen and hydrogen in the ground water in the aquifer system is important geochemical evidence for such recharge. The distribution of $\delta^{18}O$ and δD in modern precipitation shows excellent covariation with both mean annual air temperature and latitude because of isotope fractionation by the Raleigh distillation effect (Dansgaard, 1964). Covariation between $\delta^{18}O$ and δD of modern precipitation defines an average meteoric water line (Craig, 1961), expressed as

$$\delta D = 8\,\delta^{18}O + 10, \qquad (13)$$

to which the isotopic content of ground water can be compared. If past ground-water recharge occurred under climatic conditions similar to those of today, then the isotopic composition of the ground water should be similar to that of modern recharge. However, if the ground water originally precipitated at temperatures colder than today, its isotopic composition should be lighter than modern recharge but should still plot near the meteoric water line (eq. 13). Deviations of the data from the trend of the line indicate that geochemical processes, such as water-rock interaction, evaporation, or ultrafiltration, have modified the isotopic composition of the water.

The relationship of $\delta^{18}O$ to δD in ground water in the Cambrian-Ordovician aquifer system exclusive of the Illinois basin is similar to the isotopic composition of modern precipitation (fig. 35). This indicates that the water in the Cambrian-Ordovician aquifer system outside the Illinois basin retains its meteoric nature and has been relatively unaltered by significant reactions with the aquifer matrix. Water in the Illinois basin is enriched in oxygen-18 because of probable exchanges between carbonate rock and water at temperatures more than twice the temperature in the fresher and shallower parts of the aquifer system (Clayton and others, 1966). The average $\delta^{18}O$ and δD of modern precipitation in the study area ranges from about −8 to −6 ‰ and from −70 to −50 ‰, respectively, from

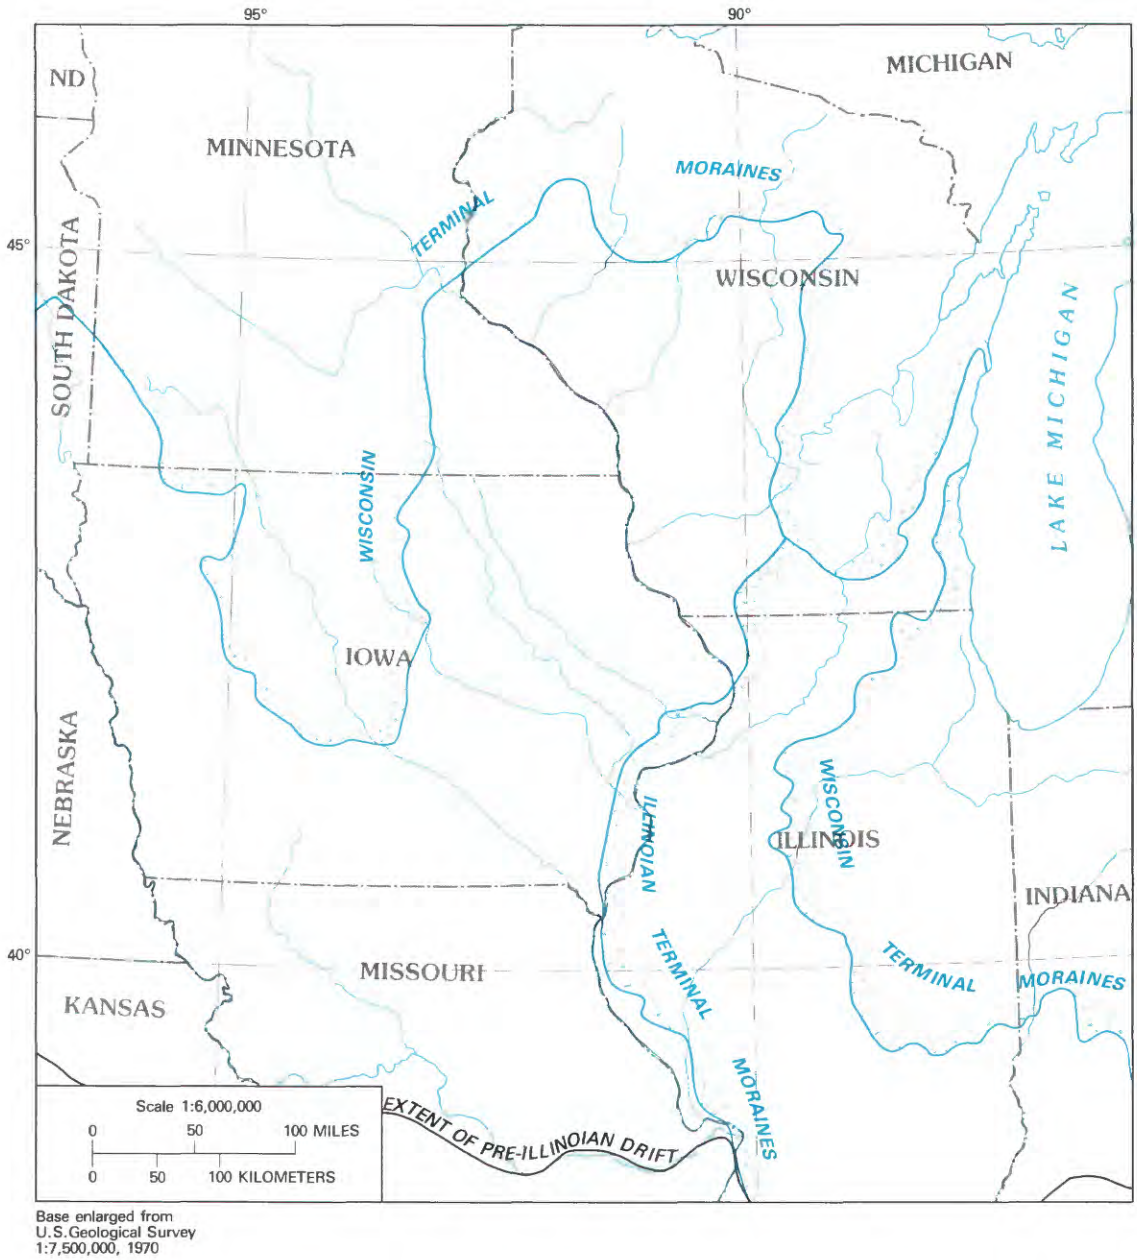

FIGURE 34.—Extent of major glaciations in the northern Midwest during the Pleistocene Epoch.

north to south (Yurtsever, 1975). The difference in $\delta^{18}O$ and δD between water in the aquifer and in modern precipitation, as much as −9 and −70 o/oo, respectively, indicates past recharge to the aquifer system that is isotopically similar to water now precipitated at colder latitudes hundreds of miles north of the study area. No shift occurs in the isotopic content of water across the Holocene-Pleistocene boundary in regional aquifers unaffected by glaciation (Hanshaw and others, 1978). This suggests that the light isotopic composition of the ground water is not a result of continental differences in the isotopic composition of interstadial precipitation.

Isotopically light ground water in the aquifer system in northern Illinois has been described previously and explained as Pleistocene recharge (Clayton and others, 1966; Gilkeson and others, 1981; Perry and others, 1982). Regional distribution of the isotopic composition of water in the aquifer system (figs. 36, 37) closely approximates the distribution of dissolved solids (fig.

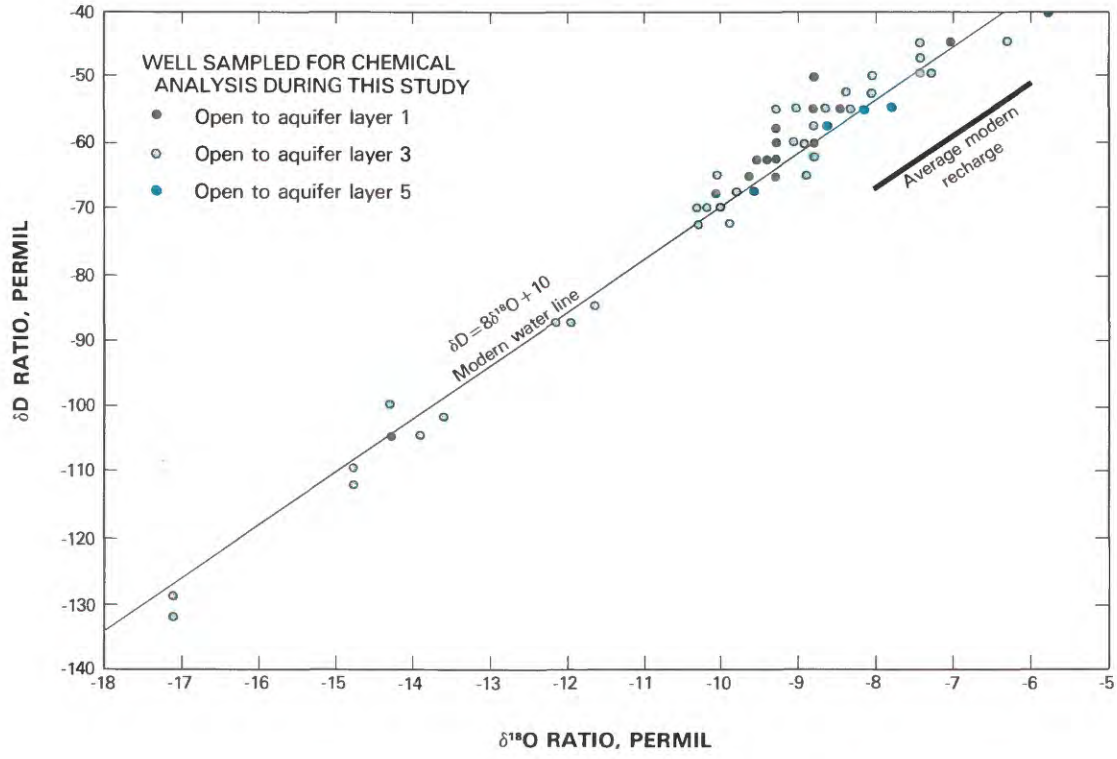

FIGURE 35.—$\delta^{18}O$-δD relationship for ground water in the northern Midwest.

7). In Iowa and Missouri, ground water is isotopically lighter toward the south, approximately perpendicular to the direction of the modern hydraulic gradient. The boundary of the dilute plume in central Iowa is coincident with the −10 o/oo $\delta^{18}O$ isoline. The plume, although isotopically about 2 to 4 o/oo lighter with respect to $\delta^{18}O$ than modern recharge at the same latitude, is isotopically heavier than surrounding ground water. The extension of the −10 o/oo line into south-central Iowa and the distribution of dissolved solids suggest a ground-water flow direction approximately perpendicular to that of today.

The $\delta^{18}O$ content of North American ice sheets could have ranged from about −40 o/oo (Dansgaard and Tauber, 1969) to −9 o/oo (Emiliani, 1971). Yapp and Epstein (1977), using calculations from δD of cellulose in plant material entrained in drift, suggest an intermediate $\delta^{18}O$ of −15 o/oo for the ice of the latest Wisconsin advance. If the isotopically lightest water in the aquifer system in southern Iowa were emplaced during this time, virtually all the ground water in the southwestern part of the study area would be recharged from glacial meltwater. This is unlikely because the dissolution of carbonate and silicate minerals at aquifer temperatures (less than 40 °C) would not produce concentrations of dissolved solids exceeding 2,500 mg/L or the large equivalent percentages of chloride and sodium found in the southwestern part of the aquifer. Therefore, the isotopic content of the ground water probably represents a mixture of meltwater with $\delta^{18}O$ depleted to less than −17 o/oo and pre-Pleistocene ground water with $\delta^{18}O$ enriched to more than −17 o/oo, and perhaps similar to the isotopic content of modern recharge.

The shape of the dilute plume looks similar to the shape of the Des Moines lobe which covered part of north-central Iowa during the last advance of Wisconsin ice. This suggests that the plume may be related to this ice advance. The isotopic content of water in the dilute plume would be lighter than −10 o/oo if the plume were caused by meltwater recharge under the lobe through the outcrop area in southern Minnesota. However, the possible displacement of ground water having low dissolved solids from overlying Paleozoic aquifers to aquifer layer 3 by vertical leakage of subglacial meltwater cannot be ruled out unequivocally at this time.

Scant data indicate that dissolved-solids concentrations in aquifer layer 4 are generally more than 1,000 mg/L where the aquifer is overlain by Mississippian rocks in central Iowa but are generally less than 500 mg/L in outcrop areas north of the Mississippian erosional edge (U.S. Geological Survey, unpub. data).

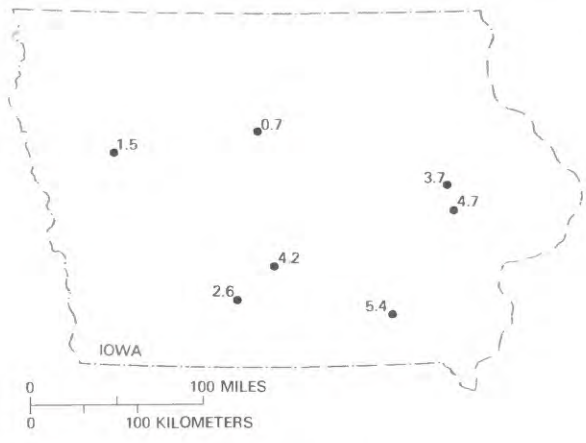

FIGURE 38.—Carbon-14 data for water from selected wells in aquifer layer 3 in Iowa.

Dissolved-solids concentration in ground water from Mississippian rocks in north-central Iowa is more than 500 mg/L. The 1,000-mg/L isoline of dissolved solids in the Mississippian rocks roughly outlines a dilute plume trending from north-central to southwestern Iowa (Horick and Steinhilber, 1973), similar to the plume in aquifer layer 3.

Downward movement of meltwater from the base of the Des Moines lobe into the Mississippian rocks could have started a series of downward displacements of water from layer to layer: recharge of water with low dissolved solids into the Mississippian; higher disolved-solids water (more than 1,000 mg/L) from the Mississippian into aquifer layer 4; and water with low dissolved solids from aquifer layer 4 into aquifer layer 3, forming the dilute plume. Water in aquifer layer 4 could have had a $\delta^{18}O$ content ranging from −8 to −6 o/oo if it were not mixed with meltwater recharge from previous glaciations. Downward flow of water from aquifer layer 4 to aquifer layer 3 could have resulted in both dilution and isotopic enrichment. However, additional isotopic data for ground water from aquifer layer 4 and the Mississippian in central Iowa are needed to evaluate better the influence of the Des Moines lobe on the Cambrian-Ordovician aquifer system.

The time, or times, of meltwater emplacement is unknown. Seven carbon-14 analyses of ground water from aquifer layer 3 in Iowa have a range of 0.7 to 5.4 percent modern carbon (fig. 38). These values correspond to apparent ages ranging from more than 30,000 to about 15,000 yr B.P., respectively, corrected for isotopic dilution by dissolution of carbonate aquifer minerals. The smallest amount of modern carbon occurs in central Iowa within the dilute plume. This could reflect either the age of water in aquifer layer 3 or a composite age of water from aquifer layers 3 and 4, if vertical recharge occurred beneath the ice of the Des Moines lobe. A small amount of modern carbon may have been introduced in the sampling procedure at other sites as contamination from atmospheric carbon dioxide (E.C. Alexander, University of Minnesota, written commun., 1982; L.N. Plummer, U.S. Geological Survey, oral commun., 1982). Water in aquifer layer 1 at St. Paul, Minn., has an apparent age of more than 35,000 yr B.P. (Alexander and others, 1983), and very likely water in the Cambrian-Ordovician aquifer system in southern Iowa and northern Missouri also contains little or no measurable carbon-14 because flow paths are many times longer than in Minnesota.

The possible emplacement of meltwater during the late Pleistocene was independently tested using the steady-state three-dimensional ground-water flow model of Mandle and Kontis (in press) to simulate the Cambrian-Ordovician aquifer system under the pressure head caused by the weight of the glacial ice about 18,000 yr B.P. The head values for the water-table aquifer (aquifer layer 5) in the ice-covered areas (fig. 39) were estimated as the sum of the elevation head at the land surface and the pressure head from the ice. The water-table aquifer is represented by constant-head nodes in the model and provides the hydraulic driving force to simulate ground-water flow. An average Wisconsin glacial ice-sheet configuration was assumed similar to that described by Denton and Hughes (1981). The static steady-state topography of the ice sheets at maximum advance calculated by Denton and Hughes (1981) was based on the modern analog of the Greenland and Antarctic ice sheets. This may be incorrect because geologic evidence suggests that the Laurentide ice sheet did not attain a steady-state profile everywhere but may have been highly dynamic (Clark, 1980; Andrews, 1982). Nevertheless, the Denton and Hughes (1981) model is probably a first approximation for the general morphometry of the major ice lobes that entered the northern Midwest during Wisconsin time. Hydraulic parameters, boundaries, and nodal distribution for all aquifer layers were those used in a steady-state flow model of the modern Cambrian-Ordovician aquifer system described by Mandle and Kontis (in press). The position of the ancestral Mississippi River was assumed to be similar to its present position. Although the ancestral Mississippi River was displaced in some areas during the late Pleistocene, the displacement did not significantly alter the general drainage pattern from

north to south near the border of Iowa and Illinois (Flint, 1972).

Results of the steady-state flow model show that the distribution of ice at the average Wisconsin advance probably did not significantly change the direction of ground-water flow in most of Iowa and Missouri (fig. 40). Ground-water flow paths, in general, were from northwestern Iowa southeastward to the Illinois basin.

GENERALIZED GROUND-WATER FLOW PATH

MODELED LAYER 3 BOUNDARY

BOUNDARY OF GROUND-WATER FLOW MODEL

FIGURE 40.—Simulated hydraulic head in aquifer layer 3 at the average advance of ice, about 18,000 yr B.P., during late Wisconsin time.

Some ground-water flow was diverted from central to northeastern Iowa from a local ground-water divide that is symmetrical with the axis of the Des Moines lobe in Iowa. In eastern Wisconsin and Illinois, simulated ground-water flow was opposite from that of today: ground-water recharge zones were in the vicinity of Lake Michigan, and discharge zones were the outcrop areas in Wisconsin, northeastern Iowa, southeastern Minnesota, and northern Illinois. Results of the flow model show that, during late Wisconsin time, the net movement of ground water was not in the direction of the dilute plume, from northeastern to southwestern Iowa. Much of the outcrop area of the aquifer in Wisconsin, Iowa, and Illinois was probably a discharge zone, as suggested by the results of the flow model, and not a recharge zone, as suggested by the geochemical data.

Model-calculated horizontal flow rates of the present flow system in Iowa are extremely slow, ranging from a few feet per year in the recharge area in northwestern Iowa to less than 1 ft/yr in deeper parts of the aquifer (Mandle and Kontis, in press). These flow rates indicate that residence time for most of the water in the aquifer system could be tens of thousands to hundreds of thousands of years. The slow flow rates compare favorably with the carbon-14 date of more than 35,000 yr B.P. for water in aquifer layer 1 from a well in St. Paul, Minn. (Alexander and others, 1983).

Model-calculated horizontal flow rates under the Des Moines lobe are about 10 times larger than present flow rates. Model-calculated vertical leakage from aquifer layer 4 to aquifer layer 3 in the confined part of Iowa is less than 5,000 (ft^3/mi^2)/yr, even under simulated glacial head from the Des Moines lobe. This amount of vertical leakage is insignificant with respect to the total amount of water in aquifer layer 5. The volume of water per square mile in aquifer layer 3 is approximately 2×10^9 ft^3, assuming an average thickness of 300 ft and a porosity of 0.25. Only about 2.5 percent of the water in the aquifer would be replaced in 10,000 yr at the maximum calculated flow rates owing to glacial-ice loading.

This computed result suggests that downward leakage from younger Paleozoic rocks to aquifer layer 3 probably did not cause the dilute (low dissolved solids) plume in Iowa. However, fracture permeability in younger confining units and in the carbonate rocks of the aquifer system was not specifically addressed in the model because of the paucity of field data needed to define fracture locations and patterns. Consequently, the possibility of larger amounts of vertical leakage during glaciation still exists and needs to be tested by additional isotopic data, as discussed previously.

An alternative hypothesis to explain the isotopically defined plume in Iowa is a southerly displacement of ground water having an isotopic content similar to that of modern recharge from the outcrop area in southern Minnesota. Model-calculated flow rates in aquifer layer 3 for the average ice advance in south-central Minnesota range from 10^{-6} to 10^{-5} ft/s. At the fastest rate, meltwater would move downgradient about 60 mi in 1,000 yr. The Des Moines lobe probably was on the outcrop area in southern Minnesota for 2,000 yr, from about 16,000 to 14,000 yr B.P. (Wright, 1972), so the model results indicate that it is possible to have had significant meltwater displacement of ground water ($\delta^{18}O$ content of about −8 o/oo) toward Iowa. The meltwater that replaced the ambient ground water would be isotopically very light. This characteristic should be identifiable today in southern Minnesota, where the aquifer is confined and flow rates are low. On the contrary, $\delta^{18}O$ content of water in aquifer layer 3 in south-central Minnesota is about −9 o/oo; this $\delta^{18}O$ content is only slightly depleted relative to modern recharge and is not characteristic of isotopically depleted water, such as is found in southern Iowa and central Illinois.

The hypothetical steady-state model of the ground-water flow system at the maximum glacial advance during Wisconsin time shows that flow rates are increased significantly only under, and immediately next to, the ice sheets. The simulated effect of the additional pressure head on the potentiometric gradient contributed by the ice sheets is dampened considerably within 30 to 50 mi from the edge of the ice (fig. 40). The steady-state model simulations of predevelopment conditions and with glacial-ice loading during Wisconsin time suggest that the time necessary for a unit volume of recharge in northeastern Iowa and in southern Minnesota to reach north-central Missouri would have been at least tens of thousands of years. Confinement by the ice could accelerate flow rates in Iowa south of the Maquoketa Shale outcrop.

HYPOTHETICAL GEOCHEMICAL MODELS

Previous studies of the chemistry of regional aquifer systems have used mass-balance and reaction models to evalute, at least semiquantitatively, the extent of chemical mass transfer from solid to aqueous phases and the evolution of different water types—for example, Thorstenson and others (1979), Plummer (1977), Chapelle (1983), Plummer and Back (1980), and Plummer and others (1983). These models have been particularly useful for evaluating chemical changes associ-

ated with mixing of different water types—for example, Plummer (1975) and Wigley and Plummer (1976).

The extent to which these approaches can be successfully used in the present study of the geochemistry of the Cambrian-Ordovician aquifer system is limited, because critical data are still unavailable on the solid phases in the aquifer, the isotopic composition of Pleistocene glacial meltwater and precipitation, the pre-Pleistocene topography and water table, and local values for hydraulic characteristics.

The chemical composition of major solid phases, such as calcite, in the aquifer matrices in central Iowa is unknown. Information on bulk chemistry of the rocks and petrographic information on the type and nature of cementation in the rocks are necessary to check the accuracy of mass-balance calculations of net dissolution or precipitation of carbonate minerals (Chapelle, 1983). Identification of clay minerals in the aquifer matrix also is needed to determine appropriate ion-exchange selectivity coefficients for use in thermodynamic models of reaction progress. Estimates of ion-exchange selectivity coefficients from water chemistry (Thorstenson and others, 1979) are not applicable because of possible multiple sources and mechanisms for observed increases in sodium concentrations in southern Iowa and northern Missouri. No direct information is available on the isotopic composition of carbon in the aquifer matrix. Such data are critical to the use of $\delta^{13}C$ information to check the mass-balance models. Furthermore, detailed mass-transfer models that have been used to evaluate carbon isotopes in other aquifer systems (Wigley and others, 1978) cannot be applied to the Cambrian-Ordovician aquifer system because location and magnitude of past recharge were pulselike, depending on the configuration, timing, and duration of the ice sheets during the Pleistocene. Present-day concentrations of solutes may not represent steady-state conditions, and effects of hydrodynamic dispersion on the isotopic composition of ground water during recharge events cannot be excluded.

The $\delta^{18}O$ and δD composition of ground water in the Cambrian-Ordovician aquifer system is probably a composite derived from numerous episodes of Pleistocene recharge to the aquifer system. Assuming that the isotopic composition of the water is conservative, based on the clustering of data around the modern meteoric water line discussed previously (fig. 35), a mixing model can be prepared. However, to prepare such a model, the isotopic composition of both the pre-Pleistocene ground water and the Pleistocene recharge must be known. Within the aquifer system, the isotopic gradient toward lighter water from central to southwestern Iowa shows *no reversal* in trend (figs. 36, 37). The isotopically lightest water may, consequently, be even more depleted in $\delta^{18}O$ than −17 o/oo. Estimation of the $\delta^{18}O$ of Pleistocene recharge is also difficult because the $\delta^{18}O$ of meltwater from glacial ice could have ranged at least from −40 to −15 o/oo. The isotopic composition of precipitation in the region during the Pleistocene may have been different from what it is today.

A mixing model of a chemically conservative constituent is made using the generalized equation

$$C_1(1-Q_2)+ C_2Q_2=C_{mixture}, \quad (14)$$

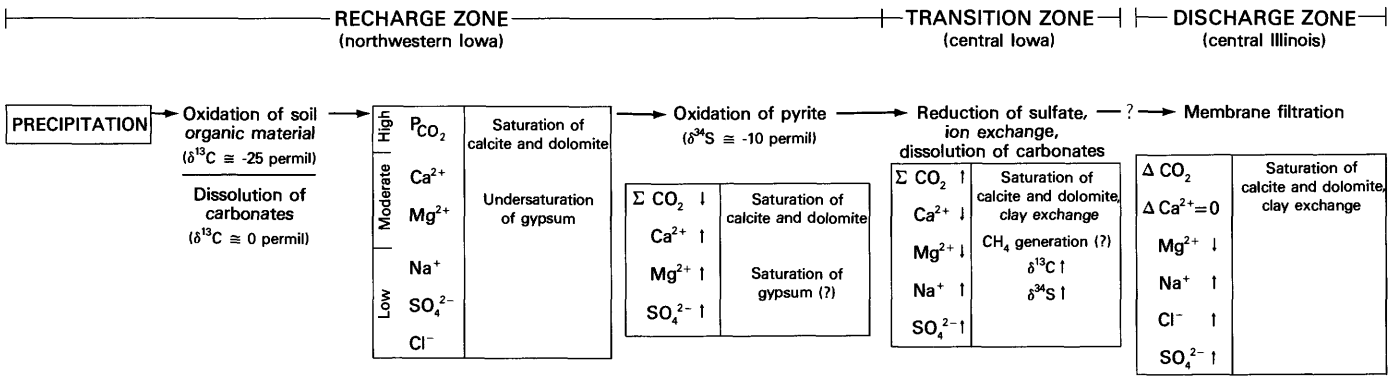
where

C_1=concentration in water 1,
C_2=concentration in water 2, and
Q_2=fraction of water 2 in the mixture.

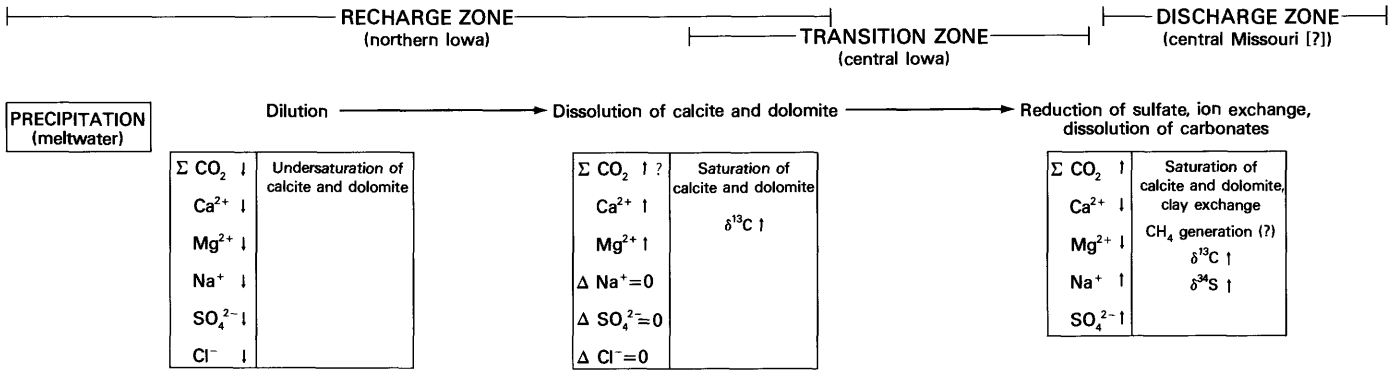
As an example of a mixing model, the following conditions were assumed:

1. Pre-Pleistocene ground water had an istotopic composition similar to the present-day recharge water of about −7 o/oo of $\delta^{18}O$.
2. Glacial meltwater entered the aquifer, resulting in a $\delta^{18}O$ of −17 o/oo, the most isotopically depleted water identified.
3. Subsequent recharge southwestward caused the plume outlined by the −10 o/oo line of $\delta^{18}O$. This recharge water is assumed to have a $\delta^{18}O$ value of −8 o/oo, which is about 1 o/oo lighter than modern recharge.

It follows from these assumptions and for equation 14 that a 1:2.3 mixture of meltwater ($\delta^{18}O$ of −40 o/oo) and pre-Pleistocene ground water ($\delta^{18}O$ of −7 o/oo) would produce an observed $\delta^{18}O$ of −17 o/oo. This first-phase mixture subsequently would have had to be mixed with Pleistocene recharge ($\delta^{18}O$ of −8 o/oo) at ratios of up to 1:9 to produce the present isotopically heavier plume in central Iowa. If the $\delta^{18}O$ of the first mixture were lighter than −17 o/oo, the second-phase dilution would be larger. If recharge in the second mixing phase was isotopically heavier, that is, derived from precipitation during warm interstadial periods (Emiliani, 1955; Ruddiman and McIntyre, 1976), a smaller volume of recharge would have been required. For example, if in the hypothesized second mixing phase $\delta^{18}O$ of Pleistocene recharge in the plume area was about 1 o/oo heavier than in modern precipitation (−6 rather than −7 o/oo), the mixing ratio of ground water with $\delta^{18}O$ of −17 o/oo and recharge with −6 o/oo would have been about 1:2 to produce the heavier plume. These exercises indicate that the amount of Pleistocene meltwater currently in the plume area of aquifer layer 3 could be as much as 90 percent, depending on which isotopic values were chosen in the calculations. If the



EVOLUTION OF WATER CHEMISTRY FROM NORMAL RECHARGE



EVOLUTION OF WATER CHEMISTRY FROM MELTWATER RECHARGE

FIGURE 41.—Hypothetical geochemical models for the evolution of water chemistry in the Cambrian-Ordovician aquifer system.

$\delta^{18}O$ of the pre-Pleistocene ground water was heavier than that of modern precipitation, the total percentage of Pleistocene glacial meltwater in the aquifer system would be less.

The hypothetical hydrologic and geochemical processes that may have affected the water quality of the Cambrian-Ordovician aquifer system are illustrated in figure 41. Preglacial water quality in the major recharge areas in Wisconsin, Minnesota, and northeastern Iowa may be controlled by dissolution of carbonate minerals in the aquifer matrix. Dissolution of carbonate minerals, ion exchange, and oxidation of pyrite may modify the water quality in northwestern Iowa and southwestern Minnesota. Oxidation of pyrite in the Dakota Formation and in glacial till derived from the Dakota Formation produces sulfuric acid (eq. 7) that would increase both the dissolution of carbonate minerals and the concentration of sulfate. Activities of sulfate and calcium may locally approach the solubility of gypsum, although, generally, ground water in the aquifer system and the overlying Dakota Formation and glacial drift is undersaturated with respect to gypsum and other evaporite minerals. Sulfate reduction, oxidation of organic material, and methane generation decrease concentrations of sulfate and increase inorganic carbon content. Downgradient into the transition zones of Ca-Na-SO_4-HCO_3 and Na-Ca-SO_4-HCO_3 facies in Iowa, additional sulfate reduction, unaccompanied by ion exchange, could cause carbonate precipitation. Membrane filtration near and in the Illinois basin may have caused precipitation of calcite, possible dolomitization of the aquifer matrix in the Illinois basin (Graf and

others, 1966; Nesbitt, 1980; R. Shedlock, U.S. Geological Survey, written commun., 1982), and increases in sodium and chloride concentrations.

Glaciation and emplacement of Pleistocene meltwater in the aquifer system in Iowa and Missouri could cause dilution of all ground-water solutes. Although concentrations of conservative solutes, such as bromide and chloride, remained low, redissolution of carbonate minerals in the aquifer matrix increased the bicarbonate, calcium, and magnesium until equilibrium with the carbonate minerals was reestablished. This dilution and reequilibration process could have occurred many times. Glaciation also could temporarily enhance the extent of pyrite oxidation in Iowa because additional pyrite was exposed to the atmosphere by glacial erosion of the Dakota Formation.

The hypothetical model can be tested by evaluating the variations in $\delta^{13}C$ in dissolved inorganic carbon. $\delta^{13}C$ inorganic carbon in ground water from wells in aquifer layer 1 in southeastern Minnesota, southern Wisconsin, and northeastern Iowa ranges from about −14 to −8 o/oo (fig. 42). $\delta^{13}C$ is more than −9 o/oo in aquifer layer 3 in northern Illinois and less than −17 o/oo in northwestern Iowa. Of major interest is the enrichment of $\delta^{13}C$ from about −11 to more than −8 o/oo from northeast to southwest in Iowa, approximately perpendicular to the direction of the present hydraulic gradient.

The average of $\delta^{13}C$ in the major recharge areas in Minnesota and Wisconsin is close to −12 o/oo in aquifer layer 1, a value that is typically obtained by the simple closed-system dissolution of carbonate minerals with $\delta^{13}C$ of 0 o/oo (Wigley and others, 1978) by soil carbon dioxide with $\delta^{13}C$ of about −25 o/oo. Recharge to the aquifer system through the Dakota Formation in northwestern Iowa would obtain dissolved carbon from the oxidation of isotopically depleted organic material from both soils and lignite. The $\delta^{13}C$ of the lignite is also probably about −25 o/oo, and consequently the observed −17 to −18 o/oo $\delta^{13}C$ of inorganic carbon in the ground water in aquifer layer 3 is probably caused by fractionation processes. One likely process is bacterially mediated oxidation of methane, which would produce isotopically depleted carbon dioxide with $\delta^{13}C$ of less than −25 o/oo (Fenchel and Blackburn, 1979), and ultimately result in $\delta^{13}C$ of dissolved inorganic carbon in the ground water of less than −12 o/oo. However, sulfate reduction followed by methane production can also enrich the $\delta^{13}C$ of inorganic carbon (Nissenbaum and others, 1972; Claypool and Kaplan, 1974).

The enrichment in $\delta^{13}C$ in aquifer layer 3 from about −11 o/oo in northeastern Iowa to more than −8 o/oo in southwestern Iowa can be explained by successive episodes of glacial-meltwater dilution, dissolution of carbonate minerals in the aquifer matrix, and reequilibration of ground water with respect to the carbonate system. However, it is necessary to assume that the inorganic carbon in the meltwater that recharged the aquifer system had a $\delta^{13}C$ of more than −10 o/oo. The involvement of organic carbon in the dissolution of carbonate rock beneath modern glaciers is minimal, although the presence of atmospheric carbon dioxide in meltwater cannot be overlooked (Hanshaw and Hallet, 1978). The $\delta^{13}C$ of modern atmospheric carbon dioxide is about −7 o/oo (Hoefs, 1980). If most of the meltwater recharge occurred subglacially and if the carbon isotopic composition of Pleistocene atmospheric carbon dioxide was similar to that of today, then the observed enrichment of $\delta^{13}C$ from −11 to −8 o/oo of the dissolved inorganic carbon in the ground water would be conceptually consistent with the meltwater recharge model. During glacial-meltwater emplacement, $\delta^{13}C$ of inorganic carbon also could be enriched by sulfate reduction followed by methane production, as discussed earlier.

Infiltration of meltwater through soils could result in soil carbon dioxide of varying isotopic composition depending on the type of vegetation (Fontes, 1980; Hoefs, 1980). Studies of plant succession after the latest Wisconsin glacial retreat in the Midwest indicate that many stages in plant succession can occur after glaciation and could range from black spruce forests to open woodlands (Wright, 1976). These vegetation types can develop even on the mantle of rock debris that covers stagnant ice. The simplest interpretation of the succession in central Minnesota, for example, is probably that the earlier colonization of herb tundra vegetation was followed by shrub and forest tundra, spruce forest, and, ultimately, pine (Birks, 1975; Gordon and Birks, 1982). These types of vegetation, as well as prairie grasses, have $\delta^{13}C$ values between about −37 and −24 o/oo (Hoefs, 1980). The isotopic composition of carbon dioxide derived from the oxidation of this vegetation would not be too different from that of modern soils. Repeated dissolution of carbonate minerals by meltwater with such dissolved soil carbon dioxide would result in $\delta^{13}C$ of dissolved inorganic carbon of about −12 o/oo, rather than the observed enriched values of carbon-13.

SUMMARY AND CONCLUSIONS

The evolution of the water quality in the Cambrian-Ordovician aquifer system in the northern Midwest United States is complicated because of many possible geochemical processes and the probable effects of Pleistocene glaciation on the aquifer system. Modern

ground-water types may be, in part, a result of ground-water types prior to Pleistocene ice advances.

Ground water in recharge areas in Wisconsin, southern Minnesota, northeastern Iowa, and north-central Illinois is the Ca-Mg-HCO_3 type and is identical in both the glacial drift and the underlying Cambrian-Ordovician aquifer system. Dissolved-solids concentrations are less than 500 mg/L, and the major geochemical process probably is dissolution of carbonate minerals by soil carbon dioxide. In northwestern Iowa and southwestern Minnesota, however, the ground-water type in both the drift and the Cambrian-Ordovician aquifer system is Ca-Na-SO_4-HCO_3 because of the oxidation of pyrite in the Dakota Formation that overlies the aquifer system. Ground water is generally undersaturated with gypsum, and the negative $\delta^{34}S$ values in sulfate indicate that pyrite is a primary sulfur source. Dissolved-solids concentrations in places exceed 1,000 mg/L.

Ground-water type changes from Na-Ca-SO_4-HCO_3 to Na-Cl along the major flow path from northwestern Iowa to the Illinois basin. This is probably due to membrane filtration that would result in calcite precipitation coincident with increases in sodium and chloride.

A plume of dilute water containing less than 500 mg/L of dissolved solids trends north to south in central Iowa under the confining Maquoketa Shale. The plume suggests that paleo-ground-water flow probably was perpendicular to the present hydraulic gradient. This interpretation also is suggested by the general trend of increasing dissolved solids perpendicular to the present hydraulic gradient in Iowa and Missouri.

Ground water in southern Iowa and northern Missouri is considerably more depleted in the heavier stable isotopes, oxygen-18 and hydrogen-2, than is modern recharge water. This evidence may suggest a Pleistocene, and probably a glacial-meltwater, origin of recharge. A plume of ground water isotopically heavier than ground water in southern Iowa, but isotopically lighter than modern recharge, is coincident with the plume of low-dissolved-solids water in central Iowa. It is hypothesized that the isotopic content and dilution of ground water in Iowa and Missouri probably was caused by glacial meltwater emplaced in the aquifer system when glacial ice covered the present recharge areas in northeastern Iowa and southern Minnesota. The emplaced water extends hundreds of miles from the recharge areas. This may suggest that some of the recharge occurred subglacially, under considerably steeper hydraulic gradients than those of the present.

Dilution by the emplaced water decreased the concentrations of solutes such as chloride and sulfate in central Iowa, but bicarbonate concentrations remained about the same. Reequilibration of ground water with carbonate minerals in aquifer matrices, suggested by marked enrichment of $\delta^{13}C$ in dissolved inorganic carbon, could have maintained the level of bicarbonate concentrations. Dilution and re-reaction of the water with the aquifer matrix did not significantly change the ground-water types that are present down the modern hydraulic gradient. The overall chemical character of the ground water in the aquifer system in Iowa was probably established prior to glaciation and the recharge of meltwater.

Reconnaissance data on the distribution of trace solutes show that concentrations of cadmium, arsenic, and selenium seem to be related to the proximity of the Dakota Formation, which onlaps the western edge of the aquifer system in northwestern Iowa and southwestern Minnesota. Iron, manganese, cobalt, cadmium, copper, and lead concentrations are higher in proximity to the Dakota Formation in northwestern Iowa and on the edge of the Forest City basin in southwestern Iowa. Concentrations of beryllium and molybdenum are generally higher near the Forest City basin than elsewhere in the aquifer system. Silica concentrations correlate roughly with ground-water temperature in south-central Iowa and northern Missouri; however, the solid phases controlling the solubility of silica are unknown.

Concentrations of lithium, strontium, boron, and fluoride increase from north to south in Iowa and northern Missouri in a direction perpendicular to the present hydraulic gradient. Distributions of lithium, radium-226, and bromide show a plume of lower concentration similar to the plumes of low dissolved solids and the distribution of stable isotopes of water. Uranium isotopes are at disequilibrium and show activity ratios of uranium-234 to uranium-238 as large as 100. High barium concentrations in northern Illinois and eastern Wisconsin are probably due to a zone of reducing conditions that markedly lower the sulfate concentration. Thus, barium concentrations increase until the solubility limit of barite is reached. Increased concentrations of sulfate and positive $\delta^{34}S$ values of sulfur in sulfate east of the reducing zone in eastern Wisconsin and northeastern Illinois probably indicate emplacement of sulfate derived from evaporitic gypsum. This may have occurred during Pleistocene glaciation, when the load of glacial ice could have reversed ground-water flow from east to west. Ground water from the Michigan basin could have discharged through the present recharge area in central Wisconsin and northern Illinois, where the aquifer either crops out at the land surface or subcrops beneath glacial drift.

It is possible to derive scenarios for the net dilution and dissolution process from calculations using data on the stable isotopes of the water. Such calculations are

nonunique and are used only for the hypothetical interpretation of geochemical data because (1) the number of glacial advances in Wisconsin and Minnesota prior to Wisconsin time is uncertain, (2) the pre-Pleistocene regional ground-water flow system and topography are unknown, (3) information on the chemical and clay-mineral composition of the aquifer matrix in central Iowa is scant, (4) estimates of the isotopic composition of Pleistocene ice sheets have a large range, (5) different interpretations are made of the shape of the continental ice lobes, (6) no direct information is available on the leakance of younger rocks that overlie the aquifer south of the Maquoketa Shale outcrop, and (7) the extent of isotopic depletion in ground water south of the study area is unknown.

SELECTED SERIES OF U.S. GEOLOGICAL SURVEY PUBLICATIONS

Periodicals

Earthquakes & Volcanoes (issued bimonthly).
Preliminary Determination of Epicenters (issued monthly).

Technical Books and Reports

Professional Papers are mainly comprehensive scientific reports of wide and lasting interest and importance to professional scientists and engineers. Included are reports on the results of resource studies and of topographic, hydrologic, and geologic investigations. They also include collections of related papers addressing different aspects of a single scientific topic.

Bulletins contain significant data and interpretations that are of lasting scientific interest but are generally more limited in scope or geographic coverage than Professional Papers. They include the results of resource studies and of geologic and topographic investigations; as well as collections of short papers related to a specific topic.

Water-Supply Papers are comprehensive reports that present significant interpretive results of hydrologic investigations of wide interest to professional geologists, hydrologists, and engineers. The series covers investigations in all phases of hydrology, including hydrogeology, availability of water, quality of water, and use of water.

Circulars present administrative information or important scientific information of wide popular interest in a format designed for distribution at no cost to the public. Information is usually of short-term interest.

Water-Resources Investigations Reports are papers of an interpretive nature made available to the public outside the formal USGS publications series. Copies are reproduced on request unlike formal USGS publications, and they are also available for public inspection at depositories indicated in USGS catalogs.

Open-File Reports include unpublished manuscript reports, maps, and other material that are made available for public consultation at depositories. They are a nonpermanent form of publication that may be cited in other publications as sources of information.

Maps

Geologic Quadrangle Maps are multicolor geologic maps on topographic bases in 7 1/2- or 15-minute quadrangle formats (scales mainly 1:24,000 or 1:62,500) showing bedrock, surficial, or engineering geology. Maps generally include brief texts; some maps include structure and columnar sections only.

Geophysical Investigations Maps are on topographic or planimetric bases at various scales; they show results of surveys using geophysical techniques, such as gravity, magnetic, seismic, or radioactivity, which reflect subsurface structures that are of economic or geologic significance. Many maps include correlations with the geology.

Miscellaneous Investigations Series Maps are on planimetric or topographic bases of regular and irregular areas at various scales; they present a wide variety of format and subject matter. The series also includes 7 1/2-minute quadrangle photogeologic maps on planimetric bases which show geology as interpreted from aerial photographs. Series also includes maps of Mars and the Moon.

Coal Investigations Maps are geologic maps on topographic or planimetric bases at various scales showing bedrock or surficial geology, stratigraphy, and structural relations in certain coal-resource areas.

Oil and Gas Investigations Charts show stratigraphic information for certain oil and gas fields and other areas having petroleum potential.

Miscellaneous Field Studies Maps are multicolor or black-and-white maps on topographic or planimetric bases on quadrangle or irregular areas at various scales. Pre-1971 maps show bedrock geology in relation to specific mining or mineral-deposit problems; post-1971 maps are primarily black-and-white maps on various subjects such as environmental studies or wilderness mineral investigations.

Hydrologic Investigations Atlases are multicolored or black-and-white maps on topographic or planimetric bases presenting a wide range of geohydrologic data of both regular and irregular areas; principal scale is 1:24,000 and regional studies are at 1:250,000 scale or smaller.

Catalogs

Permanent catalogs, as well as some others, giving comprehensive listings of U.S. Geological Survey publications are available under the conditions indicated below from the U.S. Geological Survey, Books and Open-File Reports Section, Federal Center, Box 25425, Denver, CO 80225. (See latest Price and Availability List.)

"Publications of the Geological Survey, 1879-1961" may be purchased by mail and over the counter in paperback book form and as a set of microfiche.

"Publications of the Geological Survey, 1962-1970" may be purchased by mail and over the counter in paperback book form and as a set of microfiche.

"Publications of the U.S. Geological Survey, 1971-1981" may be purchased by mail and over the counter in paperback book form (two volumes, publications listing and index) and as a set of microfiche.

Supplements for 1982, 1983, 1984, 1985, 1986, and for subsequent years since the last permanent catalog may be purchased by mail and over the counter in paperback book form.

State catalogs, "List of U.S. Geological Survey Geologic and Water-Supply Reports and Maps For (State)," may be purchased by mail and over the counter in paperback booklet form only.

"Price and Availability List of U.S. Geological Survey Publications," issued annually, is available free of charge in paperback booklet form only.

Selected copies of a monthly catalog "New Publications of the U.S. Geological Survey" available free of charge by mail or may be obtained over the counter in paperback booklet form only. Those wishing a free subscription to the monthly catalog "New Publications of the U.S. Geological Survey" should write to the U.S. Geological Survey, 582 National Center, Reston, VA 22092.

Note.--Prices of Government publications listed in older catalogs, announcements, and publications may be incorrect. Therefore, the prices charged may differ from the prices in catalogs, announcements, and publications.

U.S. EPA, Office of Solid Waste and Emergency Response, OSWER Technical Guide for Assessing and Mitigating the Vapor Intrusion Pathway from Subsurface Vapor in Indoor Air, June 2015.

OSWER Publication 9200.2-154

OSWER TECHNICAL GUIDE FOR ASSESSING AND MITIGATING THE VAPOR INTRUSION PATHWAY FROM SUBSURFACE VAPOR SOURCES TO INDOOR AIR

U.S. Environmental Protection Agency

Office of Solid Waste and Emergency Response

June 2015

DISCLAIMER

This document presents current technical recommendations of the U.S. Environmental Protection Agency (EPA) based on our current understanding of vapor intrusion into indoor air from subsurface vapor sources. This guidance document does not impose any requirements or obligations on the EPA, the states or tribal governments, or the regulated community. Rather, the sources of authority and requirements for addressing subsurface vapor intrusion are the relevant statutes and regulations. Decisions regarding a particular situation should be made based upon statutory and regulatory authority. EPA decision-makers retain the discretion to adopt or approve approaches on a case-by-case basis that differ from this guidance document, where appropriate, as long as the administrative record supporting its decision provides an adequate basis and reasoned explanation for doing so.

EXECUTIVE SUMMARY

Definition and Description of Vapor Intrusion

Vapor intrusion is the general term given to migration of hazardous vapors from any subsurface vapor source, such as contaminated soil or groundwater, through the soil and into an overlying building or structure. These vapors can enter buildings through cracks in `basements and foundations, as well as through conduits and other openings in the building envelope. Vapors can also enter structures that are not intended for human occupancy (e.g., sewers, drain lines, access vaults, storage sheds, pump houses) through cracks and other openings.

All types of buildings, regardless of foundation type (e.g., basement, crawl space, slab-on-grade), have openings that render them potentially vulnerable to vapor intrusion. Buildings subject to vapor intrusion include, but are not limited to, residential buildings (e.g., detached single-family homes, trailer or 'mobile' homes, multi-unit apartments and condominiums), commercial workplaces (e.g., office buildings, retail establishments), educational and recreational buildings (e.g., schools and gyms), and industrial facilities (e.g., manufacturing plants).

Vapor intrusion is a potential human exposure pathway -- a way that people may come into contact with hazardous vapors while performing their day-to-day indoor activities. For purposes of this Technical Guide, the vapor intrusion pathway is referred to as "complete" for a specific building or collection of buildings when the following five conditions are met under current conditions:

1) A subsurface source of vapor-forming chemicals is present (e.g., in the soil or in groundwater) underneath or near the building(s) (see Sections 2.1, 5.3, 6.2.1, and 6.3.1);

2) Vapors form and have a route along which to migrate (be transported) toward the building (see Sections 2.2 and 6.3.2);

3) The building(s) is(are) susceptible to soil gas entry, which means openings exist for the vapors to enter the building and driving 'forces' (e.g., air pressure differences between the building and the subsurface environment) exist to draw the vapors from the subsurface through the openings into the building(s) (see Sections 2.3 and 6.3.3);

4) One or more vapor-forming chemicals comprising the subsurface vapor source(s) is(are) present in the indoor environment (see Sections 6.3.4 and 6.4.1); and

5) The building(s)[1] is(are) occupied by one or more individuals when the vapor-forming chemical(s) is(are) present indoors.

[1] For purposes of this Technical Guide and its recommendations for evaluating human health risk posed by vapor-forming chemicals, "building" refers to a structure that is intended for occupancy and use by humans. This would include, for instance, homes, offices, stores, commercial and industrial buildings, etc., but would not normally include sheds, carports, pump houses, or other structures that are not intended for human occupancy.

A complete vapor intrusion pathway indicates that there is an opportunity for human exposure, which warrants further analysis (see Section 7.4) to determine whether there is a basis for undertaking a response action(s) (see Section 7.7). Depending upon building- and site-specific circumstances, concentrations of chemical vapors indoors arising from a complete vapor intrusion pathway may threaten the health of building occupants (e.g., residents, workers, etc.), which may warrant a response action(s).

On the other hand and for purposes of this Technical Guide, if one (or more) of the five foregoing conditions is currently absent and is reasonably expected to be absent in the future (e.g., vapor migration is significantly and persistently impeded by natural geologic, hydrologic, or biochemical (e.g., biodegradation) processes and conditions), the vapor intrusion pathway is referred to as "incomplete." EPA recommends that any determination that the vapor intrusion pathway is incomplete be supported by site-specific evidence to demonstrate that the nature and extent of vapor-forming chemical contamination in the subsurface has been well characterized (Section 6.3.1) and the types of vapor sources and the conditions of the vadose zone and surrounding infrastructure do not present opportunities for unattenuated or enhanced transport of vapors (Sections 5.4 and 6.5.2) toward and into any building (see Section 7.3 for further discussion). When the vapor intrusion pathway is determined to be incomplete, then vapor intrusion mitigation is not generally warranted.

EPA recommends that site managers also evaluate whether subsurface vapor sources that remain have the potential to pose unacceptable human health risks due to vapor intrusion in the future[2] if site conditions were to change. The vapor intrusion pathway is referred to as 'potentially complete' for a building when:

- a subsurface source of vapor-forming chemicals is present underneath or near an existing building or a building that is reasonably expected to be constructed in the future;
- vapors can form from this source(s) and have a route along which to migrate (be transported) toward the building; and
- three additional conditions are reasonably expected to all be met in the future, which may not all be met currently; i.e.,
    - the building is susceptible to soil gas entry, which means openings exist for the vapors to enter the building and driving forces exist to draw the vapors from the subsurface through the openings into the building;
    - one or more vapor-forming chemicals comprising the subsurface vapor source(s) is (or will be) present in the indoor environment; and
    - the building is or will be occupied by one or more individuals when the vapor-forming chemical(s) is (or are) present indoors.

[2] "Both current and reasonably likely future risks need to be considered in order to demonstrate that a site does not present an unacceptable risk to human health and the environment." (EPA 1991a).

In addition to their toxicity threats, methane and certain other vapor-forming chemicals can also pose explosion hazards depending upon structure-, building-, and site-specific circumstances. Explosion hazards may pose an imminent and substantial danger to human health and public welfare.

Technical Guide Development and Recommended Uses

To help assess the subsurface vapor intrusion pathway, the Office of Solid Waste and Emergency Response (OSWER) released in November 2002 for comment EPA's *Draft Guidance for Evaluating the Vapor Intrusion to Indoor Air Pathway from Groundwater and Soils* ("Draft VI Guidance"). Since the Draft VI Guidance was released, EPA's knowledge of and experience with assessment and mitigation of the vapor intrusion pathway has increased considerably, leading to an improved understanding of and enhanced approaches for evaluating and managing vapor intrusion. In addition, EPA received hundreds of comments from the public since 2002 on the Draft VI Guidance, on a public review draft issued in April 2013, and on emerging practices and science considerations.

This Technical Guide presents current technical recommendations of the EPA based on our current understanding of vapor intrusion into indoor air from subsurface vapor sources. One of its main purposes is to promote national consistency in assessing the vapor intrusion pathway.[3] At the same time, it provides a flexible science-based approach to assessment that accommodates the different circumstances (e.g., stage of the cleanup process) in which vapor intrusion is first considered at a site and differences among pertinent EPA programs. This Technical Guide is intended for use at any site (and any building or structure on a site) being evaluated by EPA pursuant to the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) or the corrective action provisions of the Resource Conservation and Recovery Act (RCRA), EPA's brownfield grantees, or state agencies acting pursuant to CERCLA or an authorized RCRA corrective action program where vapor intrusion may be of potential concern. This document and the accompanying *Technical Guide For Addressing Petroleum Vapor Intrusion At Leaking Underground Storage Tank Sites* (EPA 2015b)[4] supersede and replace the Draft VI Guidance.

Although this Technical Guide is intended for use at any site subject to federal statutes, regulations, and rules, it is not intended to alter existing requirements, guidance, or practices among OSWER's programs about development, selection, or documentation of final remediation[5] plans (addressing subsurface vapor sources, for example).

---

[3] If EPA staff wish to consider using any specific guidance that is not explicitly recommended in this Technical Guide, they should consult with Headquarters.

[4] For petroleum hydrocarbons that arise from petroleum that has been released from Subtitle I UST systems, EPA has developed a companion to this Technical Guide (*Technical Guide For Addressing Petroleum Vapor Intrusion At Leaking Underground Storage Tank Sites* (EPA 2015b)), which provides information and guidance about how EPA recommends vapor intrusion be assessed for petroleum hydrocarbons in these settings.

[5] For purposes of this Technical Guide, "remediation" is intended to apply to interim and final cleanups, whether conducted pursuant to RCRA corrective action, the CERCLA removal or remedial programs, or using EPA brownfield grant funds with oversight by state and tribal response programs. In addition to permanent remedies for subsurface vapor sources, site remediation may also entail implementation of institutional controls and construction and operation of engineered systems for exposure control.

Document Content and Key Recommendations

This document is comprised of eleven sections and three appendices, including a list of acronyms, which precedes this summary, and a glossary of terms in Section 10. Section 3 provides an overview of the entire Technical Guide and can be further summarized as follows:

- Broadly speaking, two general levels of vapor intrusion assessments can be distinguished:

  1) A preliminary analysis, which utilizes available and readily ascertainable information to develop an *initial* understanding of the potential for human health risks to be posed by vapor intrusion, which would typically be performed as part of an initial site assessment (Section 5).

  2) A detailed investigation (Section 6), which is generally recommended when the preliminary analysis (e.g., Section 5.3) indicates that subsurface contamination with vapor-forming chemicals may be present underlying or near buildings. A detailed investigation of the vapor intrusion pathway is typically performed as part of the site investigation stage.

  The approach for assessing vapor intrusion will vary from site to site, because each site will differ in the available data when vapor intrusion is being evaluated. This Technical Guide, therefore, recommends a framework for planning and conducting vapor intrusion investigations, rather than a prescriptive step-by-step approach to be applied at every site.

- Response actions to address vapor intrusion when it poses unacceptable human health risks (Sections 7.7 and 8) typically entail a combination of:

  - remediation to reduce or eliminate subsurface vapor sources (Section 8.1);
  - engineered exposure controls for specific buildings to reduce vapor intrusion or reduce concentrations of vapor-forming chemicals that have already entered the building (Section 8.2);
  - monitoring to assess and verify the performance and effectiveness of the remediation systems and engineered exposure controls (Section 8.4); and
  - institutional controls (ICs) to restrict land use and/or to alert parties (e.g., prospective developers, owners, and municipalities) of the presence of subsurface sources of vapor-forming chemicals and to foster operation, maintenance, and monitoring of the remediation systems and engineered exposure controls (Section 8.6).

  Additional response actions to avoid or reduce human exposure may also warrant consideration in circumstances where “early” or prompt response action is appropriate to address indoor air exposure conditions or a potential for explosion hazards.

Additional key recommendations and policies comprising this document include the following:

Planning, Scoping and Conducting Investigations (see Sections 5.4 and 6.2 for further information)

- Consider site and building access agreements, equipment security, and locations of underground utilities and piping, such as storm and sewer lines within buildings, when planning vapor intrusion investigations (Section 6.2).

- Develop an initial conceptual site model, use this model to guide planning and scoping of the investigation, and update this model as additional information and insights are generated (Sections 5.4, 7.1, and 7.2).

- Generally limit chemical analyses to those vapor-forming chemicals known or reasonably expected to be present in the subsurface environment.

- Consider a "worst first" approach to prioritize buildings for investigation at sites where numerous buildings are potentially subject to vapor intrusion (Section 6.2.2).

- To the extent practical, plan and implement investigations within buildings and on individual properties with the goal of limiting return visits, which can cause disruption and inconvenience for building occupants and owners (Section 6.2).

- Generally assess the vapor intrusion pathway by collecting, weighing, and evaluating multiple lines of evidence (Sections 6.3, 7.1, and 7.2).

- Utilize 100 feet to define an initial lateral inclusion zone for vapor intrusion assessment (i.e., for identifying buildings that are 'near' a subsurface vapor source and generally warrant assessment) for purposes of a preliminary analysis). Investigate soil vapor migration distance (e.g., define inclusion zone(s) for assessing vapor intrusion in specific buildings) on a site-specific basis. That is, distances larger or smaller than 100 feet (i.e., beyond or within an initial 100-foot inclusion zone) may need to be considered when developing objectives for detailed vapor intrusion investigations and interpreting the resulting data (Section 6.2.1).

- To support evaluations of sources of indoor air concentrations, identify in individual buildings known or suspected indoor sources of the vapor-forming chemicals also found in the subsurface and characterize ambient air quality in the site vicinity for these same chemicals (Sections 6.3.5 and 6.4).

- Select sampling and analytical methods that are capable of obtaining reliable analytical detections of concentrations less than project-appropriate, risk-based screening levels (e.g., vapor intrusion screening levels, or VISLs).

- When groundwater is a subsurface source of vapors, collect groundwater samples from wells screened across the top of the water table to characterize the source strength for vapor intrusion (Sections 6.3.1 and 6.4.5).

- Collect indoor air samples to characterize exposure levels in indoor air, account for seasonal variations in climate and the habits of building occupants, and ensure that

related risk management decisions are based upon a consideration of a reasonable maximum vapor intrusion condition for a given building (Sections 6.3.4 and 6.4.1).

- When sampling indoor air,
  - employ time-integrated sampling methods (e.g., evacuated canisters, sorbent-based sampling devices). Indoor air concentrations can be temporally variable and time-integrated exposure estimates over appropriate exposure durations (e.g., chronic typically; less-than-chronic in some cases) are generally most useful for exposure and human health risk assessment (Sections 6.4.1 and 7.4);
  - remove potential indoor sources[6] of vapor-forming chemicals from the building to strive to ensure that the concentrations measured in the indoor air samples are attributable to the vapor intrusion pathway (Sections 6.3.5 and 6.4.1); and
  - measure the pressure difference between the indoors and the subsurface, which provides a complementary line of evidence to support data evaluation and interpretation (Section 6.4.1) and is a more direct means of assessing building under-pressurization than is monitoring weather/climate factors (e.g., air temperature, wind speed).
- Mathematical modeling of vapor intrusion is most appropriately used in conjunction with other lines of evidence (Section 6.6).
- Confirm the reliability of modeling results, especially when limited site-specific data are available as inputs (Section 6.6).
- Collect and evaluate appropriate site-specific information to demonstrate that the property fulfills the conditions and assumptions of the generic conceptual model underlying the vapor intrusion screening levels (Section 6.5.2).

Data Evaluation and Decision-making

- Assess (and seek) concordance among the lines of evidence to more confidently support decision-making (Sections 7.1, 7.2, and 7.3).[7] Multiple lines of evidence are generally recommended for supporting conclusions, such as the following:
  - The subsurface vapor source(s) at a specific site has the potential to pose an unacceptable vapor intrusion exposure under current or reasonably expected future conditions, due to its vapor strength (Section 6.5) and proximity relative to one or more existing buildings or a building that may be constructed in the future (Section 6.2.1).

[6] As mentioned in Section 6.3.5, indoor sources can sometimes be identified and located using portable instruments.

[7] Confidence in the assessment and risk management decisions is expected to be higher when multiple independent lines of evidence come together to provide mutually supporting evidence for a common understanding of the site conditions/scenarios and the potential for vapor intrusion (EPA 2010b).

- The vapor intrusion pathway is complete for one or more buildings under current or reasonably expected future conditions (Section 7.3).

- The vapor intrusion pathway is incomplete for one or more buildings near a subsurface source of vapor-forming chemicals (Section 7.3), due to

  - inadequate source strength (i.e., chemicals comprising subsurface contamination and/or their potential vapor concentrations cannot pose an unacceptable human health risk via the vapor intrusion pathway) (Section 6.5); or

  - geologic, hydrologic, and/or biochemical (e.g., biodegradation) processes that provide substantial and persistent attenuation of vapors extending laterally over large distances relative to the footprint of the building(s) and the extent of the vapor source (Section 6.3.2).

- Indoor air concentrations attributable to vapor intrusion pose (or, alternatively, are unlikely to pose) an unacceptable human health risk in one or more existing buildings under current or reasonably expected future conditions, based upon currently available information about a chemical's toxicity (Section 7.4).

- Indoor air concentrations measured in one or more buildings can (or alternatively, cannot) be reasonably attributed to indoor or ambient air sources (i.e., background – see Glossary) (Sections 6.3.5 and 7.4.2).

Multiple lines of evidence are particularly important for supporting "no-further-action" decisions regarding the vapor intrusion pathway (e.g., pathway incomplete determinations) to reduce the chance of reaching a false-negative conclusion (i.e., concluding vapor intrusion does not pose unacceptable human health risk, when it actually poses an unacceptable human health risk). Collecting and weighing multiple lines of evidence can also reduce the chance of reaching a false-positive conclusion (i.e., concluding vapor intrusion poses unacceptable human health risk, when it does not). On the other hand, parties may implement engineered exposure controls for vapor intrusion, even though only limited lines of evidence or measurements may be available to characterize the overall vapor intrusion pathway.

- Consider reasonably expected future conditions, in addition to current conditions, when reaching conclusions about the vapor intrusion pathway (Sections 3.2 and 7.3). For example, EPA recommends that vapor intrusion be evaluated for reasonably expected future land use conditions, including new building construction and new uses and occupants for uninhabited buildings.

- Identify any conditions that warrant prompt action (Section 7.5) and respond, consistent with applicable statutes and regulations and considering EPA guidance, with actions that eliminate, avoid, reduce or otherwise address the human health risk posed by vapor intrusion (Sections 7.7 and 8.2):

  - Explosive conditions and threats that warrant prompt action (Section 7.5.1) are reasonably suspected to exist when measured concentrations of vapors in the building, utility conduits, sumps, subsurface drains, or other structure directly

connected to the building exceed one-tenth (10%) of the lower explosive limit (LEL).[8] EPA recommends evacuation of buildings with potential explosion and fire hazards, along with notification to the local fire department about the situation.

- o Conditions posing health concerns that warrant prompt action are reasonably suspected to exist when estimated exposure concentrations of vapors in the building exceed health-protective concentrations for short-term or acute exposure (Section 7.5.2).

- When making decisions pertaining to the assessment of vapor intrusion at nonresidential buildings, consider the characteristics of the populations potentially exposed to vapor-forming chemicals in the indoor air, the relative contributions of vapors from background (including anthropogenic background), and any existing or planned engineering or institutional controls for the building, in addition to the potential for vapor intrusion (Sections 4, 6.3.5, 6.4.1 and 7.4.2).

- When evaluating environmental sampling results to assess the vapor intrusion pathway, first determine that the samples were collected appropriately (Sections 5.5 and 6.4).

- Before conducting risk-based screening, verify that the site fulfills the conditions and assumptions of the generic conceptual model underlying the VISLs (Section 6.5.2).

- Compare groundwater concentrations to the VISLs (Section 6.5) for groundwater to estimate the boundaries of the plume, when contaminated groundwater is the subsurface vapor source for vapor intrusion (Section 6.2.1).

- Generally support the decision to collect indoor air data (Section 6.4.1) by lines of site- or building-specific evidence that demonstrate vapor intrusion has the potential to pose a significant human exposure [e.g., data on strength and proximity of subsurface vapor source(s) (Sections 6.2.1, 6.3.1, and 6.5), or preferential vapor migration in the vadose zone or into buildings (Sections 5.4, 6.3.2, and 6.3.3)].

- Consider variability in laboratory analyses when evaluating sampling data.

- Generally conduct a human health risk assessment to determine whether the potential human health risks posed to building occupants are within or exceed acceptable levels consistent with applicable statutes and considering EPA guidance (Section 7.4).

- Consider the potential for adverse non-cancer health effects from short-duration exposures (i.e., acute, short-term, or subchronic exposure durations), as well as longer term exposure (i.e., chronic exposure) conditions, and select toxicity values considering OSWER's preferred hierarchy of sources (EPA 2003) (Sections 7.4 and 7.5.2).

[8] The Occupational Safety and Health Administration of the U.S. Department of Labor (OSHA) considers concentrations in excess of one-tenth of the LEL to be a hazardous atmosphere in confined spaces [29 CFR 1910.146(b)]. The National Institute for Occupational Safety and Health (NIOSH) has designated such concentrations as immediately dangerous to life or health (IDLH).

- Consider collecting multiple rounds of indoor air samples,[9] using time-integrated measurements (Section 6.4.1) to estimate exposure concentrations appropriate for the exposure (occupancy) scenario being evaluated (e.g., residential versus commercial), when the risk assessment for an existing building would support a conclusion that the human health risks are acceptable (Section 7.4).[10]

- In the risk characterization of the human health risk assessment, discuss 'background' contributions to indoor air exposure and associated human health risks (Section 7.4.2). (For purposes of this Guide, 'background' refers to a vapor-forming chemical(s) or location(s) that is(are) not influenced by the releases from a site – see Glossary). Information on 'background' contributions of site-related, vapor-forming chemicals in indoor air is important to risk managers because generally EPA does not clean up to concentrations below natural or anthropogenic background levels[11] (EPA 2002e).

- If data are available, distinguish the contribution of 'background' to total exposure concentration(s). With such information, EPA can help advise affected individuals about the environmental and human health risks they face. Other parties, including building owners and operators, may help with risk communication.

- If background vapor sources (see Glossary) are found to be primarily responsible for indoor air concentrations (see Section 6.3.5), then response actions for vapor intrusion would generally not be warranted for current conditions.

<u>Engineered Exposure Controls and Building Mitigation</u>

- When vapor intrusion has been determined to pose unacceptable human health risks,

    - Aim to achieve a permanent remedy by eliminating or substantially reducing the level(s) of vapor-forming chemical(s) in the subsurface source medium (e.g., groundwater, subsurface soil, sewer lines) (Sections 7.7 and 8.1); and
    - In cases where subsurface vapor sources cannot be remediated quickly, implement engineered exposure controls to reduce or eliminate vapor intrusion in buildings (i.e., "mitigate" vapor intrusion) or reduce indoor air exposure levels (Sections 7.7 and 8.2).

[9] Because weather conditions and building operations can lead to time-variable contributions from vapor intrusion and ambient air infiltration, indoor air concentrations of vapor-forming chemicals can be expected to vary over time (see, for example, Section 2.6). An individual sample (or single round of sampling) would be insufficient to characterize seasonal variability, or variability at any other time scale.

[10] EPA recommends basing the decision about whether to undertake response action for vapor intrusion (i.e., a component of risk management; see Section 7.4) on a consideration of a reasonable maximum exposure (e.g., EPA 1989, 1991a), which is a semi-quantitative term, referring to the lower portion of the high end of the exposure distribution (see Glossary).

[11] With respect to vapor intrusion mitigation (see Sections 3.5 and 8.2), some options for reducing indoor air exposure levels (e.g., ventilation, indoor air treatment) unavoidably act on background concentrations arising from indoor or outdoor sources, as well as vapor concentrations arising from vapor intrusion. Most options for interrupting the vapor intrusion pathway (e.g., active depressurization technologies – see Section 8.2) unavoidably interrupt the intrusion of naturally occurring radon also. It should also be noted that some EPA regulations (e.g., indoor radon standards under 40 CFR 192.12) are inclusive of background.

- When developing monitoring programs to assess effectiveness of building mitigation, consider the degree of human health risk or hazard being mitigated, the building use, the technology used to mitigate vapor intrusion, and coordination with site remediation efforts.

- Establish cleanup levels and criteria for terminating engineered exposure controls and other building mitigation methods, institutional controls, and remediation systems for subsurface vapor sources (Sections 7.6 and 8.7).

Document Activities and Decisions

- Document objectives and methods of vapor intrusion investigations, preferably in a vapor intrusion work plan (Section 6.2).

- Base decisions upon data and information in the administrative record.

- Base decisions to undertake response actions on lines of site- or building-specific evidence (e.g., characterization of subsurface vapor source(s) strength and proximity to building(s); building conditions) that demonstrate that vapor intrusion has the potential to pose an unacceptable human health risk (Section 7).

- Document, consistent with statutory requirements and considering prevailing guidance for the respective land restoration program (e.g., CERCLA, RCRA corrective action, brownfields, etc.), any and all decisions pertaining to vapor intrusion, including decisions to undertake (or not to undertake) investigation or mitigation of specific buildings at a contaminated site.

- Prepare and publish system manuals to document building mitigation and remediation systems (Section 8.5).

- Prepare and implement operations and maintenance manuals and practices to foster continued effective operation and performance of engineered exposure controls and remediation systems for subsurface vapor sources (Section 8.5).

- Document monitoring programs that assess the performance and effectiveness of remediation and mitigation systems.

Community Outreach and Involvement (Section 9)

- Develop or refine a community involvement or public participation plan while planning a vapor intrusion investigation and implement this plan throughout the assessment, remediation, and mitigation phases.

- Conduct building-by-building contact and communication as means of educating the community and obtaining access needed to assess, mitigate, and monitor the vapor intrusion pathway. Personal contact is further recommended to establish a good working relationship with each building owner or occupant and to build trust.

- Generally provide validated results and interpretations (e.g., chemicals of concern, associated risk assessment implications) to property owners and occupants in a timely manner (e.g., within approximately 30 days of receiving these results).

- Provide adequate opportunities for public participation (including potentially affected landowners and communities) when considering appropriate use of ICs.

The science and technology to assess and mitigate vapor intrusion have evolved significantly over the past decade. EPA will continue to monitor these evolving developments and will update these recommendations in the future, if and as appropriate.

1.0 INTRODUCTION

This technical guide was prepared by the U.S. Environmental Protection Agency (EPA) through the cooperative efforts of a team of EPA Headquarters and Regional staff, known as the Vapor Intrusion Intra-Agency Workgroup (Workgroup). Drafts of this document were subjected to a comprehensive, consultative peer-input process in 2012, as described in EPA's *Peer Review Handbook* (EPA-SPC 2006), which included comments and other contributions from Workgroup members representing several EPA offices and the EPA's Vapor Intrusion Forum.[12] Public comments submitted from 2002 through 2013 and recommendations of the Office of Inspector General (OIG) were also considered in developing this document.

This document comprises EPA's 'final' vapor intrusion technical guide[13] and is referred to herein as "this Technical Guide." It describes a recommended framework for assessing vapor intrusion that relies upon collecting and evaluating multiple lines of evidence to support risk management decisions. It also provides technical recommendations about monitoring and terminating building mitigation systems.

This Technical Guide relied upon a large body of scientific information found in the peer-reviewed literature. Additionally, EPA developed three technical support documents that were externally peer reviewed (EPA 2011a, 2012a, 2012b). This approach is consistent with EPA's peer review handbook and policy (EPA-SPC 2006). Peer-reviewed literature, peer-reviewed technical reports, existing and relevant EPA guidance (e.g., for conducting human health risk assessment; for planning and conducting investigations of environmental contamination), and other pertinent information that support development or implementation of this Technical Guide are cited within.

This introductory section: defines the term "vapor intrusion"; summarizes EPA's statutory authorities to protect human health from vapor intrusion; summarizes the intended uses of this Technical Guide, including its applicability to petroleum hydrocarbons and other potentially biodegradable chemicals and to nonresidential buildings; identifies key technical resources that facilitate consideration of its recommendations; provides a concise historical accounting of its development; describes how the public was involved in its development; and provides an overview of its organization.

1.1 Definition of Vapor Intrusion

Certain chemicals that are released into the subsurface[14] as liquids or solids may form hazardous vapors that migrate or are transported through the vadose zone[15] and eventually

[12] The EPA Vapor Intrusion Forum is an intra-Agency group engaged in sharing information, technical resources, and perspectives pertaining to vapor intrusion assessment and mitigation.

[13] This document is intended to fulfill EPA's commitment to the OIG to issue "updated, revised, and finalized" vapor intrusion guidance (EPA 2009a, Appendix B; EPA 2010b).

[14] For purposes of this Technical Guide, the phrases 'released into the subsurface' and 'release to the subsurface' are intended to encompass any and all mechanisms by which chemical contamination arises in the subsurface, including, for example, spills and releases above the ground surface that result in subsurface (e.g., soil and groundwater) contamination.

enter buildings as a component of a gas[16] by migrating (being transported) through cracks, seams, interstices, and gaps in basement floors, walls, or foundations ("adventitious openings"), through intentional openings (e.g., perforations due to utility conduits, sump pits), and/or within conduits (e.g., drain and sewer lines). Vapor intrusion is the general term given to migration of hazardous vapors from any subsurface contaminant source, such as contaminated soil or groundwater or contaminated conduit(s), into an overlying building or unoccupied structure via any opening or conduit.

Recognition of soil vapor intrusion to buildings and other enclosed spaces occurred in the 1980s with concerns over radon intrusion.[17] Subsequently, there was an increasing awareness that anthropogenic chemicals (e.g., petroleum hydrocarbons and chlorinated solvents) in soil and ground water could also pose threats to indoor air quality via the vapor intrusion pathway (Little et al. 1992; Moseley and Meyer 1992).

Vapor intrusion can occur in a broad range of land use settings, including residential, commercial, and industrial, and affect buildings with virtually any foundation type (e.g., basement, crawl space(s), or slab on grade). In the last 20 years, vapor intrusion impacts have been demonstrated in occupied buildings at a number of sites across the country (e.g., Little et al. 1992). As a result, vapor intrusion is widely recognized as a potential pathway of human exposure to "volatile" hazardous chemicals in indoor spaces. When and where vapor intrusion occurs, concentrations of vapors can increase gradually in amount in buildings or structures as time passes (i.e., "accumulate"). Depending upon site- and building-specific circumstances, vapors of potentially toxic chemicals may accumulate to a point where the health of the occupants (e.g., residents, workers, etc.) in those buildings could be threatened.

In addition to their toxicity threats, methane and certain other vapor-forming chemicals can pose explosion hazards depending upon structure-, building-, and site-specific circumstances. Explosion hazards may pose an imminent and substantial danger to human health and public welfare.

Careful consideration of the vapor intrusion pathway is warranted at all sites where vapor-forming chemicals are present in the soil or groundwater aquifer (NRC 2013).

Section 2.0 describes the vapor intrusion pathway in greater detail.

---

[15] The 'vadose zone' is the soil zone between land surface and the groundwater table within which the moisture content is less than saturation (except in the capillary fringe). It is also referred to as the "unsaturated zone."

[16] The terms 'gas' and 'vapor' refer the gaseous state, as distinguished from the liquid or solid state, of matter. Whereas "vapor' refers to a volatile chemical that may comprise only a portion of the total volume, 'gas' refers to the entire volume. For economy of words, this Technical Guide refers to vapor concentrations in soil gas as "soil gas concentrations."

[17] Radon is a colorless, odorless, radioactive gas that is formed from the decay of radium, a radioactive element that occurs naturally in the soil and bedrock in many areas of the United States. Radon can also be emitted from certain uranium- or radium-containing products and wastes. For more information about radon, see: http://www.epa.gov/radon/index.html.

1.2 Statutory Authorities

Protection of human health is a critical mandate underlying several federal statutes, including the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), as amended,[18] and the Resource Conservation and Recovery Act (RCRA), as amended.[19] Protection of human health is also a critical objective of the National Oil and Hazardous Substances Pollution Contingency Plan (NCP), which is the federal government's blueprint for responding to oil spills and releases of hazardous substances, pollutants, or contaminants.

The sources of authority and requirements for addressing subsurface vapor intrusion are the relevant statutes and regulations. On this basis, the EPA has broad authority and distinct responsibilities[20] to assess and, if warranted, mitigate vapor intrusion in residential and nonresidential[21] settings arising from a chemical release that causes subsurface contamination by volatile hazardous chemicals.[22] These actions may include sampling indoor air to assess exposure levels of building occupants to subsurface vapors and implementing interim mitigation measures to control, reduce, or eliminate exposure indoors to vapors emanating from subsurface vapor sources. Where such subsurface contamination includes vapor-forming chemicals (see Section 3.1) and underlies or is near buildings, EPA recommends that the potential for human health risk from vapor intrusion be evaluated throughout the cleanup life

[18] Amendments to CERCLA include the Small Business Liability Relief and Brownfields Revitalization Act.

[19] Application of these statutory authorities to a particular situation generally entails site- and fact-specific analysis.

[20] On January 23, 1987, the President of the United States signed Executive Order 12580 entitled, "Superfund Implementation," which delegates to a number of Federal departments and agencies the authority and responsibility to implement certain provisions of CERCLA. The policies and procedures for implementing these provisions (e.g., carrying out response actions) are spelled out in the NCP. The provisions of Executive Order 12580 appear at 52 *Federal Register* 2923.

[21] The EPA and the Occupational Safety and Health Administration (OSHA) of the Department of Labor each have a distinct statutory responsibility to ensure the safety and health of America's workforce through the timely and effective implementation of a number of federal laws and implementing regulations. On November 23, 1990, the Secretary of the Department of Labor and Administration of the EPA signed a Memorandum of Understanding (MOU) with the goal of establishing a program for improved environmental and workplace health and safety, which continues in effect. Implementation of the MOU is intended "to improve the combined efforts of the agencies to achieve protection of workers, the public, and the environment at facilities subject to EPA and OSHA jurisdiction; to delineate the general areas of responsibility of each agency; and to provide guidelines for coordination of interface activities between the two agencies with the overall goal of identifying and minimizing environmental or workplace hazards." An additional MOU was signed in February 1991 to establish a process and framework for notification, consultation and coordination between EPA and OSHA to aid both agencies in identifying environmental and workplace health and safety problems and to more effectively implement enforcement of their respective national environmental and workplace statutes. For additional information, see https://www.osha.gov/pls/oshaweb/owasrch.search_form?p_doc_type=MOU&p_toc_level=1&p_keyvalue=Agency&p_status=CURRENT.

EPA's recommended approach for evaluating vapor intrusion exposures is based upon its existing risk assessment guidance, as summarized in Section 7.4.

[22] Section 3.1 of this Technical Guide describes technical criteria for identifying which specific chemicals are sufficiently volatile and hazardous to generally warrant routine evaluation during vapor intrusion assessments, when they are present as subsurface contaminants. These sufficiently volatile and hazardous chemicals are referred to as "vapor-forming chemicals" for purposes of this Technical Guide.

cycle (i.e., initial site assessment, site investigation, interim and final response actions,[23] and periodic reviews of the selected remedy), as described in Sections 5 and 6 of this Guide.

Although this Technical Guide is intended for use at any site subject to federal statutes, regulations, and rules, it is not intended to alter existing requirements, guidance, or practices among OSWER's programs about development, selection, or documentation of final remediation[24] plans (addressing subsurface vapor sources, for example).

EPA may need access to private property to conduct investigations, studies and response actions pursuant to CERCLA and RCRA, as amended. The Superfund Amendments and Reauthorization Act of 1986 and RCRA explicitly grant EPA the authority to enter property for these purposes (EPA 1986, 1987, 2010a). EPA generally prefers to obtain access through consent and cooperation. If consent is denied, however, EPA can use the judicial process or an administrative order to gain access. Application of legal doctrines to a particular access situation warrants site- and fact-specific analysis.

Provisions under CERCLA, RCRA, federal regulations, and federal guidance also provide authority and support for taking early actions to mitigate actual and potential human health risks, as discussed below. In the context of vapor intrusion, "early action" may include response measures such as engineered exposure controls to reduce or eliminate vapor intrusion in buildings (i.e., "mitigate" vapor intrusion) or reduce indoor air exposure levels (see Sections 7.8 and 8.2) and 'prompt' response actions to address more urgent threats to human health or public welfare (see Section 7.5).

1.2.1 Taking Action with Limited Data under CERCLA and the NCP

CERCLA and the NCP both contain provisions that support and encourage taking early actions to mitigate actual and potential threats to human health associated with vapor intrusion. For example, CERCLA sections 104 and 106 provide the federal government with broad authority to take response action(s) to address a release or threatened release of hazardous substances that "may present" a human health risk. Similarly, the preamble to the final NCP issued in the *Federal Register* on March 8, 1990 (55 FR 8704), states, "EPA expects to take early action at sites where appropriate, and to remediate sites in phases using operable units as early actions to eliminate, reduce or control the hazards posed by a site or to expedite the completion of total site cleanup. In deciding whether to take early actions, EPA balances a number of considerations, including the desire to definitively characterize site risks and analyze alternative remedial approaches for addressing those threats in great detail with the desire to implement protective measures quickly. EPA intends to perform this balancing with a bias for initiating

[23] The words "response action" or "response" are used generically in this Technical Guide to include remedial and removal actions under CERCLA as amended and similar actions under RCRA as amended.

[24] For purposes of this Technical Guide, "remediation" is intended to apply to interim and final cleanups, whether conducted pursuant to RCRA corrective action, the CERCLA removal or remedial programs, or using EPA brownfield grant funds with oversight by state and tribal response programs. In addition to permanent remedies for subsurface vapor sources, site remediation may also entail implementation of institutional controls and construction and operation of engineered systems.

response actions necessary or appropriate to eliminate, reduce, or control hazards posed by a site as early as possible."[25]

For sites that are not on the National Priorities List (NPL), EPA may use its removal authority under CERCLA to undertake early action to mitigate vapor intrusion threats. For sites that are on the NPL, EPA's Superfund program may use its remedial or removal authority under CERCLA to undertake early action to ensure the protection of human health during existing or future property uses that could be affected by vapor intrusion. Building mitigation, control of subsurface vapor source(s), and associated ICs could be part of a final remedy selected for the site, or where appropriate, could represent an early action that (1) is evaluated and selected on a faster track and (2) complements the anticipated final remedial action for the site.

Because of state cost-share consequences, EPA recommends that state concurrence be sought for any Fund-lead mitigation under CERCLA where there is a reasonable expectation that the state will need to take over responsibility for operations and maintenance (O&M) as part of a long-term, final remedy.

EPA's guidance for preparing Superfund decision documents states: "An interim action is limited in scope and only addresses areas/media that also will be addressed by a final site/operable unit ROD [Record of Decision]….Early actions can be taken throughout the RI/FS [remedial investigation/feasibility study] process to initiate risk reduction activities…. "Early" in this case is simply a description of when the action is taken in the Superfund process. Thus, an early action is one that is taken before the RI/FS for the site or operable unit has been completed. Hence, early actions may be either interim or final" (EPA 1999b). The primary goals of an early action are to "achieve prompt risk reduction and increase the efficiency of the overall site response" (EPA 1992b). Although preparation of an RI/FS Report is not essential for an early action, documentation that supports the rationale for the action and becomes part of Administrative Record is recommended, consistent with the NCP and CERCLA. For interim actions, EPA's guidance for preparing Superfund decision documents states: "A summary of site data collected during field investigations should be sufficient to document a problem in need of response. In addition, a short analysis of remedial alternatives considered, those rejected, and the basis for the evaluation (as is done in a focused FS) should be summarized to support the selected action" (EPA 1999b).

For response actions selected in an Action Memorandum or Record of Decision which are carried out by potentially responsible parties (PRPs), and where the PRP(s) agree to implement preemptive mitigation (PEM) for vapor intrusion, EPA recommends that PRP commitments to proceed with response action (including early action) be obtained through settlements or other enforcement documents (for example, administrative orders). Such response action commitments could include performance of O&M and monitoring. EPA recommends that settlement with PRPs concerning PEM/early action response actions specify that PRPs agree not to challenge the basis of the response based on inadequate characterization.

[25] So, for example, EPA cited the NCP in its *Compilation of Information Relating to Early/Interim Actions at Superfund Sites and the TCE IRIS Assessment* (EPA 2014b).

1.2.2 Taking Action with Limited Data under RCRA Corrective Action

EPA has emphasized the importance of interim actions and site stabilization in the RCRA corrective action program to control or abate "ongoing risks" to human health and the environment while site characterization is underway or before a final remedy is selected (see the *Federal Register* of May 1, 1996 [61 FR 19446]). Interim actions encompass a wide range of institutional and physical corrective action activities to achieve stabilization and can be implemented at any time during the corrective action process. EPA recommends that interim actions, including PEM, be employed as early in the corrective action process as possible, consistent with the human health and environmental protection objectives and priorities for the site. EPA recommends that, as further information is collected, program implementers continue to look for opportunities to conduct additional interim response actions.

1.3 Scope and Recommended Uses of this Technical Guide

This Technical Guide presents EPA's current recommendations for how to identify and consider key factors when assessing vapor intrusion, making risk management decisions, and implementing mitigation pertaining to this potential human exposure pathway. This Technical Guide and the accompanying *Technical Guide For Addressing Petroleum Vapor Intrusion At Leaking Underground Storage Tank Sites* (EPA 2015b) supersede and replace EPA's *Draft Guidance for Evaluating the Vapor Intrusion to Indoor Air Pathway from Groundwater and Soils* (EPA 2002c) ("Draft VI Guidance"). One of the main purposes of this Technical Guide is to promote national consistency in assessing the vapor intrusion pathway.[26] At the same time, it provides a flexible science-based approach to assessment that accommodates the different circumstances (e.g., stage of the cleanup process) at a site and differences among pertinent EPA programs.

This Technical Guide is intended for use at any site[27] being evaluated by EPA pursuant to CERCLA or RCRA corrective action, EPA's brownfield grantees, or state agencies acting

[26] If EPA staff wish to consider using any specific guidance that is not explicitly recommended in this Technical Guide, they should consult with Headquarters.

[27] The term "site" is used generically in this Technical Guide to represent areas of contamination managed in a cleanup project under CERCLA as amended, under RCRA as amended, at a federal facility, or pursuant to an EPA Brownfields grant.

pursuant to CERCLA or an authorized RCRA corrective action program[28] where vapor intrusion may be of potential concern. EPA recommends consideration of this Technical Guide when:

- Making "Current Human Exposures Under Control" environmental indicator (EI) determinations at RCRA corrective action facilities (EPA 1999a, 2002b)[29] and National Priorities List (NPL) sites under CERCLA (EPA 2008b);

- Undertaking removal actions, remedial actions, pre-remedial investigations,[30] remedial investigations, and five-year reviews (FYRs)[31] and selecting remedies under CERCLA; and

- Undertaking RCRA facility investigations and corrective actions and site investigations and cleanups at federal facilities and brownfield sites.

This Technical Guide addresses both residential and nonresidential buildings that may be impacted by vapor intrusion from subsurface vapor sources.

The broad concepts of this Technical Guide generally may be appropriate when evaluating any of a large number and broad range of vapor-forming chemicals— described in Section 3.1 — that potentially can provide subsurface sources for vapor intrusion into buildings. These chemicals include, for example, chlorinated hydrocarbons (CHCs), petroleum hydrocarbons, other types of both halogenated and non-halogenated volatile organic compounds (VOCs),

[28] EPA believes that states, tribes, and local governments will find this Technical Guide useful for their respective programs. EPA recommends that state agencies that have delegated authority to implement CERCLA or RCRA consider this Technical Guide when implementing their state-specific guidance for vapor intrusion assessment and mitigation, if any, (e.g., ensure they incorporate features such as: using multiple lines of evidence to support pathway-incomplete determinations and "no-further-action" decisions; collecting multiple rounds of indoor air sampling to characterize exposure levels in indoor air in existing buildings and reduce the chance of reaching a false-negative conclusion (i.e., concluding exposure is at an acceptable risk level when it is not) or a false-positive conclusion (i.e., concluding vapor intrusion poses unacceptable human health risk, when it does not); focusing lab analyses of indoor air, ambient air, and sub-slab soil gas samples on vapor-forming chemicals known or suspected to be released to the subsurface environment; invoking the recommended criteria described in Section 6.5.2 as a condition for using risk-based screening levels for vapor intrusion; assessing human health risk posed by less-than-chronic exposure durations; and considering reasonably expected future conditions, as well as current conditions, when making risk management decisions and selecting cleanup and building mitigation plans).

[29] Also see http://www.epa.gov/osw/hazard/correctiveaction/eis/faqs.htm.

[30] CERCLA authorizes the EPA to identify and prioritize which sites warrant further investigation to ascertain whether remedial action is needed. The Hazard Ranking System (HRS) is the statutorily required method for evaluating and identifying sites for placement on the NPL.

[31] Section 121 of CERCLA specifies that remedial actions that result in any hazardous substances, pollutants, or contaminants remaining at the site be re-evaluated every five years to ensure that the remedy is and will continue to be protective of human health and the environment. OSWER Directive 9200.2-84 (*Assessing Protectiveness at Sites for Vapor Intrusion: Supplemental Guidance to the Comprehensive Five-Year Review Guidance* (EPA 2012c)) provides supplemental guidance for considering vapor intrusion while evaluating remedy protectiveness in the context of the Superfund five-year review process (even if vapor intrusion was not addressed as part of the original remedial action).

elemental mercury, and radon when it arises from uranium- or radium-bearing solid wastes in the subsurface.[32]

This Technical Guide addresses risk management (e.g., exposure control or avoidance methods) for indoor air contamination that arises from vapor intrusion from subsurface sources of these vapor-forming chemicals. It is not intended as a guide for assessing or mitigating indoor air exposures that arise solely from other sources (e.g., indoor use and storage of certain consumer products[33]).

The exposure route of general interest for vapor intrusion is inhalation[34] of vapors present in indoor air that have entered via soil gas entry from the subsurface.[35] Other human exposure routes that may warrant consideration during site investigations of subsurface contamination (e.g., ingestion of soil or water, dermal contact with soil or water, inhalation of particulate material, inhalation of vapors while outdoors, and inhalation of vapors while showering or washing with contaminated groundwater while indoors) are not addressed in this Technical Guide.

EPA recommends that risk management and response action decisions for the vapor intrusion pathway generally consider reasonably expected future conditions, which may differ from current conditions due to changes in land use, building and infrastructure construction and conditions, and vadose zone hydrology and oxygenation, among other factors. This Technical Guide provides general information regarding how these factors may enhance or impede vapor intrusion. It also provides recommendations for institutional controls and monitoring where a subsurface vapor source(s) is(are) present and has the potential to pose unacceptable human health risks.

Although this Technical Guide is intended for use at any site subject to federal statutes, regulations, and rules, it is not intended to alter existing requirements, guidance, or practices among OSWER's programs about circumstances for reviewing past risk management and cleanup decisions. As noted, remedy reviews are required by Section 121 of CERCLA when

[32] Radon emanating from natural geological materials may also affect indoor air quality in occupied buildings, but is not a subject of this Technical Guide. According to EPA estimates, inhalation of toxic radon decay products is the leading cause of lung cancer among non-smokers. For more information about radon emanating from natural geological materials, see: http://www.epa.gov/radon/index.html.

[33] Indoor air in most buildings will contain detectable levels of a number of volatile compounds, whether or not the building overlies a subsurface source of vapor-forming chemicals (EPA 2011a). As discussed further in Section 2.7 of this Technical Guide, these chemicals originate from indoor uses of chemical-containing products (e.g., household or consumer products) and from outdoor (ambient) air. EPA's indoor air quality program provides useful advice for control of indoor air exposures (see http://www.epa.gov/iaq/).

[34] Among human exposure pathways involving contamination of land and water, vapor intrusion is distinct. Whereas contact with contaminated surface soil, contaminated fish, and contaminated drinking water generally can be readily avoided for prolonged periods, breathing cannot.

[35] In addition, certain hazardous chemicals (e.g., methane) can pose explosion hazards when they gradually increase in amount in structures (e.g., confined spaces) or buildings as time passes to a point where there is an imminent and substantial danger to human health and public welfare.

hazardous substances remain on site.[36] EPA's other land restoration programs (e.g., RCRA corrective action, brownfield redevelopment) will continue to rely upon their existing, respective practices to address the need, if any, for periodic reviews of cleanup decisions, including consideration of the vapor intrusion pathway.

Finally, this Technical Guide does not aim or intend to:

- Offer recommendations for vapor intrusion assessments that private parties choose to conduct as part of real estate transactions;
- Modify existing guidance regarding landowner liability protection (e.g., all appropriate inquiries, the *bona fide* prospective purchaser provision); or
- Offer recommendations for responding to leaks from natural gas transmission lines.

1.3.1 Petroleum Hydrocarbons

The approaches in this Technical Guide are recommended for evaluating the vapor intrusion pathway pursuant to CERCLA or RCRA corrective action for petroleum hydrocarbons that are mixed with other types of volatile hazardous chemicals or are the result of releases from sources other than Subtitle I underground storage tank (UST) systems.[37] For petroleum hydrocarbons that arise from petroleum that has been released from Subtitle I UST systems, EPA has developed a companion to this Technical Guide (*Technical Guide For Addressing Petroleum Vapor Intrusion At Leaking Underground Storage Tank Sites* (EPA 2015b)), which provides information and guidance about assessing vapor intrusion from petroleum hydrocarbons in these settings and may also be useful in informing decisions about vapor intrusion and petroleum hydrocarbons at non-UST sites that are similar in size to a typical Subtitle I UST release.

Many petroleum hydrocarbons may naturally biodegrade in the vadose zone through the actions of microorganisms found naturally in soil. When oxygen supply from the atmosphere is sufficient, biodegradation of petroleum hydrocarbons can occur relatively quickly, will generally produce less harmful compounds (i.e., biodegradation products), and can result in substantial attenuation of petroleum hydrocarbon vapors over relatively short distances in the vadose zone.

Numerous site-specific factors can influence the biodegradation rate of petroleum hydrocarbons (and other biodegradable vapor-forming chemicals) in the vadose zone. These factors include quantities, distribution, types, and mixtures of vapor-forming chemicals, which can differ substantially among sites where petroleum hydrocarbons are released to the subsurface

[36] The NCP states [40 *CFR* 300.430(f)(4)(ii)]: "If a remedial action is selected that results in hazardous substances, pollutants, or contaminants remaining at the site above levels that allow for unlimited use and unrestricted exposure, the lead agency shall review such action no less often than every five years after initiation of the selected remedial action." For further information, see, for example, http://www.epa.gov/superfund/cleanup/postconstruction/5yr.htm

[37] For example, the approaches in this Technical Guide are recommended for evaluating the vapor intrusion pathway associated with subsurface releases of petroleum, petroleum derivatives, and petroleum hydrocarbons from refineries, bulk storage facilities, oil exploration and production sites, pipelines and transportation, chemical manufacturing facilities, former manufactured gas plants, creosote (wood-treating) facilities, large-scale fueling and storage operations at federal facilities, and dry cleaners that use petroleum solvents.

environment. This Technical Guide allows site-specific observations of the effects of biodegradation to be considered in its approach for petroleum hydrocarbons (and any other biodegradable, vapor-forming chemical). Sections 6.3.2 and 7.3 expand on EPA's recommended approach to evaluating biodegradation of vapor-forming chemicals in the vadose zone at sites with subsurface contamination.

1.3.2 Nonresidential Buildings

EPA has broad authority and distinct responsibilities to assess and, if warranted, mitigate vapor intrusion in nonresidential settings arising from a chemical release that causes subsurface contamination by volatile hazardous chemicals (see Section 1.2). EPA[38] is authorized to take all appropriate actions to protect human health and the environment from subsurface vapor sources of chemical exposure consistent with applicable federal statutes[39,40] and regulations and considering EPA guidance,[41] taking into account the nonresidential setting. These actions may include sampling indoor air to assess exposure levels of building occupants to subsurface vapor sources and implementing interim mitigation measures to control, reduce, or eliminate exposure indoors to vapors emanating from a subsurface vapor source(s).

As used in this Technical Guide, the phrase "nonresidential buildings" may include, but is not limited to, institutional buildings (e.g., schools, libraries, hospitals, community centers and other enclosed structures for gathering, gyms and other enclosed structures for recreation); commercial buildings (e.g., hotels, office buildings, many (but not all) day care facilities, and retail establishments); and industrial buildings where vapor-forming chemicals may or may not be routinely used or stored. Section 4.0 expands on EPA's recommended approach to evaluating and mitigating vapor intrusion in nonresidential buildings.

1.4 Companion Documents and Technical Resources

Technical information pertaining to vapor intrusion has also been prepared to support development of and facilitate implementation of the technical approaches and recommendations in this Technical Guide. Key technical information is described in this section and can be found on OSWER's vapor intrusion website (see Section 11.0 for citations and internet links).

---

[38] On January 23, 1987, the President of the United States signed Executive Order 12580 entitled, "Superfund Implementation," which delegates to a number of Federal departments and agencies the authority and responsibility to implement certain provisions of CERCLA. The policies and procedures for implementing these provisions (e.g., carrying out response actions) are spelled out in the NCP. The provisions of Executive Order 12580 appear at 52 *Federal Register* 2923. At federal facilities on the NPL, EPA may not be the lead agency, but does have oversight responsibilities pursuant to CERCLA Section 120.

[39] CERCLA and RCRA authorize EPA to protect human health and the environment, as summarized in Section 1.2 of this Technical Guide. The NCP also addresses protection of human health and the environment.

[40] See, for example, CERCLA Section 101(22).

[41] See, for example, OSWER Directive 9355.0-30 (*Role of the Baseline Risk Assessment in Superfund Remedy Selection Decisions*) (EPA 1991a) and *Rules of Thumb for Superfund Remedy Selection,* OSWER Directive 9355.0-69, August 1997 (EPA 1997).

.

1.4.1 Vapor Intrusion Screening Level Calculator

The Vapor Intrusion Screening Level (VISL) Calculator (2015a) is a technical resource, developed by EPA that:

(1) Identifies chemicals considered to be typically vapor-forming and known to pose a potential cancer risk or noncancer hazard through the inhalation pathway (as described further in Section 3.1 herein);

(2) Provides generally recommended screening-level concentrations for groundwater, near-source soil gas (exterior to buildings), sub-slab soil gas, and indoor air based upon default residential or nonresidential exposure scenarios, a target cancer risk level of one per million (10^{-6}), and a target hazard quotient of one for potential non-cancer effects; and

(3) Facilitates calculation of site-specific screening levels (see Section 6.5) and/or candidate cleanup levels (see Section 7.6) based on user-defined target risk levels, exposure scenarios, and semi-site-specific (Appendix A) or site-specific (Section 7.6) attenuation factors.

The VISL Calculator is comprised of an MS Excel workbook. It can be used in evaluating whether the vapor intrusion pathway has the potential to pose a human health risk by helping to:

(1) Identify whether volatile hazardous chemicals that can pose a threat through vapor intrusion are present;

(2) Determine if those volatile hazardous chemicals are present at potentially explosive levels;

(3) Compare subsurface or indoor data against recommended screening levels provided in the VISL Calculator; and

(4) Prioritize buildings and sites for investigation and response action.

The recommended screening-level concentrations in the spreadsheet are calculated using the recommended approaches in existing EPA guidance for human health risk assessment, as described further in Sections 6.5.2 and 6.5.3 herein, and are based on current understanding of the vapor intrusion pathway.

1.4.2 Technical Support Documents

Key technical documents supporting development of the technical approaches and recommendations in this Technical Guide include:

Background Indoor Air Concentrations of Volatile Organic Compounds in North American Residences (1990-2005): A Compilation of Statistics for Assessing Vapor Intrusion (EPA 2011a): This technical report presents (1) a summary of indoor air studies that measured background concentrations of VOCs in the indoor air of thousands of North American residences and (2) an evaluation and compilation of the statistical information reported in these studies. The objective of this compilation is to illustrate the ranges and variability of

VOC concentrations in indoor air during the study period (1990-2005), resulting from sources other than vapor intrusion. This technical report was externally peer reviewed, consistent with EPA's peer review policy (EPA-SPC 2006) for scientific and technically based work products that are intended to inform Agency decisions.

EPA's Vapor Intrusion Database: Evaluation and Characterization of Attenuation Factors for Chlorinated Volatile Organic Compounds and Residential Buildings (EPA 2012a): This technical report presents technical information about sites in the U.S. that have been investigated for vapor intrusion. The primary focus of the report is the evaluation of concentrations of chlorinated VOCs in and underneath residential buildings based upon the EPA's vapor intrusion database as of 2010. This report provides the technical basis for the generic and semi-site-specific attenuation factors recommended in this Technical Guide to calculate vapor intrusion screening levels (see Section 6.5 and Appendix A). This technical report was externally peer reviewed, consistent with EPA's peer review policy (EPA-SPC 2006) for scientific and technically based work products that are intended to inform Agency decisions.

Conceptual Model Scenarios for the Vapor Intrusion Pathway (EPA 2012b): This technical report provides simplified simulation examples to illustrate graphically how subsurface conditions and building-specific characteristics determine: (1) the distribution of vapor-forming chemicals in the subsurface; and (2) the indoor air concentration relative to a source concentration. It was prepared to help environmental practitioners gain insights into the processes and variables involved in the vapor intrusion pathway and to provide a theoretical framework with which to draw inferences about and better understand the complex vapor fate and transport conditions typically encountered at actual, contaminated sites. This technical report was externally peer reviewed, consistent with EPA's peer review policy (EPA-SPC 2006) for scientific and technically based work products that are intended to inform Agency decisions.

These technical tools and documents, as well as others, can be found at http://www.epa.gov/oswer/vaporintrusion, a website developed to support the development of this Technical Guide and enhance public communication about the topic. This website also allows certain sections of this Technical Guide to be more dynamic and facilitates updates to information.

Technical documents intended to facilitate consideration of the recommendations in the *Technical Guide For Addressing Petroleum Vapor Intrusion At Leaking Underground Storage Tank Sites* (EPA 2015b) can be found at http://www.epa.gov/oust/cat/pvi/.

1.5 Historical Context

To help assess the subsurface vapor intrusion pathway, the Office of Solid Waste and Emergency Response (OSWER) released in November 2002 for comment EPA's Draft VI Guidance, which presents EPA's technical information and recommendations for evaluating subsurface vapor intrusion, based on the understanding of vapor intrusion at that time (EPA 2002c). This Technical Guide and the accompanying *Technical Guide For Addressing Petroleum Vapor Intrusion At Leaking Underground Storage Tank Sites* (EPA 2015b) supersede and replace the Draft VI Guidance.

Since the Draft VI Guidance was released, EPA's knowledge of and experience with assessment and mitigation of the vapor intrusion pathway has increased considerably, leading to an improved understanding of and enhanced approaches for evaluating and managing vapor intrusion. In addition:

- Other federal agencies with responsibilities and obligations for environmental cleanup or for response to reports of vapor intrusion have developed vapor intrusion guides for their respective programs (e.g., ATSDR 2008; DoD 2009; DoN 2011a; USPS 2009).

- A number of state agencies involved with environmental quality or public health protection have developed vapor intrusion guides for their programs, which they may continue to implement under their respective statutory authorities (e.g., see ASTSWMO [2009], a compilation).

- The Interstate Technology & Regulatory Council (ITRC), a state-led coalition of environmental regulatory professionals, prepared three guidelines for assessing the vapor intrusion pathway (ITRC 2007ab, 2014).

EPA has considered these guides in developing this Technical Guide.

In addition, in December 2009, the OIG made recommendations regarding EPA's Draft VI Guidance, which are documented in the evaluation report *Lack of Final Guidance on Vapor Intrusion Impedes Efforts to Address Indoor Air Risks* (Report No. 10-P-042; EPA 2009a). Among other things, the OIG recommended that the final guidance incorporate:

- Updated toxicity values.

- A recommendation(s) to collect and weigh multiple lines of evidence in evaluating and making decisions about human health risks posed by vapor intrusion.

- How risks from petroleum hydrocarbon vapors should be addressed.

- How the guidance applies to Superfund FYRs.

- When or whether preemptive mitigation is appropriate.

- Operations, maintenance, and termination of mitigation systems.

- When institutional controls are appropriate.

In its response letter dated March 11, 2010, OSWER generally agreed with OIG's recommendations to finalize guidance on vapor intrusion. In addition, the OIG recommended

that EPA identify and publicly report the portions of its Draft VI Guidance that remain valid and the portions that would be updated.[42]

This Technical Guide and the companion documents identified in Sections 1.3 and 1.4 fulfill EPA's commitment to address the OIG's recommendations. Table 1-1 identifies specific updates prepared by EPA in response to OIG's specific recommendations. Table 1-2 describes additional updates identified and publicly announced by EPA (EPA 2010b).

TABLE 1-1
DIRECTORY TO UPDATES IN THIS TECHNICAL GUIDE ADDRESSING RECOMMENDATIONS OF EPA OFFICE OF INSPECTOR GENERAL (EPA 2009A)

Topics to Be Addressed	Location Within This Technical Guide	Companion Documents
Update toxicity values		*VISL Calculator* (EPA 2015a)
Use of multiple lines of evidence in evaluating and making decisions about risks from vapor intrusion	Sections 5, 6, and 7	
How risks from petroleum hydrocarbon vapors should be addressed	Sections 1.3.1, 6.3.2 and 7.3	*Technical Guide for Addressing Petroleum Vapor Intrusion at Leaking Underground Storage Tank Sites* (EPA 2015b)
How this Technical Guide applies to Superfund Five-year Reviews (FYRs)		*Assessing Protectiveness at Sites for Vapor Intrusion: Supplemental Guidance to the Comprehensive Five-Year Review Guidance* (EPA 2012c)
When or whether preemptive mitigation/early action is appropriate	Sections 3.3 and 7.8	
Operations and maintenance of mitigation systems	Section 8.3	
Termination of mitigation systems	Section 8.7	
When ICs and deed restrictions are appropriate.	Section 8.6	

[42] OSWER carried out this recommendation by issuing a memorandum in August 2010, entitled *Review of the Draft 2002 Subsurface Vapor Intrusion Guidance* (EPA 2010b). The guidance reflected in this memorandum is incorporated in this Technical Guide.

TABLE 1-2
DIRECTORY TO ADDITIONAL UPDATES IN THIS TECHNICAL GUIDE PUBLICLY IDENTIFIED BY OSWER (EPA 2010B)

Topics to Be Updated, Including References to the Draft VI Guidance	Location Within This Technical Guide	Companion Technical Document or Resource
Updated a few chemical-specific physical parameters used for identifying the vapor-forming chemicals of concern.	Section 3.1	VISL Calculator (EPA 2015a)
Updated the toxicity-based criteria in Table D-1 in the draft guidance.	Section 3.1	VISL Calculator (EPA 2015a)
Observation-based conservative attenuation factors have been updated with a larger database. The generic attenuation factor for external soil gas has been updated, as well as the Reliability Assessment, using the newer available data.	Section 6.5.3 and Appendix A	*U.S. EPA's Vapor Intrusion Database: Evaluation of Attenuation Factors for Chlorinated Volatile Organic Compounds and Residential Buildings* (EPA 2012a)
Observational data since 2002 indicates that the "single line of evidence" approach with site-estimated attenuation factors is generally not appropriate for external soil gas samples.	Section 6.4.4 and Appendix A	
Experiences since 2002 illustrate the value of collecting indoor air samples earlier in the investigations. The "indoor air last" approach has been updated, which will allow more flexibility in the sequencing of subsurface and interior/indoor sample collection.	Sections 6.3.4 and 6.3.6	
The portions addressing background contamination have been updated. EPA also updated with more specific methodologies for evaluating and/or decision-making and managing background contamination.	Sections 6.3.5, 7.4 and 7.6	*Background Indoor Air Concentrations of Volatile Organic Compounds in North American Residences (1990-2005): A Compilation of Statistics for Assessing Vapor Intrusion* (EPA 2011a)
The portion of this Technical Guide focusing on testing indoor air has been updated to allow more flexibility in the duration of sampling to take advantage of other sampling durations and methods.	Section 6.4.1	
The Draft VI Guidance allows site-specific decisions to be made based on indoor air concentrations in a relatively few representative buildings. This portion of this Technical Guide has been updated to increase the confidence that the approach fully addresses building-by-building variability.	Sections 6.2.2 and 7.8	
Updated and expanded the community involvement information to be more specific to vapor intrusion sites, including guidelines for effective risk communication and available resources, outreach products and tools for outreach.	Section 9	

1.6 Public Involvement in Developing this Vapor Intrusion Technical Guide

On November 29, 2002, EPA published a notice in the *Federal Register* (67 FR 71169) announcing and soliciting comment on its Draft VI Guidance. Since that time, EPA continued to gather information and learn more about vapor intrusion, in part by convening periodic forums where practitioners, regulated parties, and regulators could discuss the emerging science and engineering pertaining to vapor intrusion assessment and mitigation. In addition, on March 17, 2011, EPA published a notice in the *Federal Register* (76 FR 14660) re-opening the docket and soliciting additional comment on its development efforts for this Technical Guide. The docket was re-opened again in March 2012 to receive comments about specific technical documents that were prepared to support development of this Technical Guide; these technical documents are listed in Section 1.4. Finally, another review draft was released on April 16, 2013 for public comment. In developing and refining this Technical Guide, EPA considered all public comments and input received since 2002.

EPA also proactively engaged communities beyond the traditional outreach practices, especially environmental justice communities and communities subject to multiple stressors.[43] Aspects of this engagement have included:

- Conducting public listening sessions in communities impacted by vapor intrusion to solicit input on developing this Technical Guide.

- Using Internet sites and other communication tools to update stakeholders on the progress of developing this Technical Guide.

Table 1-3 identifies specific vapor intrusion topics that have received substantive public comment as a result of EPA's outreach efforts.

1.7 Organization

The next nine sections of this Technical Guide are as follows:

- Section 2.0 Conceptual Model of Vapor Intrusion further describes vapor intrusion and identifies many of the variables that influence vapor migration in the vadose zone and soil gas entry into buildings.

- Section 3.0 Overview of this Vapor Intrusion Technical Guide provides an overview of this Technical Guide and the general recommended framework for vapor intrusion assessment and response action.

- Section 4.0 Considerations for Nonresidential Buildings provides information regarding EPA roles, responsibilities, and risk management decision-making in nonresidential settings, including those (e.g., manufacturing facilities) where workers handle volatile hazardous chemicals similar to or different from those contaminating the subsurface.

[43] For more information about the Community Engagement Initiative visit: http://www.epa.gov/oswer/engagementinitiative/

TABLE 1-3
VAPOR INTRUSION TOPICS RECEIVING SUBSTANTIVE PUBLIC COMMENT

Topics	Location Within This Technical Guide	Companion Document(s)
Applicability to petroleum hydrocarbons	Sections 1.3.1, 6.3.2 and 7.3	*Technical Guide for Addressing Petroleum Vapor Intrusion at Leaking Underground Storage Tank Sites* (EPA 2015b)
Applicability to nonresidential buildings	Sections 1.3.2, 4.0 and 7.4.3	
Conditions warranting prompt response action	Sections 5.2, 7.5 and 8.2.1	
Planning investigations and applying data quality objectives	Section 6.2 and Appendix B	
Sampling and monitoring methods for indoor air	Section 6.4.1	
Attenuation factors and risk-based screening	Section 6.5 and Appendix A	*U.S. EPA's Vapor Intrusion Database: Evaluation of Attenuation Factors for Chlorinated Volatile Organic Compounds and Residential Buildings* (EPA 2012a)
Semi-site-specific screening and application of mathematical models	Sections 6.5 and 6.6	
Use of conceptual site models and multiple lines of evidence in evaluating risks posed by vapor intrusion	Sections 2, 3.2, 5.4, 6.3 and 7	
Risk management benchmarks and decision-making	Section 7	
Use of institutional controls for building mitigation	Section 8.6	
Monitoring and termination of mitigation systems	Sections 8.4 and 8.7	
Risk communication	Section 7.4 and 9	

- Section 5.0 Preliminary Analysis of Vapor Intrusion provides technical information for situations where only limited site-specific data may be available (e.g., initial site assessment).

- Section 6.0 Detailed Investigation of Vapor Intrusion provides technical information for conducting site-specific vapor intrusion assessments emphasizing multiple lines of evidence, including consideration of background concentrations.

- Section 7.0 Risk Assessment and Management Framework provides general recommendations about data evaluations and risk-informed decision-making pertaining to vapor intrusion, including consideration of background concentrations.

- Section 8.0 Building Mitigation and Subsurface Remediation provides technical information for mitigating vapor intrusion and describes how subsurface vapor source remediation and other final cleanup actions are combined with engineered and non-engineered exposure controls to ensure protection of human health.

- Section 9.0 Planning for Community Involvement provides information and describes available resources for engaging affected communities and communicating risk-related information.

- Section 10.0 Glossary provides definitions and descriptions of key terms used in this document.

This Technical Guide concludes with Section 11.0, Citations and References, and three supporting appendices:

- Appendix A: Recommended Subsurface-to-Indoor-Air Attenuation Factors.

- Appendix B: Data Quality Assurance Considerations.

- Appendix C: Calculating Vapor Source Concentration from Groundwater Sampling Data.

2.0 CONCEPTUAL MODEL OF VAPOR INTRUSION

This section presents a general (i.e., not site-specific) conceptual model of vapor intrusion, borrowing from published depictions (EPA 2008a; EPA 2012b; ITRC 2007a; McAlary et al. 2011; DoD 2009). It identifies and describes the 'what', 'where', 'how' and 'why' of vapor intrusion, to provide insights about the many of the lines of evidence pertinent to evaluating vapor intrusion on a site-specific basis, which are discussed further in Sections 5, 6, and 7 of this Technical Guide.[44] It concludes with several general observations that may assist practitioners when planning and conducting detailed vapor intrusion investigations at specific sites, which is the subject of Section 6 of this Technical Guide.

Vapor intrusion is a potential human exposure pathway — a way that people may come into contact with hazardous vapors while performing day-to-day indoor activities. Figure 2-1 summarizes the vapor intrusion pathway for soil gas entry. For purposes of this Technical Guide, the vapor intrusion pathway is referred to as "complete" [45] for a specific building or collection of buildings when the following five conditions are met under current conditions:

1. A subsurface source of vapor-forming chemicals is present (e.g., in the soil or in groundwater) underneath or near the building(s);

2. Vapors form and have a route along which to migrate (be transported) toward the building(s);

3. The building(s) is(are) susceptible to soil gas entry, which means openings exist for the vapors to enter the building and driving 'forces' exist to draw the vapors from the subsurface through the openings into the building(s);

4. One or more vapor-forming chemicals comprising the subsurface vapor source(s) is (or are) also present in the indoor environment; and

5. The building(s) is (or are) occupied by one or more individuals when the vapor-forming chemical(s) is (or are) present indoors.[46]

If one (or more) of these conditions is currently absent and is reasonably expected to be absent in the future (e.g., vapor migration is significantly and persistently impeded by natural geologic, hydrologic, or biochemical (e.g., biodegradation) processes and conditions), the vapor intrusion pathway is referred to as "incomplete."

---

[44] In general, a conceptual site model integrates all lines of site-specific evidence into a three-dimensional conceptualization of site conditions that includes contaminant sources, release mechanisms, vapor migration route(s), and potential receptors. Section 5.4 provides additional information about developing conceptual site models.

[45] A complete vapor intrusion pathway indicates that there is an opportunity for human exposure in the subject building(s), whereas an incomplete pathway would not provide an opportunity for human exposure,

[46] The exposure route of general interest for vapor intrusion is inhalation of toxic vapors present in indoor air. Because breathing is not avoidable for prolonged periods, individuals in occupied buildings are presumed to be exposed by the inhalation route to any hazardous vapors present in indoor air. Hence, the presence of a human exposure route is implied in the fifth condition.

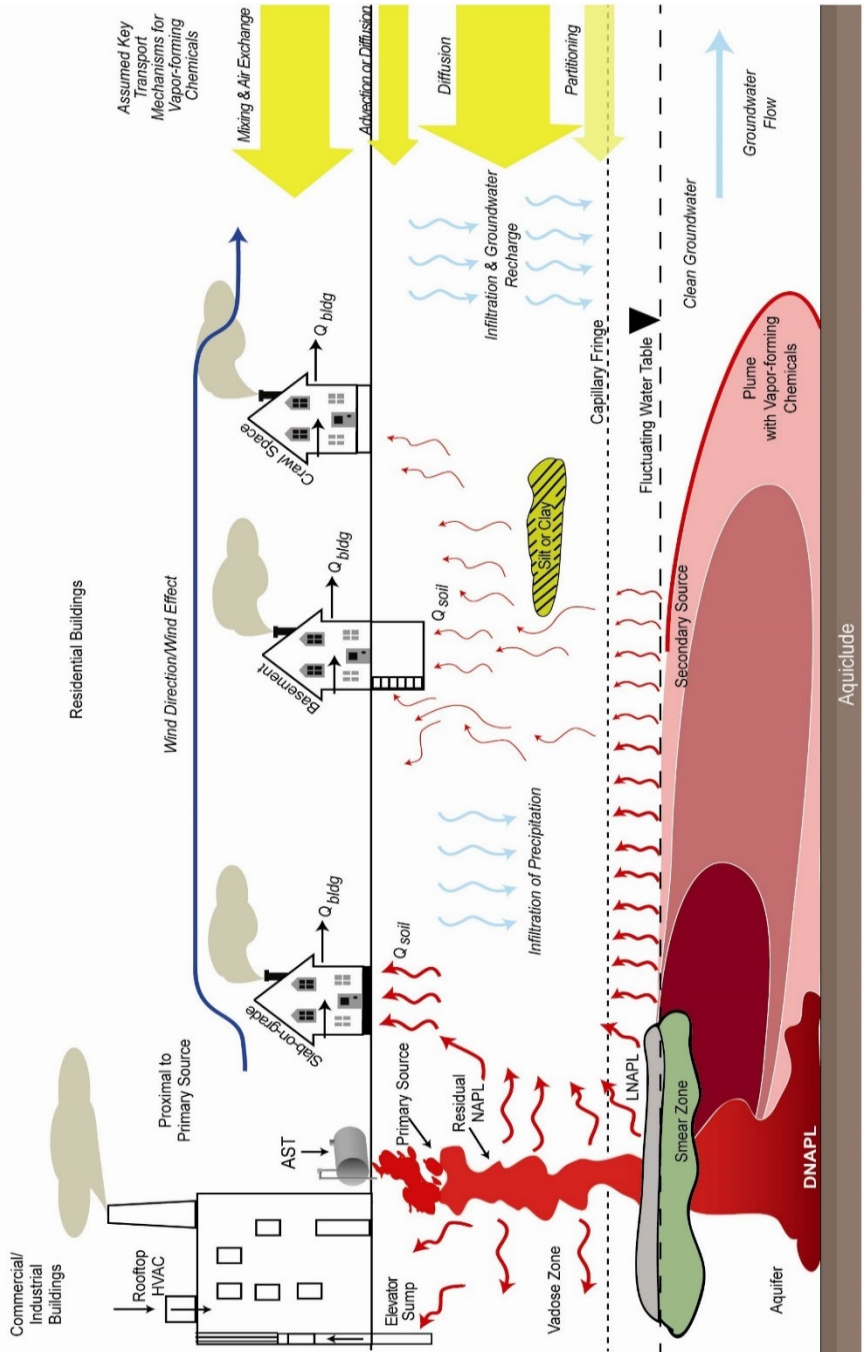

Figure 2-1 Illustration of Key Elements of the Conceptual Model of Soil Vapor Intrusion
Note: Q_{soil} represents soil gas entry; Q_{bldg} represents air exchange.

The first three of these five conditions are further discussed in the next three subsections. Knowledge of potential vapor sources and vapor fate and transport mechanisms is essential for interpreting the data collected during a site-specific investigation of vapor intrusion. Knowledge of the factors that influence the vapor intrusion pathway is also invaluable for identifying, prioritizing, and sequencing data collection activities, which allows a phased and efficient overall investigation plan to be developed. Practitioners are encouraged to refer to quantitative discussions of these subjects, which are provided in *Conceptual Model Scenarios for the Vapor Intrusion Pathway* (EPA 2012b).

The human population of primary interest is comprised of individuals living in, working in, or otherwise occupying a building subject to vapor intrusion. All types of buildings have openings and conduits that render them potentially vulnerable to vapor intrusion. This includes residential buildings (e.g., single-family homes, trailer or 'mobile' homes, multi-unit apartments and condominiums), commercial workplaces (e.g., office buildings, retail establishments), industrial facilities (e.g., manufacturing plants), and educational and recreational buildings (e.g., schools and gyms). Vapor intrusion can occur in buildings with any foundation type (e.g., basement, crawl space, slab-on-grade).

As noted previously, methane and certain other vapor-forming chemicals can also pose explosion hazards in buildings and unoccupied structures,[47] depending upon building-, structure-, and site-specific circumstances. The discussion in the next three sections pertains also to methane and other vapor-forming chemicals that can pose explosion hazards, because similar processes and conditions are involved in explosive vapors migrating towards the interior of buildings or non-occupied structures from the subsurface environment; i.e.,

1) A subsurface source of vapor-forming chemicals is present (i.e., in the soil or in groundwater) underneath or near the structure(s) or building(s).

2) Vapors form and have a route along which to migrate (be transported) toward the structure(s) or building(s).

3) The structure(s) or building(s) is (or are) susceptible to soil gas entry, which means openings exist for the vapors to enter the structure(s) or building(s) and driving 'forces' exist to draw the vapors from the subsurface through the openings into the structure(s) or building(s).

[47] For purposes of evaluating potential explosion hazards, non-occupied structures, in addition to buildings, are relevant structures for intrusion and accumulation of vapors.

2.1 Subsurface Vapor Sources

The originating (i.e., primary) source(s) of subsurface contamination may include, but are not limited to, leaking tanks (above or below ground), discharges to sewer lines[48], septic tanks, and floor drains, landfills and other land disposal management units, fire-training areas, spills, discharge areas, and vapor leaks from pressurized tanks and pipelines. The resulting subsurface contamination may be comprised of non-aqueous-phase liquids (NAPLs) [49] (e.g., solvents; petroleum-related products, such as gasoline) and contaminated soil. These are often referred to as the source zone(s). Groundwater and sewer lines[50] flowing through or underneath[51] the source zone(s) can become contaminated and in turn become a (secondary or derivative) subsurface vapor source of contaminant vapors at locations distant from the source zone.

Contaminants in soil, NAPLs, and groundwater can become sources for vapor intrusion if they are likely to volatilize under normal temperature and pressure conditions. Water solubility is also a factor for chemicals in source zones that come into contact with migrating groundwater. Common classes of chemicals of concern for vapor intrusion that exhibit the foregoing characteristics are VOCs, such as tetrachloroethylene (PCE), trichloroethylene (TCE), vinyl chloride, carbon tetrachloride, and benzene, toluene, ethylbenzene and xylenes (collectively, BTEX). Other compounds that are not as volatile as these VOCs (e.g., so-called semi-volatile organic compounds), but that may be cause for concern, include some polycyclic aromatic hydrocarbons (PAHs) (e.g., naphthalene), some polychlorinated biphenyl (PCB) congeners, and elemental mercury, a dense NAPL (DNAPL).[52]

---

[48] Historically, sanitary sewers and septic tanks have been common disposal points for aqueous and chemical wastes from commercial and industrial operations. Contaminated water, non-aqueous phase liquid (NAPL), and VOC vapors can leak from sewer lines through cracks, joints, or breaks. A study of solvent contamination in California arising from dry cleaning operations concluded that discharges to and leakage from sewer lines is an important source of PCE contamination of soil and groundwater: "Where a source investigation has been done in connection with PCE contamination, the … data strongly indicate that leakage through the sewer lines is the major avenue through which PCE is introduced to the subsurface." (Izzo 1992). In the South Weber neighborhood near the Hill Air Force Base in Utah, sewer lines carrying discharged contaminated groundwater to the municipal treatment system were identified as a source of vapor intrusion in homes [Source: *EnviroNews* - Updating environmental issues and activities at Hill Air Force Base, Utah (March 2011); Currently available on-line at: http://www.hillrab.org/news.aspx]

[49] EPA's Contaminated Site Cleanup Information website (http://www.clu-in.org/) provides information describing NAPLs that are denser than water (DNAPLs) or less dense than water (LNAPLs), and methods for their detection and remediation in the subsurface environment.

[50] In addition to receiving direct discharges, sewers can be indirect receptacles of subsurface contamination via infiltration of NAPL, soil gas, or contaminated groundwater through cracks in piping and manholes. For example, Vroblesky et al (2011) found that infiltration of contaminated groundwater into sewers and its transport via and exfiltration from sewers caused complex and unanticipated patterns of groundwater contamination at a site in South Carolina.

[51] Figure 2-1 illustrates a NAPL release/source (near the commercial/industrial building on the left) that fully penetrates the vadose zone. A partially penetrating NAPL release/source may also cause groundwater contamination, however, as infiltrating water passes through the source zone and migrates to the groundwater table.

[52] Once volatilized into soil or sewer gas from a subsurface vapor source(s), these less volatile chemicals will migrate under the influence of diffusion and advection (see Section 2.2) as do more volatile chemicals, although there may be chemical-specific differences in their susceptibility to biodegradation in the vadose zone.

Landfill gases, such as methane and hydrogen sulfide, also can be associated with the vapor intrusion pathway for buildings located near current or former landfills or other degrading wastes. These gases are actively produced as a result of anaerobic biodegradation processes. Methane can also be associated with the vapor intrusion pathway for buildings located near degrading petroleum hydrocarbons or fuel-grade ethanol released into the subsurface environment (Ma et al. 2014, 2012; Sihota et al. 2013).

Properties with potential contamination by vapor-forming chemicals can be found in many industrial and commercial areas. These properties include current and former manufacturing and chemical processing plants, warehouses, landfills and other land disposal units, coal gasification plants, chemical handling or transfer facilities and areas (e.g., train yards), dry cleaners, and retail fueling outlets (also known as gas stations). Use, storage, or transport of chemicals at these facilities may have resulted in a release of vapor-forming chemicals to the environment creating the potential for future vapor intrusion issues. In addition to industrial and commercial activities, roadside dumping, pesticide spraying, or even disposal of household chemicals via a septic field may also release volatile chemicals that may eventually migrate to the subsurface environment.

The primary contamination source need not, however, be on the property of interest to pose a vapor intrusion problem.[53] As illustrated in Figure 2-1, the primary source(s) of vapor intrusion (e.g., contaminated soil, or leaked tanks) may be present on a neighboring property or on a property some distance away. Even "greenspace" properties that have not previously been occupied or developed may contain contamination by vapor-forming chemicals due to migrating plumes of contaminated groundwater or migrating soil gases.[54]

In the case of groundwater as a subsurface vapor source for vapor intrusion, the source strength will be influenced by the vertical distribution of contaminant concentrations in the upper reaches (e.g., top foot) of the water table and by seasonal fluctuations in the groundwater table groundmass flux of vapors. If vapor-forming chemicals are not present in the upper reaches (e.g., within the uppermost foot) of the groundwater table (e.g., due to the presence of an overlying zone of clean water from recharge; i.e., "fresh water lens"),[55] vapor transport to the overlying vadose zone will be impeded due to the slower diffusion of volatile chemicals in water

[53] Depending on the geology and amount and form of contamination in the source zone(s), contaminated groundwater plumes can be long and narrow and can flow beneath a property located a mile or more away from the primary source. Soil gas plumes tend to extend in both lateral directions and can be larger in lateral extent relative to groundwater plumes.

[54] See Section 6.2.1 for further discussion on which buildings and non-occupied structures are considered "near" for purposes of a preliminary analysis.

[55] Infiltrating precipitation is important in recharging aquifers with fresh water, as well as in wetting vadose zone soils. At locations distant from "source zones," infiltrated water that reaches the upper surface of a plume of contaminated groundwater (i.e., recharges groundwater) in an unconfined aquifer will tend to dilute concentrations of vapor-forming chemicals and may form a lens of relatively "clean" water at the groundwater table, which overlies the plume. Because diffusion of dissolved-phase volatile chemicals will tend to control the mass transfer of vapors into the soil gas at the groundwater table, the presence of a lens of clean water as little as a foot in thickness overlying a plume may be sufficient to impede vapor flux to the vadose zone (McAlary et al. 2011). This condition is less likely to occur where fluctuations of the groundwater table are large, relative to local recharge, and would not generally be expected in arid climates.

than in soil gas. For this reason, Figure 2-1 does not show vapors emanating from the leading (i.e., right-most) edge of the plume.

If the vapor-forming chemicals are present in the upper reaches of the groundwater table (i.e., volatile chemicals are in the uppermost reaches of an unconfined – "water table" – aquifer), fluctuations in the water table will tend to transport the volatile chemicals upward (during periods of rising water table) or expose impacted water above the water table to soil gas (during periods of falling water table). The latter will facilitate the episodic formation of vapors in the vadose zone. Rising water tables also will bring the vapor source closer to the building(s).

2.2 Subsurface Vapor Migration

At many sites, the subsurface vapor source (e.g., in soil or groundwater) is not in contact with the bottom of the subject building. Under these circumstances, vapors emanating from the source medium enter the pore space around and between the subsurface soil particles in the soil column above the groundwater table, which is called the unsaturated soil zone or vadose zone. If the subsurface vapor source is in the vadose zone, the vapors have the potential to migrate radially in all directions from the source via diffusion (i.e., upward toward the atmosphere, laterally outward, and downward toward the water table; downward migration may eventually lead to groundwater contamination). If the subsurface vapor source is in the upper-most zone of groundwater, the vapors have the potential to migrate upwards toward the atmosphere via diffusion. Figure 2-1 illustrates these conditions and this process.

Regardless of source type, soil gas concentrations emanating from a subsurface vapor source generally attenuate, or decrease, as the volatile chemicals move from the source through the soil and into indoor air. If and when soil vapor monitoring data at a given site are not consistent with this trend, the conceptual site model may be incomplete (e.g., additional, unrecognized sources or a preferential migration route(s) may exist at the site) and/or bias or error may have been imparted by the sampling and analysis techniques.

Diffusion, which is caused by the random motion of molecules, affects the distribution of soil vapors when there are spatial differences in chemical concentrations in the soil gas. The net direction of diffusive transport is toward the direction of lower concentrations.

Advection occurs in the vadose zone when there is bulk movement of soil gas induced by spatial differences in soil gas pressure. The direction of advective vapor transport is always toward the direction of lower air pressure. Advection is generally expected to occur in the vicinity of buildings, because differences in temperature between the building interior and the subsurface environment or the operation of combustion units or fans within the building can create driving forces for soil gas entry (See Section 2.3). Advection of soil gas may also occur:

- near the ground surface due to fluctuations in barometric (atmospheric) pressure, which can either release soil gas into the atmosphere (Clements and Wilkening 1974) or

introduce ambient air into the subsurface environment (the latter process may be important in oxygenating surface soil horizons);[56]

- wherever methane generation from anaerobic degradation is sufficiently high (e.g., near some landfills, some locations with degrading fuels).

Advection may be hindered where extensive surface barriers, such as asphalt, concrete, or frozen soil are present.

Vapors also can migrate via advection (and diffusion) along a preferential subsurface pathway, such as a utility corridor or more porous zones of soil or rock, or beneath surface barriers that limit the direction(s) of vapor migration, such as frozen ground or asphalt.[57]

Vapor migration in the vadose zone can be impeded by several factors, including high soil moisture, low-permeability (generally fine-grained) soil, and biodegradation:

- High moisture levels in the vadose zone can significantly reduce the effective rate of diffusive transport, owing to the substantially smaller diffusion coefficient of vapor-forming chemicals in water compared to air. Where ground covers, such as asphalt or concrete, are absent, soil cores taken external to building structures can reasonably be expected to show greater soil moisture than underneath buildings (Tillman and Weaver 2007), particularly after episodes of precipitation and infiltration. Fluctuations in the elevation of the groundwater table can also contribute to temporal changes in soil moisture profiles, in addition to changing the thickness of the vadose zone.

- A low-permeability layer in the vadose zone, particularly one with high moisture content or perched water, may impede or prevent upward migration of vapors from deeper sources in the vadose zone. Figure 2-1 illustrates partial impedance due to a silty or clay layer of limited lateral extent.[58] In some cases, soil or rock can impose sufficient resistance to vapor migration to make the vapor intrusion pathway insignificant, because low-permeability layers are laterally extensive over distances that are large compared to the size of the building(s) or the extent of subsurface contamination with vapor-forming chemicals.

[56] Under certain conditions, such as periods during which indoor–outdoor pressure differences are small, atmospheric pressure fluctuations may contribute to the vapor flux into a building (Robinson and Sextro, 1997).

[57] Whether the subsurface vapor source is contaminated soil or groundwater, soil gas concentrations emanating from a subsurface source generally attenuate, or decrease, as the vapors move from the source through the soil and into indoor air due to diffusion and advection and are subject to any degradation. If and when soil vapor monitoring data at a given site are not consistent with this trend, the possible existence of a preferential migration route(s) warrants consideration. Sewer lines also warrant consideration as potential sources of vapors, as well as conduits for preferential (e.g., unattenuated) transport of vapors towards buildings. Preferential migration routes are discussed further throughout this Technical Guide, including in Sections 5.4, 6.3.2, and 6.5.2.

[58] Low-permeability layer(s) overlying contaminated groundwater (i.e., "aquicludes") can, likewise, impede the flux of vapors from the contaminated plume to the vadose zone. The aquiclude shown at the base of Figure 2-1 would not impede the flux of vapors from the contaminated plume to the vadose zone, however, because the aquiclude is below both. The aquiclude would impede vapor flux from any additional contaminated plume located below it.

- Some chemicals (e.g., benzene, methane, and other petroleum hydrocarbons; vinyl chloride (Patterson et al. 2013) and some other chlorinated hydrocarbons) may experience reductions in their soil gas concentrations due to biodegradation in the vadose zone under certain conditions. Depending upon the potential for oxygen to migrate into the subsurface and underneath buildings from the ambient air, biodegradation may be anaerobic or aerobic. The rate of biodegradation *in situ* will be chemical-specific (i.e., chemicals have different degradation rates even within a similar microbial environment), will be site-specific (i.e., the microbial environment will depend upon soil moisture, nutrient and oxygen levels, and the chemical mixture,[59] among other factors (Holden and Fierer 2005)), and may be location-specific (i.e., the microbial environment can change over time and space due to variations in soil moisture,[60] nutrient and oxygen[61] levels). In some cases, biodegradation in the vadose zone can impede vapor migration significantly.

Demonstrating the extent, if any, to which these processes act as a barrier to vapor transport at specific sites may entail intensive testing or investigative methods that are very different from the sampling and analysis techniques for indoor air and soil gas (see, for example, Sections 6.3.2 and 6.4). Where and when it occurs, biodegradation may result in the formation of by-products that are potentially hazardous (e.g., methane from ethanol, vinyl chloride from PCE or TCE).

The distribution and magnitude of soil gas concentrations immediately beneath a building are expected to reflect the interplay between vapor transport toward the building (via diffusion and advection) in the vadose zone and vapor withdrawal due to soil gas entry into the building (in the case where the building is under-pressurized), which may be spatially and temporally variable (Section 2.3). Likewise, soil vapor may become contaminated as a result of over-pressurized buildings forcing contaminated indoor air through openings in the foundation into nearby soil.

2.3 Openings and Driving Forces for Soil Gas Entry into Buildings

Hazardous vapors in the vadose zone may eventually enter buildings as a component of a gas by migrating through cracks, seams, interstices, and gaps in basement floors, walls, or foundations ("adventitious openings") or through intentional openings, such as perforations due to utility conduits and sump pits. Figure 2-2 illustrates some of these types of openings. Buildings can be expected to vary, even within a single community, in the amount of opening

[59] For example, aerobic biodegradation of benzene may be impeded by the presence of methane, due to competition for oxygen by methane-oxidizing ("methanotrophic") bacteria, depending upon site-specific conditions (Ma et al. 2012).

[60] Moisture plays a particularly important role for microorganisms in the vadose zone. Microbial growth and activity can decrease rapidly with depth, coincident with the soil moisture profile, and increase again in the capillary fringe (Holden and Fierer 2005).

[61] Site-specific infrastructure and soil conditions, climate, and other factors will determine the extent to which oxygen levels underneath a building will be different compared to locations outside the building footprint. In addition to buildings, surface covers, such as asphalt or concrete, can impede oxygenation of the vadose zone, relative to the case where the ground surface is in contact with the atmosphere, all other factors being equal.

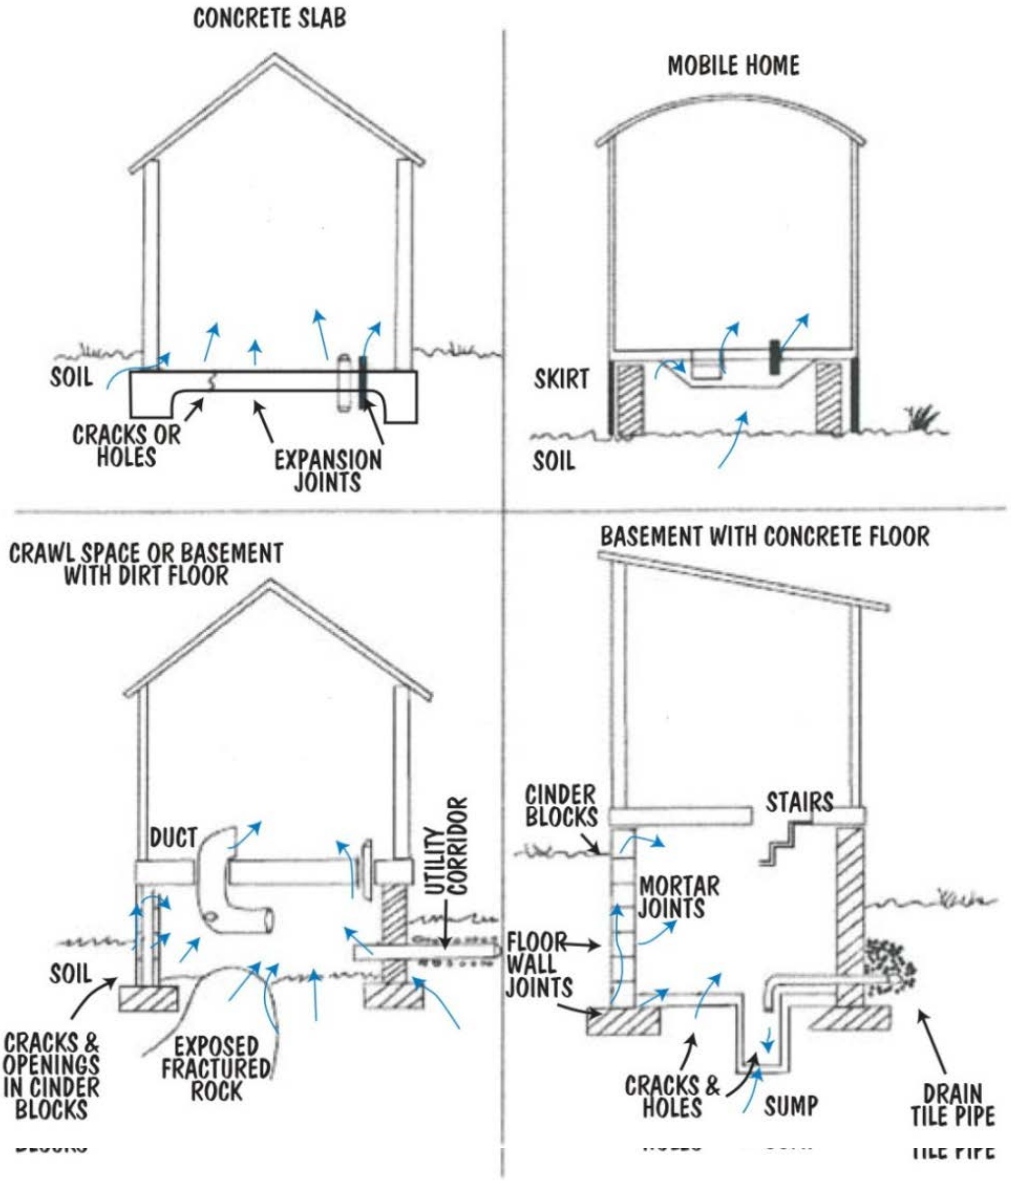

Figure 2-2 Illustration of Potential Openings in Various Building Types
Note: Blue arrows represent soil gas migration or entry. Source: EPA (2008)

area available for soil gas entry; for example, buildings with deteriorating basements and foundations or dirt floors are more susceptible to soil gas entry.

As mentioned in Section 2.2, advection in the vadose zone can arise in the vicinity of buildings whenever there is a difference between the air pressure within a building and the subsurface environment. The air pressure within a building can be lower than in the subsurface due to:

- Temperature differences between indoor and subsurface locations (e.g., the winter-time "stack effect," when buildings are commonly heated, leading to convection cells driven by heated air that rises to upper levels and leaks through roofs and upper-floor windows).

- The operation of mechanical devices, such as exhaust fans for ventilation, air conditioners, and clothes dryers, with vents to the outdoors.

- The operation of fireplaces that vent combustion (exhaust) gases to the outdoors.

- The operation of furnaces in basements of centrally heated buildings, which can incrementally depressurize the basement (EPA 1993a).

- Wind load on the building walls.[62]

Even small pressure differences may cause advective flow of soil gas into or out of the building through pores, cracks, or openings in the building floor or basement walls[63] or gas present in drain lines, sumps, and sewer lines that do not have adequate vapor traps.[64]

[62] The wind effect is caused by differences in building pressure on a building's surfaces. The outdoor air pressure will be higher on the windward side of the building, than on the leeward side, as ambient air flows around the building. The net effect of this pressure difference will vary from building to building, depending upon the location of the primary openings for soil gas entry (and the primary opening for air infiltration through the building envelope –see Section 2.4) (EPA 1993a, Section 2.3 therein).

[63] As a result of the construction of foundation walls and floor slabs, a perimeter crack (i.e., space between the floor slab and walls) may be created and serve as an entry location for soil vapors. This perimeter crack is often obscured by wall coverings, and may not be accessible for inspection or direct testing. Vapors have been observed to migrate through what appears to be intact concrete floors and walls, which may, in fact, have small unobserved fractures or porous areas from improper curing. In addition, conduits may be present that facilitate soil gas entry into buildings. These conduits may include utility (e.g., sewer, water, or electrical) penetrations and floor drains

[64] Where sewers or other conduits contain volatile contaminants, lateral lines connecting buildings to these conduits may facilitate vapor intrusion into indoor air. Although floor drains are designed to allow water to drain away from the building, they are usually not designed or constructed to eliminate gas entry. At a test house in Indianapolis, elevated levels of PCE and chloroform were found in gas in a laundry drain line, which was suspected of serving as a source of vapors found in indoor air (EPA 2012f). Although building construction codes and toilet designs are intended to prevent sewer gas from entering homes, inadequate maintenance (e.g., plumbing fixture seals) can result in loss of the intended protection. Pennell et al (2013), for example, found sewer gas entry to be a significant source of PCE in indoor air at a home in Massachusetts. In addition, sewer gas was a suspected source of benzene in indoor air in many buildings near a gasoline spill site in Hazleton, Pennsylvania (www.epa.gov/reg3hwmd/npl/PA0001409671.htm), where sewer vent traps were subsequently installed to mitigate intrusion of gasoline vapors into homes.

To date, most analytical and computational models of vapor intrusion have been predicated on the assumption that residences and other small buildings experience a constant under-pressurization (i.e., lower pressure in the building than in the subsurface), which fosters vapor intrusion. Whereas this assumption facilitates analyses and may be reasonable for some purposes (see, for example, Section 2.5), it is highly idealized. To illustrate: fluctuations in subslab-to-building pressure difference (and, hence, soil gas entry rates) over time can be reasonably expected due to:

- diurnal (daily) and seasonal changes in the temperature of ambient air, whereas indoor temperatures may be more stable, particularly during periods when mechanical heating and cooling systems are in use;
- changes in ambient air pressure;
- non-instantaneous response (i.e., lag or delay in response) of subsurface soil gas to changes in ambient air pressure (EPA 1993a, Section 2.3 therein), particularly where low-permeability soil is in direct contact with a building foundation (e.g., basement) below the ground surface;[65]
- changes in wind direction and speed; and
- intermittent operation of mechanical ventilation systems and combustion devices that vent exhaust gases to the outside.

Theoretically, these processes and variables suggest that soil gas entry rates can be expected:

- to vary over different time scales (e.g., within an day, and between seasons);
- to differ geographically due to differences in ambient air temperature, pressure, wind, and building conditions (e.g., leakage area and its distribution over the building envelope); and
- to be discontinuous over some time periods.

[65] On the other hand, where granular fill is present underneath a building, there is potential for preferential soil gas flow through the fill, especially in locations where the gas permeability of the surrounding soil is low. Where granular materials have differentially settled, air voids (also highly permeable to soil gas flow) may form beneath the foundation. Utility penetrations and other conduits may be connected to the granular fill, accentuating the potential pathway for soil gas entry into a building. Adding to the complexity, pressure differentials caused by wind flows conceivably could create a cross-flow through granular fill underneath the foundation, which may episodically dilute vapor concentrations (and oxygenate soil gas) in the building vicinity.

2.4 Air Exchange and Mixing

Air exchange refers to the flows into and out of a building, which are generally in balance, and is composed of three processes:

1) infiltration—air leakage through random cracks, interstices, and other unintentional openings in the building envelope;

2) natural ventilation—airflows through open windows, doors, and other designed (intentional) openings in the building envelope; and

3) mechanical ventilation—air movement controlled and driven by fans.

For the vapor intrusion exposure scenario, air exchange by each of these processes will generally tend to mitigate the effects of vapor intrusion (i.e., reduce indoor air concentrations) via dilution, while air inflows will also transport indoors any vapor-forming chemicals in ambient air (see Section 2.7).[66]

The air exchange rate is conventionally defined as the ratio of the airflow rate (e.g., cubic meters per second) to the building volume (e.g., cubic meters) and is generally expressed in terms of exchanges per hour (i.e., overall units of $hour^{-1}$). Values for residential air exchange rates are typically on the order of approximately 0.18 to 1.26 air changes per hour (ACH) (EPA 2011b, see Table 19-24 therein, 10^{th} and 90^{th} percentiles).[67,68] Values for non-residential buildings are highly-dependent upon building use and can range widely (on the order of approximately 0.3 to 4.1 ACH) (EPA 2011b, see Table 19-27 therein, 10^{th} and 90^{th} percentiles).

[66] The potential diluting effect of air exchange arises when ambient air has negligible presence of the volatile chemicals found in site-related contamination in the subsurface environment. In some situations, site-related contamination has the potential to impact ambient air with the same vapor-forming chemicals that pose a threat from vapor intrusion. For example, contamination of shallow soil or groundwater may release site-related vapor-forming chemicals to ambient air. In such situations, air exchange would contribute to the presence of site-related contamination in indoor air, rather than only dilute any impacts from vapor intrusion.

[67] EPA's Office of Research and Development evaluated eight studies of air exchange rate for residential buildings and selected a 1995 EPA study as the basis for recommending values for risk assessment (EPA 2011b, Table 19-24). The key study analyzed almost 3,000 time-averaged measurements of exchange rate in occupied homes in the United States, which were generally obtained using a tracer-release method. Median values ranged from 0.35 $hour^{-1}$ in the mid-western region to 0.49 $hour^{-1}$ in the northeast and southern regions. Tenth percentile values ranged from 0.16 $hour^{-1}$ in the mid-western and southern regions of the U.S. to 0.23 $hour^{-1}$ in the northeast region. Regional differences in exchange rate reflect differences in weather (e.g., temperature and wind speed), prevailing building conditions (e.g., house 'leakiness'), and the time periods (e.g., season) in which measurements were made.

[68] EPA's Office of Research and Development (EPA 2011b, Section 19.5.1.2.7) also summarized a study that conducted approximately 500 indoor-outdoor air exchange rate (AER) calculations based on residences in three urban locations (metropolitan Elizabeth, NJ; Houston, TX; and Los Angeles, CA). This study highlights how climate and season can influence air exchange rate. In Texas, the measured AERs were lower in the summer cooling season (median = 0.37 ACH) than in the winter heating season (median = 0.63 ACH), likely because windows were closed while air conditioners were in use. The measured AERs in California were higher in summer (median = 1.13 ACH) than in winter (median = 0.61 ACH), because summers in Los Angeles County are less humid than NJ or TX and residents are more likely to utilize natural ventilation through open windows and screened doors. In New Jersey, air exchange rates in the heating and cooling seasons were similar.

To date, most analytical and computational models of vapor intrusion have been predicated on the assumption that residences and other small buildings are well mixed spaces throughout which concentrations of vapor-forming chemicals are uniform. Whereas this assumption facilitates analyses and may be reasonable for some purposes (see Section 2.5), it is highly idealized. To illustrate: airflow within a building (i.e., inter-zonal airflow) can be impeded by doors, walls, and other partitions that separate rooms and other building areas. Whereas airflows within a building can be facilitated by mechanical means, spatial variation of temperature and humidity suggest that air mixing is not necessarily complete even in buildings that benefit from centralized systems for heating, air condition, and ventilation. Furthermore, many residences do not have such mechanical systems. Therefore, buildings subject to vapor intrusion may exhibit differences in concentration of vapor-forming chemicals among building areas (e.g., rooms) as a result of the differential proximity to openings for soil gas entry (see Section 2.3) and openings for air leakage and ventilation and the magnitude and balance of inter-zonal airflows. For example, rooms with perforations through the foundation (e.g., bathrooms or utility rooms) may have greater concentrations of vapor-forming chemicals in air compared to rooms that do not. Generally, basements can reasonably be expected to exhibit greater concentrations of vapor-forming chemicals than upper occupied levels.

Buildings constructed over a crawl space with a dirt floor may benefit from the dilution of soil gas by any ventilation of crawl space air, but would not have the impedance to vapor intrusion that concrete slabs can provide. Trailers enclosed at the bottom by a skirt are expected to have greater potential for vapor intrusion than would non-enclosed trailers. Wind movement between the ground surface and the bottom of the non-enclosed trailer would tend to minimize vapor buildup and associated potential for vapor flux into the building. Similarly, the existence of underground parking for a multi-story building (or other modifications to the foundation that enhance subsurface ventilation) would tend to minimize the potential for vapor intrusion.

2.5 Conceptual Model Scenarios

Based upon the foregoing conceptual model, numerous factors can influence the potential indoor air concentration arising from vapor intrusion. Some of these significant factors are illustrated in Figure 2-3.

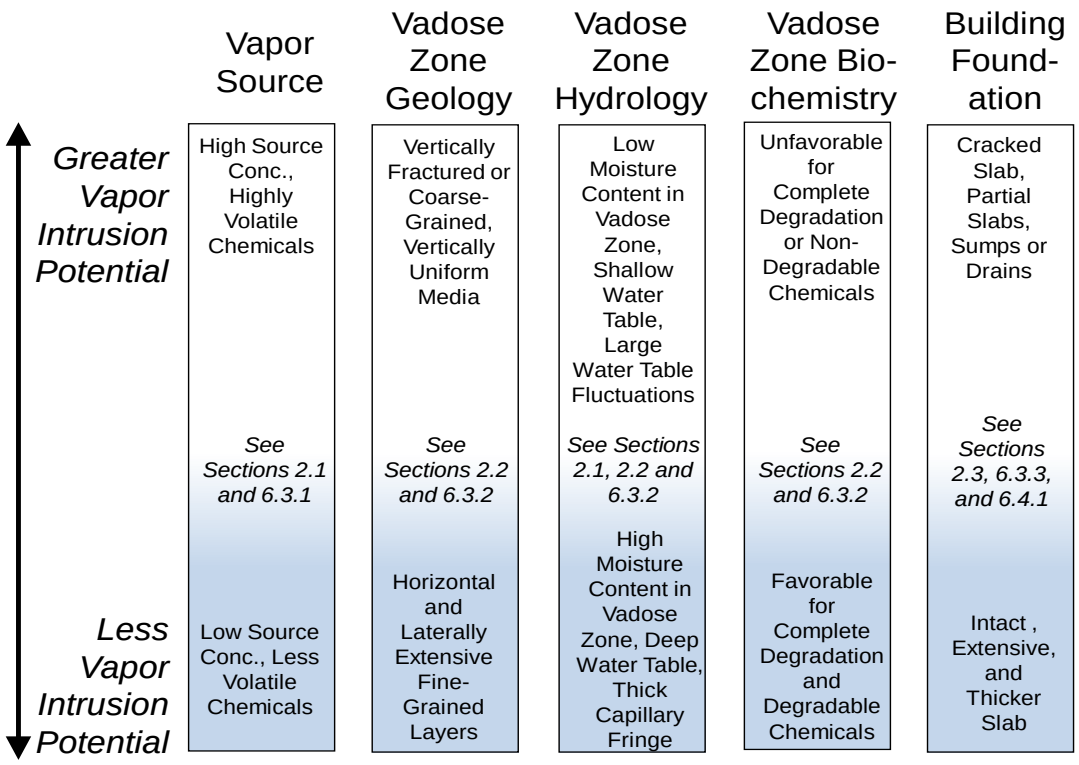

Figure 2-3 Some Factors That Affect Vapor Intrusion

The document *Conceptual Model Scenarios for the Vapor Intrusion Pathway* (EPA 2012b) provides simplified simulation examples[69] to illustrate graphically how several of the subsurface and building-specific factors work together to determine the distribution of volatile contaminants in the subsurface and the indoor air concentration relative to a source concentration. The conceptual model scenarios document offers insights into the factors influencing the vapor intrusion pathway. It provides a theoretical framework with which to draw inferences about and better understand the complex vapor fate and transport conditions typically encountered at actual, non-idealized contaminated sites. The following general observations can be made from these simplified simulation examples, and may be useful when considering the vapor intrusion pathway at a particular site:

- The horizontal and vertical distance over which vapors may migrate in the subsurface depends on the source concentration, source depth, soil matrix properties (e.g., porosity and moisture content), and time since the contaminant release to the environment occurred. Months or years of volatilization and vapor migration may be required to fully develop vapor distributions in the vadose zone at sites with deep vapor sources or with impedances to vapor migration arising from hydrologic or geologic conditions.

- Vapor concentrations, including oxygen, in the vadose zone (i.e., soil gas concentrations) may not be uniform in sub-slab soil gas or in soil gas at similar depths exterior to the building of interest. Therefore, soil gas concentrations at exterior locations (i.e., outside a building's footprint) may be substantially different from the concentration underneath the building (e.g., the sub-slab concentration), depending on site-specific conditions and the location and depth of the exterior soil gas sample.

- Simulations assuming an idealized, constructed ground cover suggest that shallow soil gas concentrations can be greater under low-permeability ground covers (e.g., asphalt) than under soil open to the atmosphere.

- The soil gas distribution beneath a building is not the only factor that determines the indoor air concentration. The indoor air concentration is also influenced by building conditions, including the presence of openings (e.g., cracks, utility penetrations) in the foundation, building pressurization, and the air exchange rate.

- Advective flow into buildings, which is presumed to occur predominantly near cracks and openings in the foundation slab, may affect the distribution of vapor-forming chemicals directly beneath the structure. Heterogeneities in the permeability of geologic materials and backfill, along with wind effects and building and atmospheric pressure temporal variation, may also contribute to the spatial and temporal variability of vapor concentrations in sub-slab soil gas and indoor air.

[69] Two important simplifications are the assumptions of constant values for the driving force for vapor intrusion (i.e., subslab to indoor air pressure difference) and air exchange rate, whereas time-variable values are reasonably expected as a result of changing weather and other conditions (as summarized in Sections 2.3 and 2.4, respectively).

- Subsurface heterogeneities in site geology, such as layering and moisture content, can influence the extent and rate of vapor migration from a contaminant source towards overlying or adjacent buildings.

- The soil gas distribution of aerobically biodegradable chemicals (e.g., BTEX) can be significantly different than that of other chemicals that are not biodegradable (i.e., are recalcitrant) in similar settings. Specifically, the soil gas concentrations of aerobically biodegradable chemicals exhibit greater attenuation than those of recalcitrant chemicals when the subsurface availability of oxygen is adequate.

2.6 Variability in Exposure Levels

Given the foregoing conceptual model of vapor intrusion and summary of modeled scenarios (EPA 2012b), the degree to which vapor intrusion is a pathway of concern can vary widely from site to site and from building to building within a site. Adding to the complexity, theoretical considerations (i.e., soil gas entry rates, air exchange rates, interior compartmentalization and inter-zonal airflows) suggest that indoor air concentrations arising from vapor intrusion can be expected to vary over time and within a building. Field observations and measurements demonstrate that indoor air concentrations can exhibit significant temporal variation within a day and between days and seasons in an individual residential building (EPA 2012a; Holton et al. 2013ab).

2.7 Consideration of Indoor and Outdoor Sources of VOCs

Indoor air in many buildings will contain detectable levels of a number of vapor-forming chemicals whether or not the building overlies a subsurface source of vapors (EPA 2011a), because indoor air can be impacted by a variety of indoor and outdoor sources. Indoor sources of volatile contaminants include the use and storage of consumer products (e.g., cleaners, air fresheners, aerosols, mothballs, scented candles, insect repellants, or other household products), combustion processes (e.g., smoking, cooking, and home heating), occupant activities (e.g., craft hobbies, home improvements, automotive repairs), and releases from interior building materials (e.g., carpets, insulation, paint, and wood-finishing products). Outdoor sources of volatile chemicals may arise due to releases from nearby sources such as industrial facilities, vehicles, yard maintenance equipment, fuel storage tanks, and paint or pesticide applications; regional sources such as air emissions from regional industry, vehicle exhaust, agricultural activities, and fires; or global sources, such as distant air emissions. The outdoor air surrounding a building is referred to as “ambient air” throughout this Technical Guide.

The contribution of indoor and outdoor sources of vapors (or both) to indoor air concentrations, which do not arise from site-related contamination,[70] is referred to as “background” throughout this Technical Guide (see, for example, Sections 2.7, 6.3.5, and 7.4.2 and the Glossary). In

[70] In some situations, site-related contamination has the potential to impact indoor or ambient air (EPA 1993c) with the same vapor-forming chemicals that pose a threat from vapor intrusion. For example, contaminated groundwater in building sumps or intruding into the building via groundwater seepage could provide an indoor source of site-related contamination. Contamination of shallow soil or groundwater may also release site-related vapor-forming chemicals to ambient air. In such situations, neither of these sources of indoor air contamination would be considered ‘background.’

some buildings, “background” sources by themselves can cause building occupants and visitors to experience significant exposures to vapor-forming chemicals.

In contrast to “background” concentrations in soil arising from naturally occurring minerals, “background” concentrations in indoor air often are not uniform in time. For example, concentrations of vapor-forming chemicals in ambient air may exhibit temporal variation over several time scales (e.g., daily, seasonal, longer term) and spatial differences across urban, suburban, and rural land use areas, reflecting differences in emission sources and rates and environmental factors that transport, disperse, and remove these pollutants (Jia et al. 2012 and citations therein). Concentrations of vapor-forming chemicals arising in indoor air in residential buildings due to indoor sources have been observed to depend upon season and other factors. Available studies suggest complex (e.g., patchy) spatial patterns in exposure concentration, which has led some researchers to refer to “microplumes” in the indoor air environment (McBride et al., 1999 and citations therein).

3.0 OVERVIEW OF THIS VAPOR INTRUSION TECHNICAL GUIDE

This section provides an overview of this Technical Guide and the general recommended framework for vapor intrusion assessment and response action, which is illustrated in Figure 3-1. This section opens with a description of subsurface contaminants that have the greatest potential to pose a health concern via vapor intrusion, based upon their volatility and potential hazards.

3.1 Contaminants of Potential Concern

Several physicochemical criteria may be considered for defining and screening for volatility.[71] For purposes of this Technical Guide, a chemical generally is considered to be "volatile" if:

1) Vapor pressure is greater than 1 millimeter of mercury (mm Hg), or

2) Henry's law constant (ratio of a chemical's vapor pressure in air to its solubility in water) is greater than 10^{-5} atmosphere-meter cubed per mole (atm m^3 mol^{-1}) (EPA 1991b, Section 3.1.1; EPA 2002c, Appendix D).

Various other criteria may be considered for identifying when volatile chemicals are present at levels of potential health concern. For purposes of this Technical Guide, a volatile chemical generally is considered to be "potentially toxic" via vapor intrusion if:

1) the vapor concentration of the pure component exceeds the indoor air target risk level, when the subsurface vapor source is in soil, or

2) the saturated vapor concentration exceeds the target indoor air risk level, when the subsurface vapor source is in groundwater.

Each of the chemicals with one or more toxicity values used to derive Regional Screening Levels (http://www.epa.gov/reg3hwmd/risk/human/rb-concentration_table/Generic_Tables/index.htm) were evaluated for volatility and toxicity, according to the foregoing recommended criteria. These criteria do not include a consideration of whether these chemicals are regulated pursuant to CERCLA, as amended, or RCRA, as amended. The universe of chemicals evaluated and the results of the evaluation are provided in EPA's on-line VISL Calculator (EPA 2015a), which is described further in Sections 1.4.1 and 6.5.2 of this Technical Guide.

Chemicals which satisfy the foregoing screening criteria for volatility and toxicity are designated as "vapor-forming chemicals" for purposes of this Technical Guide. In addition:

[71] In chemistry and physics, volatility refers to the tendency of a substance to form vapors, which are molecules in a gaseous state, and escape from a liquid or solid. Volatility is directly related to a substance's vapor pressure and Henry's law constant. EPA (1991b) also cites molecular weight as a necessary criterion for assessing volatility. Molecular weight is not retained for this Technical Guide as a volatility criterion, because it is a relatively weak predictor of volatility.

- cis-1,2-dichloroethylene, a volatile chemical that lacks sufficient toxicity information (to apply the toxicity criteria above), is identified as a vapor-forming chemical due to its potential use as an indicator of vapor intrusion when it is present as a subsurface contaminant;[72]

- methane is identified as a vapor-forming chemical due to its potential to pose an explosion hazard and to be formed via anaerobic biodegradation processes in the subsurface environment;[73] and

- radon is identified as a vapor-forming chemical when it arises from uranium- or radium-bearing solid wastes in the subsurface.[74]

Chemicals that meet these recommended screening criteria are referred hereafter in this Technical Guide as "vapor-forming chemicals." EPA recommends that these chemicals be evaluated during vapor intrusion assessments, when they are present as subsurface contaminants due to a site-related release(s). EPA recommends that chemical analyses be limited to those vapor-forming chemicals known or reasonably expected to be present in the subsurface environment due to a site-related release(s). The list of vapor-forming substances warranting consideration for potential vapor intrusion may be modified in the future.[75]

3.2 Vapor Intrusion Assessment

The approach for assessing vapor intrusion will vary from site to site, due to site-specific factors. For example, the information available for evaluating vapor intrusion potential will vary depending upon when vapor intrusion is first considered during a site's investigation-and-cleanup life cycle. Many sites can be evaluated for potential vapor intrusion during the normal course of an initial site assessment. Examples include brownfield sites that are intended for redevelopment and buildings where chemical odors have been reported. The data available for evaluating vapor intrusion may be very limited at the outset for these situations. At the other end of the investigation and cleanup life cycle, certain sites with long- term cleanups underway for contaminated groundwater may be evaluated for vapor intrusion during periodic reviews, if any,

[72] EPA (2011a) and DoN (2011a) report that cis-1,2-dichloroethylene (cis-1,2-DCE) is "rarely detected in background indoor air." When they are subsurface contaminants, volatile chemicals, such as cis-1,2-DCE, that are rarely or never present in indoor sources can be inferred to arise in indoor air via vapor intrusion "without further explanation" (DoN 2011a). Brenner (2010), for example, employed this principle to identify buildings susceptible to vapor intrusion and to diagnose the relative contributions of vapor intrusion and infiltration to indoor air concentrations.

[73] As noted previously, methane in soil gas may produce two other undesirable consequences: (1) it can exacerbate migration and intrusion of other vapors if it is generated at rates sufficient to foster advective flow of soil gas (see Section 2.3); and (2) its biodegradation in the vadose zone can reduce the oxygen available for biodegradation of other hydrocarbons (Ma et al. 2012).

[74] Radon emanating from natural geological materials may also affect indoor air quality in occupied buildings, but is not a subject of this Technical Guide. For more information about radon emanating from natural geological materials, see: http://www.epa.gov/radon/index.html.

[75] For example, inhalation toxicity values for additional volatile chemicals may become available in the future.

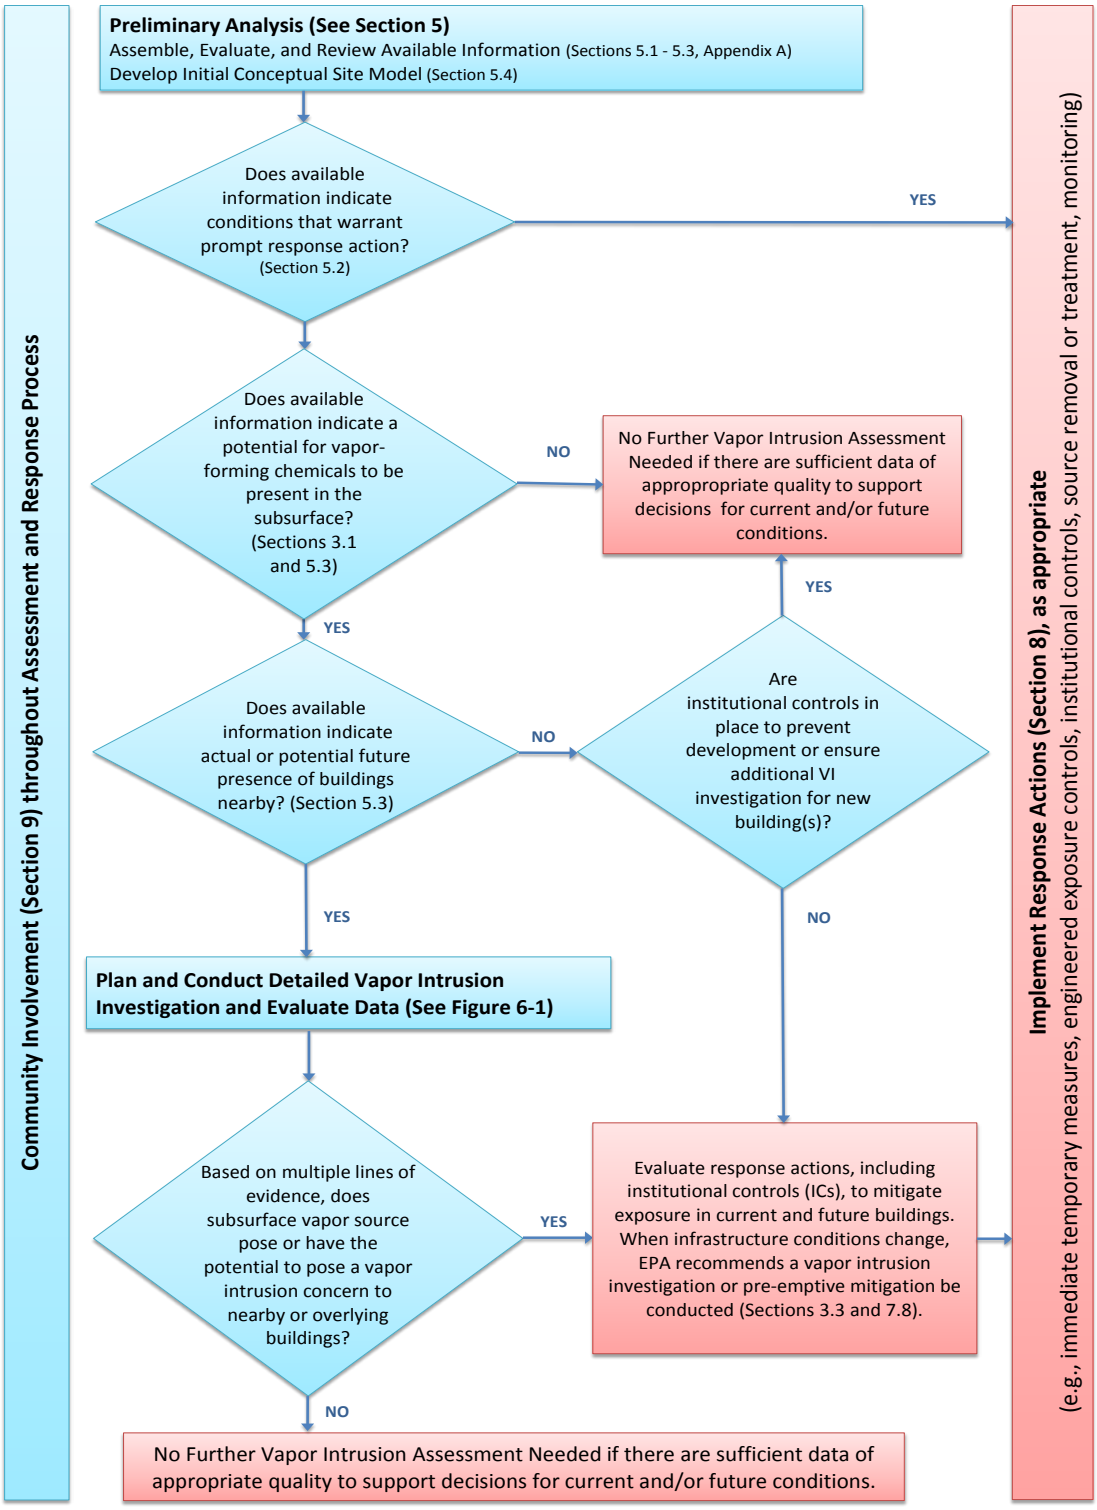

Figure 3-1 Overview of Recommended Framework for Vapor Intrusion Assessment and Response Action

of remedy performance and groundwater monitoring data.[76] In such situations, detailed information about the nature and extent of subsurface contamination and the relevant hydrogeologic conditions may already exist. In addition, there are different scenarios for vapor intrusion (EPA 2012b), depending on characteristics of the source (e.g., types, chemicals of concern, mass, distribution, and distance from building(s)), subsurface conditions and vapor migration routes (e.g., soil types and layering, existence of preferential migration routes due to geology or infrastructure, and existence of any impediments to vapor migration), building susceptibility (e.g., age, design, construction, condition), lifestyle factors (e.g., keeping windows open or closed), and regional climate. For these reasons, every site (and every building) will not warrant the same approach to or intensity of assessment for vapor intrusion. This Technical Guide, therefore, recommends a framework for planning and conducting vapor intrusion investigations, rather than a prescriptive step-by-step approach to be applied at each and every site.

Broadly speaking, two general levels of vapor intrusion assessments can be distinguished:

1) A preliminary analysis utilizes available and readily ascertainable information to develop an *initial* understanding of the potential for human health risk that are or may be posed by vapor intrusion, which would typically be performed as part of an initial site assessment. The recommended information, approaches, and practices for conducting a preliminary analysis and its potential outcomes are described in Section 5.0.

2) A detailed investigation is generally recommended when the preliminary analysis indicates that subsurface contamination with vapor-forming chemicals may be present underlying or near buildings. A detailed investigation of the vapor intrusion pathway is typically performed as part of the site investigation stage. The recommended approaches and practices for conducting detailed vapor intrusion investigations are described in Section 6.0.

Considerable information, primarily empirical, has been generated regarding evaluation of the vapor intrusion pathway since the pathway emerged as a national issue in the late 1990s and especially in the past ten years. Broadly speaking, this information demonstrates that the vapor intrusion pathway can be complex. (The conceptual model of vapor intrusion provided in Section 2.0 identifies many of the factors, variables, and conditions that warrant consideration on a site-specific basis.) As a result, current practice suggests that the vapor intrusion pathway generally be assessed using multiple lines of evidence.[77]

Specific conclusions that EPA recommends be based upon multiple lines of evidence include:

[76] These situations can arise, for example, if the groundwater remedy was selected in the 1980s (long before vapor intrusion became recognized as a potentially significant exposure pathway), or if supplemental groundwater data indicate that the plume is migrating toward new inhabited areas.

[77] As discussed further in Section 7.2, confidence in the assessment and risk management decisions is expected to be higher when multiple independent lines of appropriate site- or building-specific evidence from, for example, multiple types samples of environmental media (e.g., groundwater, soil-gas, sub-slab vapor, crawlspace, and indoor air) and/or other data come together to provide mutually supporting evidence for a common understanding of the site conditions/scenarios and the potential for vapor intrusion (EPA 2010b) (i.e., the various lines of evidence are in agreement with each other).

- The subsurface vapor source(s) at a specific site has (or, alternatively, does not have) the potential to pose an unacceptable vapor intrusion exposure under current or reasonably expected future conditions, due to its strength (e.g., concentration and mass of vapor-forming chemicals) and proximity relative to one or more existing buildings or a building that may be constructed in the future.

- The vapor intrusion pathway is complete for one or more buildings under current conditions or is potentially complete under reasonably expected future conditions.

- The vapor intrusion pathway is incomplete for one or more buildings near a subsurface source of vapor-forming chemicals, due to geologic, hydrologic, and/or biochemical (e.g., biodegradation) processes that provide substantial and persistent attenuation of vapors extending laterally over large distances relative to the footprint of the building(s) and the extent of the vapor source.

- Indoor air concentrations attributable to vapor intrusion pose (or, alternatively, are unlikely to pose) an unacceptable human health risk in one or more existing buildings under current or reasonably expected future conditions.

- Indoor air concentrations measured in one or more buildings can (or alternatively, cannot) be reasonably attributed to indoor or ambient air sources (i.e., background).

Multiple lines of evidence are particularly important for supporting "no-further-action" decisions regarding the vapor intrusion pathway (e.g., pathway incomplete determinations) to reduce the chance of reaching a false-negative conclusion (i.e., concluding vapor intrusion does not pose unacceptable human health risk, when it actually poses an unacceptable human health risk). Collecting and weighing multiple lines of evidence can also help avoid reaching a false-positive conclusion (i.e., concluding vapor intrusion poses an unacceptable human health risk, when it does not.

In summary, EPA recommends that site assessors generally collect and weigh multiple lines of evidence, including qualitative information, to support decision-making regarding the vapor intrusion pathway. Lines of appropriate evidence to evaluate the vapor intrusion pathway were identified in Section 2 and are discussed further in Sections 5 through 7.

As noted in Section 1.3, Figure 3-1, and the preceding discussion of lines of evidence, EPA recommends that site assessors consider reasonably expected future conditions, in addition to current conditions, when reaching conclusions about the vapor intrusion pathway.[78] For this reason, this Technical Guide includes recommendations for evaluating whether subsurface vapor sources that remain have the potential to pose unacceptable human health risks in the future if current conditions were to change. For example:

- Section 6.3.3 recommends that site assessors consider investigating vapor intrusion in non-residential buildings under conditions when the heating, ventilation, and air-conditioning system is not operating; and

[78] "Both current and reasonably likely future risks need to be considered in order to demonstrate that a site does not present an unacceptable risk to human health and the environment." (EPA 1991a).

- Section 7.3 identifies some factors and processes that can make the characteristics of the vadose zone (e.g., soil moisture) transitory.

EPA also recommends that vapor intrusion be evaluated for reasonably expected future land use conditions, including new building construction and new uses and occupants for any uninhabited buildings.

3.3 Building Mitigation and Subsurface Remediation

The NCP expresses the preference for response actions that eliminate or substantially reduce the level of contamination in the source medium to acceptable levels, thereby achieving a permanent remedy. In the case of vapor intrusion, such a response action would generally entail eliminating or substantially reducing the level of vapor-forming chemicals in the subsurface (e.g., in contaminated groundwater, soil, and/or sewer lines) via treatment or removal (i.e., "remediation"). Section 8 discusses source remediation to achieve a permanent remedy and associated institutional controls (ICs) and monitoring for vapor intrusion mitigation, including criteria for their termination.

Comprehensive remediation[79] of the subsurface environment often occurs over a prolonged period (e.g., several years) to attain cleanup levels. In the interim, problems of unacceptable vapor intrusion are often addressed by also installing engineered exposure controls to reduce or eliminate vapor intrusion in buildings (i.e., "mitigate" vapor intrusion) or reduce indoor air exposure levels. Engineered exposure controls can generally be deployed and generally become effective relatively quickly. They can be considered as "interim" or "early" response actions, which are also authorized by the NCP (Section 1.2), as necessary and appropriate to promptly reduce threats to human health. Section 8 summarizes technical information about specific exposure controls and provides information about their operation, maintenance and monitoring and associated ICs, including criteria for their termination.

Functionally, engineered exposure controls can be categorized into two basic strategies:

- Those that seek to prevent or reduce vapor entry into a building (e.g., active depressurization technologies). These methods are more commonly implemented when response actions are needed.[80]

- Those that seek to reduce or eliminate vapors that have entered into a building (e.g., indoor air treatment, ventilation).

[79] For purposes of this Technical Guide, "remediation" is intended to apply to interim and final cleanups, whether conducted pursuant to RCRA corrective action, the CERCLA removal or remedial programs, or using EPA brownfield grant funds with oversight by state and tribal response programs. In addition to permanent remedies for subsurface vapor sources, site remediation may also entail implementation of ICs and construction and operation of engineered systems to reduce risks to human health and the environment posed by environmental pathways other than vapor intrusion. Although this Technical Guide is intended for use at any site subject to federal statutes, regulations, and rules, it is not intended to alter existing requirements, guidance, or practices in OSWER's programs about development, selection, or documentation of final "remediation" plans (addressing subsurface vapor sources, for example) – see, for example, Sections 7.6 and 7.7.

[80] Mitigation methods that prevent or reduce vapor entry into a building from subsurface vapor sources would generally also be expected to reduce radon entry.

Neither strategy entails reducing the level of vapor-forming contamination in the subsurface source medium.[81]

As reflected in the foregoing conceptual model of vapor intrusion (Section 2.0), entry of the vapors into a building may be prevented or reduced by any of several techniques, which have the following objectives:

- Remove or reverse the driving forces for vapor intrusion into the building (e.g., install and operate an active depressurization technology to mitigate vapor intrusion from contaminated soil or groundwater; establish over-pressurization within and throughout the footprint of a nonresidential building).

- Eliminate or minimize identified openings for vapor entry into the building (e.g., caulking, grouting, or otherwise sealing all holes, cracks, sumps and other foundational openings or creating a barrier between the soil and the building that blocks openings for entry of soil gas into the building; install, repair, and/or maintain vapor traps in sewer and drain lines).

Engineered exposure controls that entail mechanical systems and forces (e.g., sub-slab depressurization or ventilation systems; building over-pressurization) are often referred to as "active." Engineered exposure controls that do not involve mechanical operations (e.g., installing a sub-slab barrier to chemical vapor entry) are often referred to as "passive." Many building mitigation systems rely on both active and passive strategies.

Engineered exposure controls that seek to reduce or eliminate vapors that have entered into a building can also be effective. In some instances, they can be implemented more readily than engineered exposure controls that reduce or eliminate entry of the vapors into a building. Typically, the simplest approach to limiting the concentration levels in occupied indoor spaces is to increase building ventilation (i.e., increase the rate at which indoor air is replaced with outdoor air), thereby diluting indoor air concentrations (see Section 2.4).[82] Alternatively, vapor-forming chemicals are removed from indoor air using an adsorbing material (such as activated carbon) that can be either properly disposed of or recycled. Building mitigation methods that act upon vapor-forming chemicals in indoor air (i.e., rely upon enhanced ventilation or treatment) are generally capable of reducing background levels of chemicals, in addition to reducing indoor levels of vapor-forming chemicals that intrude from subsurface sources.

[81] Even when operated for prolonged periods, engineered exposure controls are considered 'interim' remedies for purposes of this Technical Guide, because their implementation does not substitute for remediation of the subsurface source(s) of vapor-forming chemicals. Engineered exposure controls may, nevertheless, become part of a final cleanup plan.

[82] It can be difficult to establish a ventilation rate that mitigates vapor intrusion and yields an environment conducive to human occupancy (e.g., considering air temperature or moisture). In addition, ventilation may affect the driving forces for vapor intrusion. For example, mechanically exhausting air from the building will generally contribute to building under-pressurization (see Section 2.3), which may result in increased intrusion of soil gas into the building, which may offset the intended dilution effect of ventilation. On the other hand, introducing outdoor air at a rate slightly greater than the exhaust rate can create over-pressurization, which opposes the primary driving force for vapor intrusion.

Selection of an interim response action from these options may depend upon building- and site-specific factors (EPA 2008). For example, building-specific factors may include:

- Use (e.g., single-family residential, multi-family residential, commercial, educational, recreational, governmental, religious, industrial)
- Type of foundation/basement (e.g., basements with concrete slab floors or dirt floors, slab on grade, slab below grade) and other construction features
- Type of heating/cooling/ventilation systems (e.g., some systems will tend to increase pressure, whereas others will tend to decrease pressure, inside the building).

Each of these characteristics can influence the choice of mitigation methodology and, therefore, they are commonly identified during building surveys during a site-specific vapor intrusion investigation. Site-specific considerations may include the degree of risk or hazard being addressed and whether the subsurface vapor source(s) is stable in extent and concentration or is undergoing remediation.

Temporary relocation may warrant consideration in instances where explosion hazards are present (see Section 7.5.1), which may pose an imminent and substantial danger to human health and public welfare. Prompt response action may also be warranted where short-term or acute exposures may pose unacceptable human health risk (see Section 7.5.2) that cannot be addressed timely or feasibly by implementing engineered exposure controls. Section 8.2 discusses various prompt response actions for such situations, which may include temporary relocation.

There may be situations where a party may wish to implement mitigation or control measures for vapor intrusion, even though only limited lines of evidence or measurements may be available to characterize the overall vapor intrusion pathway. For example, a party may be aware that vapor intrusion has been documented at neighboring structures, where measures are being implemented to mitigate the vapor intrusion pathway. A party may conclude there is a reasonable basis to take action, but each building presents a fact-specific situation that calls for its own individual judgment. Likewise, it may be appropriate and cost-effective to design, install, operate, and monitor engineered exposure controls for individual buildings to mitigate vapor intrusion in newly constructed buildings, or in buildings to be constructed in the future, that are located in areas of vapor-forming subsurface contamination, rather than potentially allow vapor intrusion to occur later and assess vapor intrusion after the fact. The term “preemptive mitigation/early action” is used in this Technical Guide to describe these situations.[83]

The decision for preemptive mitigation/early action arises from precaution and from recognizing that:

- Installing engineered exposure controls in buildings is typically a cost-effective means of protecting human health and normally can be implemented relatively quickly in many buildings while subsurface contamination is being delineated or remediated.

[83] The term ‘preemptive’ has been used to describe the use of various types of controls that can prevent vapor intrusion from occurring prior to having fully demonstrated that unacceptable vapor intrusion currently exists in specific buildings being considered (EPA 2010a).

- Conventional vapor intrusion investigations can be disruptive for building occupants (residents, workers, etc.) and owners.

- Comprehensive subsurface characterization and investigation of vapor intrusion can entail prolonged study periods, during which time building occupants and owners and others may have questions and concerns about human health risk that are or may be posed via vapor intrusion.

Early action and interim action are allowed by federal environmental protection statutes, regulations, and guidance, including CERCLA, as amended, and RCRA, as amended – see Section 1.2 of this Technical Guide, for example. Other aspects of preemptive mitigation/early action are also discussed in Section 7.8, including situations and criteria for decision-makers to consider.

As noted in Figure 3-1, EPA recommends that risk managers consider reasonably expected future conditions, in addition to current conditions, when making risk management decisions about the vapor intrusion pathway. For this reason, this Technical Guide includes recommendations for response actions at sites where subsurface vapor sources remain into the future, but do not pose unacceptable human health risk under current conditions (e.g., no building is present nearby). For example, institutional control s are generally recommended to restrict land use and/or alert parties (e.g., prospective developers, owners, and municipalities) of the presence of subsurface sources of vapor-forming chemicals at levels that pose a continuing threat via vapor intrusion (see Sections 7.3, 7.4, and 8.6). When infrastructure conditions change above or near an area of known contamination with vapor-forming chemicals, EPA recommends a vapor intrusion investigation or pre-emptive mitigation be conducted, particularly if a building is constructed for human occupancy (see Section 8.2.3).

3.4 Community Outreach and Involvement

EPA is committed to transparency and upfront collaboration with community stakeholders regarding land cleanup, emergency preparedness and response, and management of hazardous chemicals and wastes. OSWER's Community Engagement Initiative (CEI), in particular, is designed to enhance OSWER's and the Regional offices' engagement with local communities and stakeholders (e.g., state and local governments, tribes, academia, private industry, other federal agencies, and nonprofit organizations) to help them participate meaningfully in government decisions regarding OSWER's nationwide programs.

Meaningful and sustained community outreach and engagement efforts are critical to the implementation of work plans for site-specific vapor intrusion assessment and mitigation. Because assessing the vapor intrusion pathway may involve sampling in a home or workplace, as well as other temporary inconveniences (e.g., assisting in reducing indoor sources of contaminants), individual, one-on-one communication with each property owner or renter generally warrants consideration. Building-by-building contact and communication are recommended as the most effective means of educating the community and obtaining access needed to assess, mitigate, and monitor the vapor intrusion pathway. Personal contact is further recommended to establish a good working relationship with each building owner or occupant and to build trust. In many instances, local religious and cultural organizations, and other community groups can be sought for assistance in reaching out to affected community members.

Vapor intrusion education and training are important components of meaningful community outreach and engagement efforts. Informing stakeholders about the vapor intrusion pathway and the cleanup process can help to build trust and can foster community participation in the overall assessment and risk management process.

Recognizing the importance of community outreach and engagement efforts, EPA staff are highly encouraged to consult with colleagues experienced in community outreach and utilize available EPA planning resources, including those discussed in Section 9, which provides OSWER's community involvement planning guide for vapor intrusion projects. Like EPA, the ITRC also recommends implementing a community outreach program that provides timely information to concerned community members and property owners.

4.0 CONSIDERATIONS FOR NONRESIDENTIAL BUILDINGS

The approach for investigating and, if necessary, mitigating vapor intrusion can vary from site to site, and from building to building, due to site- and building-specific factors and circumstances, including: the nature (e.g., mixture of vapor-forming chemicals and form), locations, and extent of subsurface contamination; geologic, hydrologic, and biochemical factors in the vadose zone; and the size, structural conditions and uses of buildings and background levels of vapor-forming chemicals in the building. Information on 'background' contributions of site-related, vapor-forming chemicals in indoor air is important to risk managers because generally EPA does not clean up to concentrations below natural or anthropogenic background levels (EPA 2003e). These statements hold true for residential and non-residential buildings.

Section 6.3.5 of this Technical Guide provides specific recommendations about how to evaluate background concentrations. Section 7.4 of this Technical Guide provides clarifications and recommendations about applying the methods in Section 6.3.5 to informing risk management decisions and recommendations. The Glossary in this Technical Guide defines various terms and types of vapor sources to foster a common understanding of EPA's approach and recommendations.

This section summarizes EPA's general recommendations to consider in making decisions about evaluating and addressing potential vapor intrusion for nonresidential buildings[84] pursuant to CERCLA and RCRA, including decisions that a response action or corrective action is not currently warranted.

When evaluating nonresidential buildings at sites that have subsurface contamination with vapor-forming chemicals, EPA generally recommends that building owners or operators (e.g., lessees) be contacted for information about vapor-forming chemicals used or stored or otherwise present in the building, the types of building occupants potentially exposed to subsurface vapor intrusion, as well as any training, equipment, or engineering controls to mitigate inhalation exposures. EPA recommends that information be provided to building owners concerning the potential for vapor intrusion so that this information can be communicated to building employees, tenants, and other occupants. Building occupants include, but are not limited to, facility employees, visitors, customers, suppliers, and building maintenance personnel.

Generally, EPA recommends the following factors be considered when making decisions pertaining to vapor intrusion at nonresidential buildings, including as to whether indoor air sampling, soil gas sampling underneath the building, or interim measures to mitigate vapor intrusion to reduce associated indoor air exposures for a nonresidential building may be warranted:

[84] As used in this Technical Guide, the phrase "nonresidential buildings" may include, but is not limited to, institutional buildings (e.g., schools, libraries, hospitals, community centers and other enclosed structures for gathering, gyms and other enclosed structures for recreation), commercial buildings (e.g., hotels, office buildings, many (but not all) day care facilities, and retail establishments); and industrial buildings where vapor-forming substances may or may not be routinely used or stored.

1) The types of populations potentially exposed to vapor-forming chemicals in the indoor air of the nonresidential building, including, for example, whether:

   a) Individuals are or may be present under current or reasonably expected future conditions who would not likely anticipate any chemical exposures (e.g., office workers, visitors, customers, suppliers, and other members of the general public) and may not benefit fully from hazard communication programs and other work practices in place to foster protection of workers who use chemicals, if any.

   b) Sensitive populations are or may be present under current or reasonably expected future conditions, who may have increased susceptibility or vulnerability.

2) The potential for vapor intrusion versus background vapor sources (See Glossary) to contribute to indoor air concentrations of vapor-forming chemicals found in the subsurface. Questions to consider include, for example:

   a) Can subsurface vapor intrusion be identified as a potential cause of unacceptable human health risk to building occupants (see Section 5 for further discussion about the preliminary analysis stage and Section 7 for further discussion and definition of acceptable versus unacceptable human health risk)? [85]

   b) Can subsurface remediation (e.g., excavation of contaminated soil or soil vapor extraction beneath the subject building) that is planned or underway reduce human health risk from vapor intrusion within a time frame that is protective for any potential current or near-term exposures in the building?

   c) Is there a known source(s) of one or more vapor-forming chemical(s) – see Section 3.1 – in indoor air in the nonresidential building other than vapor intrusion (e.g., indoor use and storage of chemicals, which would constitute a 'background' vapor source(s) and contribute to indoor air exposure concentrations; see Sections 2.7 and 6.3.5 for further discussion and recommendations about background sources and concentrations)? If such a vapor-forming chemical(s) is (or are) present:

      i. Is(are) it the same as the vapor-forming chemical(s) found in the subsurface?

      ii. How does the indoor air exposure concentration(s) arising from the indoor vapor source(s) compare to the indoor air concentration(s) estimated or reasonably expected to arise from vapor intrusion? [86]

   Information on 'background' contributions of site-related, vapor-forming chemicals in indoor air is important to risk managers because generally EPA does not clean up to concentrations below natural or anthropogenic background levels (EPA 2002e).

[85] EPA's recommended approaches to human health risk assessment are provided in Sections 7.4 and 7.5 of this Technical Guide.

[86] EPA's recommended approaches to distinguishing and considering 'background' are provided in Sections 6.3.5 and 7.4.2 of this Technical Guide.

3) Any existing or planned engineering or institutional control(s) in the building or any industrial hygiene/occupational health program that addresses workplace inhalation exposures and its scope. Questions to consider include, for example:

    a) Do work practices and engineering controls currently in place ensure protection[87] of all building occupants who may be exposed via the vapor intrusion pathway?

    b) Are enforceable institutional controls (ICs) or other control mechanisms in place to ensure that current land use and workplace practices will be sustained and will remain protective regarding indoor air exposures from vapor intrusion to all building occupants? Have these ICs and control mechanisms been communicated to all appropriate parties and documented to EPA? Can they be readily monitored and, if necessary, be enforced?

EPA recommends documenting any decision not to undertake investigation or mitigation for vapor intrusion in a nonresidential building, as well as any decision to pursue such activities. EPA may consider reviewing these decisions, as appropriate and consistent with applicable statutes and regulations and considering EPA guidance,[88] if the land use changes or new information becomes available that suggests circumstances supporting past risk management decisions have changed and prompt the need to revisit those decisions. It is recommended that EPA request from property owners and building tenants/operators timely notification of significant changes in building ownership, uses, access by the general public, or building construction (e.g., renovations), which may affect exposure of occupants and related risk management decisions pertaining to potential vapor intrusion assessment and mitigation, subsurface remediation, or ICs.

Regardless of decisions about indoor air sampling, soil gas sampling underneath the building, or interim measures to mitigate vapor intrusion, EPA[89] may proceed, consistent with applicable federal statutes and regulations (see Section 1.2) and considering EPA guidance, with activities such as the following, where appropriate:

- Subsurface investigation to delineate the areal extent of a subsurface vapor plume.
- Subsurface remediation to reduce or eliminate subsurface sources of vapors-forming chemicals to protect human health and the environment.

[87] EPA's recommended approaches to risk management are provided in Sections 7.4 and 7.5 of this Technical Guide.

[88] For the Superfund five-year review process, OSWER Directive 9200.2-84 (EPA 2012c) provides a recommended framework for considering vapor intrusion while evaluating remedy protectiveness.

[89] On January 23, 1987, the President of the United States signed Executive Order 12580 entitled, "Superfund Implementation," which delegates to a number of Federal departments and agencies the authority and responsibility to implement certain provisions of CERCLA. The policies and procedures for implementing these provisions (e.g., carrying out response actions) are spelled out in the NCP. The provisions of Executive Order 12580 appear at 52 *Federal Register* 2923. At federal facilities on the NPL, EPA may not be the lead agency, but does have oversight responsibilities pursuant to CERCLA Section 120.

5.0 PRELIMINARY ANALYSIS OF VAPOR INTRUSION

When a site is first identified and evaluated for vapor intrusion,[90] the amount, utility, and reliability of available information may be limited. A preliminary analysis utilizes available and readily ascertainable information to develop an *initial* understanding of the potential for human health risk to be posed by vapor intrusion, which would typically be performed as part of an initial site assessment.

This section describes EPA's recommended information, approaches, and practices for conducting preliminary analyses for vapor intrusion using pre-existing and readily ascertainable information to develop an initial understanding of the vapor intrusion potential at a site. This section:

- Explains the recommended types of information that generally can be obtained when a site is first considered for vapor intrusion (see Sections 5.1, 5.3, 5.4, and 5.5).
- Identifies some of the site conditions for which prompt action is generally warranted (see Section 5.2).
- Illustrates some of the site conditions for which further evaluation of the vapor intrusion pathway might be warranted (see Sections 5.3, 5.4, and 5.5).
- Describes the recommended approaches to evaluating the reliability of pre-existing information, including any sampling data (see Sections 5.1 and 5.5).

Depending upon the nature and reliability of the available information, it may be possible to determine whether a vapor intrusion investigation (see Section 6) or a response action (see Sections 7 and 8) is warranted. If the available information is not reliable or adequate for these purposes, however, additional data collection generally is recommended.

5.1 Assemble, Evaluate, and Review Available Information

The recommended first step in a preliminary analysis generally entails assembling and reviewing relevant information that is available at the time for the site. At a minimum, EPA recommends that information about potential subsurface sources of vapors and the presence and current use(s) of nearby buildings be developed and evaluated. For some sites, such as sites being evaluated for redevelopment (EPA 2008a), information about contiguous or nearby facilities also may be relevant, because vapors can encroach from nearby facilities due to migration of contaminated groundwater or soil gas, even though vapor-forming chemicals may not have been used at the subject site.

The following recommended types of information are often available through documents (e.g., federal, state, tribal and local government records) or through interviews with individuals

[90] A site may be identified, for example, based on reports to the National Response Center, citizen complaints or inquiries, state agency referrals, or other information (e.g., site history, land use, site inspections) obtained by EPA. At a brownfield site subject to an EPA grant, subsurface contamination may be discovered as a result of pre-acquisition investigation by prospective purchasers, during site redevelopment, or at other project stages.

knowledgeable about the facility or site and surrounding area (e.g., past and present owners, operators and occupants; area residents or workers):

- History and descriptions of the types of operations and activities that occurred on or near the site and nearby properties.
- Information or records about the types of chemicals that may have been used or disposed of at the site and nearby properties or are currently used and disposed at the site.
- Information about the site and nearby properties, such as the occurrence of odors, reports of dumping liquids, observations of unreported waste disposal practices, or other indications of chemical presence and release.
- Adverse physiological effects reported by building occupants (e.g., dizziness, nausea, vomiting, confusion).
- Evidence of subsurface intrusion of groundwater (e.g., wet basements) reported by building owners or occupants.

Such information usually can be reviewed and weighed together to assess whether vapor-forming chemicals (see Section 3.1) were or are being used, stored, or handled at or near the site and were or may have been released to the subsurface environment.

In addition, the following types of information may be available through documents, interviews with individuals knowledgeable about the facility or site, or reconnaissance and site inspection:

- Locations, ownership, occupancy, and intended and actual use(s) of buildings on or near the site.
- Current and reasonably anticipated future land use on and near the site.
- Location of subsurface utility corridors.

Evaluation of such information usually can help determine whether humans are present currently or are reasonably expected to be present in the future, and who may become exposed to any intrusion of vapors from the subsurface into a building(s). Zoning, land use planning, and related information may also need to be consulted to identify reasonably anticipated future land use and building types in areas where buildings do not exist or to ascertain whether reasonably anticipated uses of existing buildings are likely to change (EPA 2010c).

EPA recommends evaluating the available data to identify any data gaps for purposes of the preliminary analysis. For example, has the history of operations and primary activities been established for the site and all contiguous properties, including currently vacant land? To the extent that there are significant data gaps, EPA recommends that additional data gathering (e.g., interviews, records review) generally be planned and conducted.

EPA also recommends evaluating the available data to assess its reliability and internal consistency. For example, if the available information about operations and activities at a specific property comes only from area residents, EPA recommends additional efforts to

identify, contact, and interview current and past owners to obtain and corroborate this information. Also, if anecdotal information about current activities at a specific property is in conflict with common knowledge about local zoning, EPA recommends that additional data gathering and evaluation be identified (e.g., contact property owner), planned, and conducted to resolve the inconsistency.

Section 5.5.1 describes additional considerations for evaluating the reliability of sampling data that may be available for some sites at the preliminary analysis stage.

5.2 Identify and Respond to Conditions that Warrant Prompt Action

The following conditions may indicate a need for prompt action, including follow-up evaluations to determine whether urgent intervention is warranted to eliminate, avoid, reduce, or otherwise address a human health hazard:

- Odors reported by occupants, particularly if described as "chemical," "solvent," or "gasoline." The presence of odors does not necessarily correspond to an unacceptable human health risk due to vapor intrusion, and the odors could be the exclusive result of indoor vapor sources; however, it is generally prudent to investigate any reports of odors as the odor threshold for some vapor-forming chemicals exceeds their respective lower explosive limit (LEL) or health-protective concentrations for short-term or acute exposure.

- Physiological effects reported by occupants (e.g., dizziness, nausea, vomiting, confusion, etc.). These effects may or may not be due to subsurface vapor intrusion (or even indoor vapor sources); however, it is generally prudent to investigate any such reports.

- Wet basements in areas where groundwater is known to contain vapor-forming chemicals (see Section 3.1) and the associated water table is shallow enough that the basements are prone to groundwater intrusion or flooding. This condition is particularly important where there is evidence of light NAPL (LNAPL) on the water table directly below the building or direct evidence of intrusion of liquid-phase contamination (i.e., liquid chemical or dissolved in water) inside the building.

EPA generally recommends testing of indoor air (see Sections 6.4.1 and 6.3.4) as soon as practical in buildings where:

- chemical odors or physiologic effects are reported and there is a credible information to suggest that a release to the subsurface environment may be a contributing factor, or

- intruding contaminated groundwater is reported and observed.

Likewise, EPA generally recommends testing of unoccupied structures for explosive gases as soon as practical where chemical odors are reported and there is a credible information to suggest that a release to the subsurface environment may be a contributing factor.

Section 7.4 provides EPA's approach and recommendations for identifying when human health risks are "unacceptable." Section 7.5.2 describes EPA's recommended approaches to identifying concentration levels indicating a potential need for prompt response action. Section

8.2.1 identifies potential response actions to reduce or avoid these threats promptly, when the results of testing reveal threats or potential threats warranting prompt response action.

EPA recommends health and safety planning for all building- or site-specific actions, as discussed further in Section 6.2, which considers expected work conditions and anticipated hazards.

5.3 Determine Presence of Structures and Vapor-forming Chemicals

For purposes of this Technical Guide and as reflected in the conceptual model of vapor intrusion (Section 2), the vapor intrusion pathway is referred to as "complete" for a specific building or collection of buildings when the following five conditions are met under current conditions:

1) A subsurface source of vapor-forming chemicals is present underneath or near the building(s) (see Sections 2.1, 6.2.1, and 6.3.1);

2) Vapors form and have a route along which to migrate (be transported) toward the building(s) (see Sections 2.2 and 6.3.2);

3) The building(s) is (or are) susceptible to soil gas entry, which means openings exist for the vapors to enter the building(s) and driving 'forces' exist to draw the vapors from the subsurface through the openings into the building(s) (see Sections 2.3 and 6.3.3);

4) One or more vapor-forming chemicals comprising the subsurface vapor source(s) is (or are) present in the indoor environment (see Sections 6.3.4 and 6.4.1); and

5) The building(s) is (or are) occupied by one or more individuals when the vapor forming chemical(s) is (or are) present indoors.

EPA recommends that site managers also evaluate whether subsurface vapor sources that remain have the potential to pose a complete vapor intrusion pathway in the future if site conditions were to change (e.g., reasonably expected occupancy or construction in the future of a building above or near a subsurface vapor source). A complete vapor intrusion pathway indicates that there is an opportunity for human exposure, which warrants further analysis (see Section 7.4) to determine whether there is a basis for undertaking a response action(s) (see Section 7.7).

At the preliminary assessment stage, the available information may not be sufficient to evaluate whether all five conditions are present under current or reasonably expected future conditions. EPA recommends, however, that readily ascertainable information be reviewed for purposes of assessing whether the first and fifth conditions are present; that is:

- A subsurface source of vapor-forming chemicals is present or is reasonably expected to be present (e.g., in contaminated groundwater, soil, or sewer lines or from a primary

vapor release).[91] Section 3.1 describes chemicals that have the potential to pose an unacceptable human health risk through the vapor intrusion pathway. In the absence of environmental sampling data, the potential presence of vapor-forming chemicals in the subsurface may be inferred from site information, as identified in Section 5.1 (e.g., site history).

- At least one building is present or is reasonably expected to be constructed in the future above or "near" the subsurface vapor source(s), which is or could be occupied by humans. For purposes of this Technical Guide and its recommendations for evaluating human health risk posed by vapor-forming chemicals, "building" refers to a structure that is intended for occupancy and use by humans. This would include, for instance, homes, offices, stores, commercial and industrial buildings, etc., but would not normally include sheds, carports, pump houses, or other structures that are not intended for human occupancy. However, where the assessment identifies the potential for methane or other potentially explosive vapors to be present in the subsurface, EPA recommends reviewing readily ascertainable information for purposes of assessing whether non-occupied structures (including, but not limited to, sewers, pits, and subsurface drains) are present, which may also accumulate vapors, in addition to occupied and non-occupied buildings. Existing buildings (and non-occupied structures) can be identified during inspections of the land areas overlying and near subsurface vapor sources. The potential presence of buildings in the future may be inferred from site information, such as identified in Section 5.1. See Section 6.2.1 for further discussion on which buildings and non-occupied structures are considered "near" for purposes of a preliminary analysis.

If the available information is deemed reliable, well documented, and sufficient (see Section 5.1) and indicates that neither of these conditions is met, then further vapor intrusion assessments are not generally warranted.[92]

Example: From 1920 to 1931, the ABC Mining Company obtained and shipped iron ore from a local deposit. Ore from the mine was shipped by rail to a different location where it was milled and processed to extract the metal. Although no company records are available for the mine, a review of mining techniques indicates that solvents and other vapor-forming chemicals were not used in the mining process during the 1920s and 1930s. Former mining structures have been removed, and the site is currently vacant. The city has proposed redeveloping the site with bike and hiking trails but no buildings or other structures for storage or site maintenance support. Based on the information and

[91] As noted in Section 2.1, the primary contamination source need not be on the property of interest to pose a vapor intrusion problem. The primary source(s) of vapor-forming chemicals (e.g., contaminated soil, leaking tanks) may be present on a neighboring property or on a property some distance away. Even "greenspace" properties that have not previously been occupied or developed may contain subsurface contamination by vapor-forming chemicals due to migrating plumes of contaminated groundwater or migrating soil gases. Therefore, EPA recommends that the potential for vapor intrusion be considered at all properties being considered for redevelopment (EPA 2008a) or proximate to industrial and commercial use areas.

[92] Consistent with federal environmental protection statutes, regulations, and OSWER guidance, a subsurface investigation may still be warranted for non-volatile substances or for other potential exposure pathways such as those identified in Section 1.3.

findings, the need for further assessment of the vapor intrusion pathway due to mining-related contamination is not indicated.

If, on the other hand, there is reliable evidence to indicate that a release of vapor-forming chemicals to the subsurface has occurred (e.g., environmental sampling data indicate detectable levels of a vapor-forming chemical(s) in potential source media)[93] or may have occurred underneath or near a property, then EPA recommends further vapor intrusion assessment in areas where buildings are present or future buildings could be constructed, including development of a conceptual site model (see Section 5.4) and investigation of site-specific conditions (see Section 6).

Example: The XYZ Recycling Center site was used from 1963 to 1984 for the collection and recycling of industrial solvents and other fluids. The site was repeatedly cited by the state and city for improper handling and disposal of solvents, and was closed in 1985. Groundwater data indicate the presence of multiple chlorinated hydrocarbons. Buildings overlying the contaminated groundwater are currently used mainly for storage of non-chemical goods, but the site has been proposed for future residential or commercial redevelopment. Based on the foregoing information and findings, further assessment of the potential for vapor intrusion is warranted, possibly including risk-based screening of the groundwater data (see Section 6.5).

If a release of vapor-forming chemicals to the subsurface is known or suspected to have occurred at or near the site, but buildings are not present and none are reasonably anticipated in the future (e.g., the contaminated source underlies an open space, recreational area, or wildlife refuge), then further vapor intrusion assessments may not be appropriate under current conditions. It may be appropriate, however, to establish an institutional control (IC) requiring a vapor intrusion investigation or building mitigation[94] in the future, in case land use changes. ICs for building mitigation and subsurface vapor source remediation are discussed further in Sections 3.3 and 8.6 of this Technical Guide.

Existing guidance and practice pursuant to CERCLA and RCRA corrective action (CA) recognize and entail various phases of subsurface or site characterization, including a site investigation to determine the full nature and extent of contamination at a site, quantify risks posed to human health and the environment, and gather information to support the selection and implementation of appropriate remedies. On this basis, a subsurface investigation may be warranted at some point to characterize subsurface contamination and assess the need for subsurface remediation to protect the environment and human health for potential exposure pathways other than vapor intrusion (such as those identified in Section 1.3). For example, site investigations to characterize the nature and extent of groundwater contamination and support assessments of risk to human health through the ingestion pathway are typically conducted, consistent with federal statutes and regulations (e.g., CERCLA and RCRA) and considering EPA guidance.

[93] Section 6.5 provides information on how such data may be used in a quantitative fashion to screen the site further.

[94] If, for example, a developer is considering acquiring and building on land that contains subsurface contamination with vapor-forming chemicals, the developer could retrofit existing buildings or build new buildings with vapor mitigation systems without first conducting an extensive vapor intrusion investigation (see Sections 3.3 and 7.8). Section 8.2.3 identifies additional approaches and considerations for new buildings.

5.4 Develop Initial Conceptual Site Model

EPA recommends that the planning and data review team develop an initial conceptual site model (CSM) for vapor intrusion when the preliminary analysis indicates the presence of subsurface contamination with vapor-forming chemicals underlying or near buildings. The initial CSM (and any subsequent refined CSM) can be used to support evaluations of the adequacy of the available site-specific information, to guide any vapor intrusion investigations (see Sections 6.2 and 6.3), and to support data selection for risk-based screening (see Section 6.5). The CSM can also provide useful information for supporting prompt development of a strategy for early/interim response actions (see Sections 7.8 and 8.2).

The remainder of this section discusses recommended information that can be useful for developing a CSM. Note that some of the recommended information may not be readily available when a site is first considered for vapor intrusion. Although the CSM may be updated iteratively (and interim mitigation measures may be undertaken) as the vapor intrusion investigation unfolds, EPA recommends completing the CSM before making final risk management decisions for a given site (see Section 7).

As discussed in Section 5.3, the available information may not be sufficient at the preliminary analysis stage to evaluate whether the vapor intrusion pathway is complete under current or future conditions. Therefore, the initial CSM for vapor intrusion is likely to be incomplete. EPA recommends, however, that the initial CSM for vapor intrusion portray the current understanding of site-specific conditions pertaining to the vapor intrusion pathway. Ideally, at a minimum, the initial CSM will address:

- Nature (i.e., type, chemical composition), location, and spatial extent of the source(s) of vapor-forming chemicals in the subsurface (see Sections 2.1 and 6.3.1, for example). For example, it is useful to know which vapor-forming chemical(s) primarily comprise the subsurface vapor source[95] and whether it is also capable of posing explosion hazards. It is also useful to know whether vapor-forming chemicals are present in groundwater, vadose zone soils, sewer lines, and/or some other source underneath or near buildings.

- Location, use, occupancy, and basic construction (e.g., foundation type) of existing buildings.

The CSM can be updated as additional information is obtained through investigation (Section 6) and building surveys (Section 6.4.1).

EPA recommends the CSM also portray the current understanding of the hydrologic and geologic setting in and around the subsurface vapor source(s) and the buildings, which is expected to influence vapor migration and attenuation in the vadose zone (see Sections 2.2 and 6.3.2, for example). When these conditions are not well established from existing information, and the preliminary analysis indicates the presence of subsurface contamination with vapor-

[95] EPA also recommends that the CSM identify any site-specific chemicals of concern that may be biodegradable and identify and summarize information and data pertaining to the possible role of biodegradation *in situ* in limiting vapor migration in the vadose zone (see Section 6.3.2) or generating hazardous, volatile degradation products (e.g., methane from anaerobic biodegradation, vinyl chloride as a byproduct of PCE or TCE biodegradation).

forming chemicals underlying or near buildings, EPA recommends that a detailed vapor intrusion investigation be scoped and conducted to address these data gaps (see Section 6.3).

Furthermore, EPA recommends the CSM identify known or suspected preferential migration routes that could facilitate vapor migration to greater distances and at higher concentrations than otherwise expected. EPA recommends that buildings with significant preferential migration routes be evaluated closely. For the purposes of this Technical Guide, a preferential migration route is a naturally occurring subsurface feature or anthropogenic (human-made) subsurface conduit that is expected to exhibit little resistance to vapor flow in the vadose zone (i.e., exhibits a relatively high gas permeability) or groundwater flow (i.e., exhibits a relatively high hydraulic conductivity), depending upon its location and orientation relative to the water table and ground surface, thereby facilitating the migration of vapor-forming chemicals in the subsurface and/or into buildings.[96] Naturally occurring examples include fractures and macropores, which may facilitate a preferential route for either the vertical or horizontal migration of source materials and/or vapors. Anthropogenic examples include sewer lines and manholes,[97] utility vaults and corridors, elevator shafts, subsurface drains, permeable fill, and underground mine workings that intersect subsurface vapor sources or vapor migration routes. In highly developed residential areas, extensive networks of subsurface utility corridors may be present, which can significantly influence the migration of contaminants. A preferential migration route can be a "significant" influence on vapor intrusion when it is of sufficient volume and proximity to a building that it may be reasonably anticipated to influence vapor migration towards or vapor intrusion into the building. Significant vertical routes of preferential migration may result in higher than anticipated concentrations in the overlying near-surface soils, whereas significant horizontal routes of preferential migration may result in elevated concentrations in areas on the periphery of subsurface contamination (see Section 6.2.1).

CSMs for vapor intrusion assessments often need to consider two distinct exposure situations:

1) At some sites and contaminated locations, there are concerns as to whether vapor intrusion may pose a human health risk to current occupants of an existing building(s). For this situation, EPA recommends that building-specific information be available to support the CSM, which may be obtained through a building survey (see Section 6.4.1, for example) .

2) At other sites and contaminated locations, buildings are not present, but are expected to be constructed, and building-specific information may not be available to support the CSM. For this situation, the CSM may need to consider a hypothetical building constructed anywhere over (or near) the subsurface vapor source.

[96] For purposes of this Technical Guide, preferential migration routes are distinguished from adventitious and intentional openings in a building that may also facilitate vapor entry from the subsurface (see Section 2.3), but which are expected to typically be present in all buildings (e.g., cracks, seams, interstices, and gaps in basement floors and walls or foundations; perforations due to utility conduits).

[97] In addition to receiving direct discharges of aqueous and chemical wastes from commercial and industrial operations, sewers can be indirect receptacles of subsurface contamination via infiltration of NAPL, soil gas, or contaminated groundwater through cracks in piping and manholes (see Section 2 of this Technical Guide, for example, for further discussion).

In general, CSMs identify the potentially exposed populations, potential exposure routes, and potential adverse health effects (i.e., toxicity) arising from these exposures. As such, EPA recommends the CSM also identify and consider sensitive populations, including but not limited to:

- Elderly,
- Women of child-bearing age,
- Infants and children,
- People suffering from chronic illness, or
- Disadvantaged populations (i.e., an environmental justice situation).

By definition and as noted in Section 2, the exposure route of general interest for vapor intrusion is inhalation of vapors in indoor air and the human population of primary interest is comprised of individuals living or working in or otherwise occupying a building subject to vapor intrusion. However, EPA also recommends that the CSM identify any site-specific chemicals of concern that have potential for explosion hazards (e.g., methane) or for posing other routes of exposure (e.g., dermal exposure to shallow contaminated groundwater seeping into a basement).

EPA recommends that the CSM also identify and characterize suspected sources of site-related, vapor-forming chemicals that are also found in ambient air in the site vicinity. In some situations, site-related contamination has the potential to impact ambient air with the same vapor-forming chemicals that pose a threat from vapor intrusion. For example, contamination of shallow soil or groundwater may release site-related vapor-forming chemicals to ambient air. EPA recommends the CSM identify any such conditions, which have implications for the scope and objectives of the overall site investigation, as well as for data evaluation and the human health risk assessment.

To document current site conditions, EPA recommends that a CSM be supported by maps, cross sections, and site diagrams, to the extent practical, and that the narrative description clearly distinguish what aspects are known or determined and what assumptions have been made in its development.

EPA generally recommends that developing a CSM be incorporated into the first step in EPA's data quality objective (DQO) process (EPA 2006a). It is rare for a site to have readily available sources of sufficient information to develop a complete CSM when the vapor intrusion potential is first considered. For example, a detailed site-specific investigation may be necessary to characterize the full extent of subsurface vapor sources and geologic conditions underlying nearby buildings (see Sections 6.3.1 and 6.3.2) and to demonstrate the absence of preferential routes for vapor migration and intrusion. The CSM normally warrants updating as new information is developed and new questions are framed and answered. A well-defined, detailed CSM may also facilitate the identification of additional data needs and development of appropriate detection limits for laboratory and field analyses, which can support planning of the detailed vapor intrusion investigation (see Section 6.2) and site-specific human health risk assessment, if any (see Section 7.4). Sections 6.3, 6.4, 7.1, and 7.2 provide additional information about data collection and evaluation for purposes of supporting the CSM.

5.5 Evaluating Pre-Existing and Readily Ascertainable Sampling Data

Sites and adjacent facilities that have been the subject of previous environmental investigations or regulatory actions may already have data on contaminant concentrations in site media (i.e., sampling data) when the vapor intrusion pathway is first considered and evaluated. Some of these sites and facilities may be undergoing remediation but warrant a vapor intrusion assessment as a result, for example, of changing toxicity information for vapor-forming chemicals, as part of a periodic review of remediation effectiveness and protectiveness (if any), or for other reasons.

If the pre-existing environmental data are deemed reliable and other conditions are met (as described in the remainder of this subsection and in Section 6.5.2), the sampling data may be compared to recommended generic vapor intrusion screening criteria (see Section 6.5) for purposes of developing some preliminary insights about the potential level of exposure and risk posed by vapor intrusion. Such a screening can, for example, help focus a subsequent vapor intrusion investigation (see Section 6) or provide support for considering building mitigation as an early action (see Section 7.8.2), depending upon building- and site-specific circumstances. Note that some of the site-specific information generally recommended for supporting a risk-based screening (see Section 6.5.2) may not be available when a site is first considered for vapor intrusion.

5.5.1 Evaluate Sampling Data Reliability and Quality

To the extent that environmental sampling data are identified for the site or nearby properties, EPA recommends that these data be evaluated to determine whether they are of sufficient quality and reliability to support a comparison to recommended generic vapor intrusion screening criteria (see Section 6.5). Some questions that could be considered when reviewing historical sampling data include:

- How were the samples collected and analyzed? EPA recommends using pre-existing data when they have been collected and analyzed by methods considered reliable by today's standards.

- How old are the data? Were analyses conducted for all vapor-forming chemicals known or suspected to be present and reasonably expected degradation products? EPA recommends using pre-existing data when they can be considered representative of current conditions.

- Were the reporting limits sufficiently low for comparison with vapor intrusion screening criteria? EPA recommends use of pre-existing data with non-detect results only when they can be considered reliable on this basis.

- Were multiple locations sampled to assess spatial variability of the results? Were multiple sampling events conducted to assess temporal variability of the results? EPA recommends characterizing spatial and temporal variability to increase confidence in

data evaluation and decision-making and ensure consideration of a reasonable maximum vapor intrusion condition.[98]

EPA also recommends that the reliability of any historical sampling data be assessed by considering the principles for collecting subsurface and indoor air samples that are described in Sections 6.3.1 and 6.4 of this Technical Guide. In addition, the EPA's *Guidance for Data Usability in Risk Assessment, Part A* (EPA 1992a) outlines a recommended approach for evaluating whether the data are useable for the human health risk assessment. As such, its recommended approach is also worthwhile and complementary for evaluating the quality and usefulness of historical data collected at a site.

5.5.2 Evaluate Applicability of the VISLs and Adequacy of the Initial CSM

Before performing any comparison of existing sampling data to recommended generic vapor intrusion screening levels (VISLs) (see Section 6.5), it is important to verify that site-specific conditions reflect the conditions and assumptions of the generic model underlying the VISLs, which are summarized in Section 6.5.2. To verify that the generic vapor intrusion model applies, there is a need for basic knowledge of the subsurface source of vapors (e.g., location, form, and extent of site-specific vapor-forming chemicals) and subsurface conditions (e.g., soil type in the vadose zone, depth to groundwater for groundwater sources), which are important elements of the CSM (see Section 5.4). When these subsurface data are not available, EPA recommends they be collected (i.e., initiate a vapor intrusion investigation; see Section 6.3.2, for example) before relying upon risk-based screening using pre-existing sampling data.

5.5.3 Preliminary Risk-based Screening

If reliable pre-existing sampling data are available and an adequate CSM has been developed (i.e., sufficient subsurface characterization information exists to adequately characterize the locations, forms, and extent of site-specific vapor-forming chemicals and general subsurface conditions (e.g., hydrologic and geologic setting in and around the source(s) and the buildings)), then a risk-based screening may be useful to obtain some preliminary insights about the potential level of exposure and risk posed by vapor intrusion.

Example: A prospective developer of a vacant lot with no history of onsite chemical use is interested in evaluating the potential for vapor intrusion in the future due to potential migration onto the lot of a plume of contaminated groundwater emanating from another property. The extent and nature of this off-property plume have been adequately and recently characterized and geologic conditions near (but not on) the lot have been characterized, as documented in a publicly available report(s). In this circumstance, it may be possible to support a preliminary screening and obtain some useful insights. For example, if the maximum concentration of each chemical of concern in the off-property plume of contaminated groundwater currently and in the future is less than the generic chemical-specific screening level for groundwater, then vapor intrusion may not be a future

[98] EPA recommends basing the decision about whether to undertake response action for vapor intrusion (i.e., a component of risk management; see Section 7.4) on a consideration of a reasonable maximum exposure (e.g., EPA 1989, 1991a), which is intended to be a semi-quantitative phrase, referring to the lower portion of the high end of the exposure distribution (see Glossary).

concern on the vacant lot, provided there are sufficient data to document that conditions on the vacant lot are consistent with the generic model behind the vapor intrusion screening levels, as described in Section 6.5.2.

Depending upon lot-specific circumstances, additional data collection or evaluation, possibly including on-lot site characterization, may be warranted (i.e., proceed to a detailed vapor intrusion investigation) to verify that the expected conditions hold true (e.g., hydrogeologic conditions on the vacant lot are consistent with the generic model behind the vapor intrusion screening levels). EPA generally also recommends consideration of the vapor intrusion pathway during the development planning or initial post-construction stage (e.g., pre-emptive mitigation – Sections 3.3 and 7.8; mathematical modeling, where parameters are chosen to represent conditions that give a high-impact case – Section 6.6; indoor air testing – Section 6.4.1 -- to confirm the screening results based upon the groundwater source data) before making final risk management decisions.

This example reinforces the following general recommended guidelines:

- EPA generally recommends that site-specific data be collected and evaluated to verify that the subject property reflects the conditions and assumptions of the generic model underlying the VISLs (see Section 6.5.2).

- EPA generally recommends that multiple lines of evidence (e.g., hydrogeologic information in addition to sampling data) be collected and weighed together in supporting assessments of the vapor intrusion pathway (see Sections 7.1, 7.2, and 7.3 for further information).

- Multiple rounds of groundwater (or soil gas) sampling results can be useful in supporting conclusions that a specific vapor source is stable or shrinking and/or is not expected to pose a vapor intrusion concern (see Sections 6.3.1 and 6.4.5) under reasonably expected future, as well as current, conditions.

Similar recommended guidelines may be appropriate in situations where vapor intrusion potential is being evaluated as part of a periodic review of an existing remedy (prompted, for example, by recent construction of a new building over a contaminated plume that is undergoing remediation) (EPA 2002b, 2012c).

6.0 DETAILED INVESTIGATION OF VAPOR INTRUSION

EPA recommends that the planning and data review team plan and conduct a site investigation for vapor intrusion when the preliminary analysis (Section 5.3) indicates the presence of subsurface contamination with vapor-forming chemicals underlying or near buildings.

This section describes EPA's generally recommended approaches and practices for conducting detailed vapor intrusion investigations, which typically entail collecting and weighing multiple lines of evidence to characterize the vapor intrusion pathway. Specifically, this section:

- Identifies that a wide variety of scenarios may be encountered among sites investigated for potential vapor intrusion, which necessitates site-specific approaches to scoping investigations and sequencing investigation phases and objectives (Section 6.1);
- Provides EPA's recommendations for planning, scoping, and conducting vapor intrusion investigations (Sections 6.2, 6.3, and 6.4);
- Presents EPA's recommended screening levels for vapor intrusion and describes EPA's recommended uses of risk-based screening and suggested interpretation of the results (Section 6.5); and
- Provides recommendations for developing and using mathematical models in vapor intrusion assessments (Section 6.6).

Section 7 describes EPA's generally recommended approaches and practices for determining, on the basis of the investigation results, whether the vapor intrusion pathway poses a potential human health risk to building occupants under current and reasonably expected future conditions and whether response actions are warranted for vapor intrusion mitigation at individual facilities, buildings, or sites.

6.1 Common Vapor Intrusion Scenarios

Vapor intrusion scenarios can be quite varied, owing to the possible combinations of:

- Multiple hazardous chemicals that can form vapors.
- Multiple forms in which these chemicals may be released to or present as contaminants in the subsurface, for example:
    - Residual NAPL and adsorbed-phase chemicals, including LNAPLs that are less dense than water and DNAPLs that are denser than water.
    - Dissolved-phase chemicals in groundwater or soil moisture.
    - Primary vapor releases (e.g., from chemical vapor transmission lines).
- The variety of geologic and hydrologic characteristics and conditions in the subsurface environment in which this contamination may occur.

- The variety of buildings (in terms of size, age, condition, and use) and current or expected land use settings (e.g., residential, commercial, industrial) that may be subject to vapor intrusion from such subsurface contamination.

- Circumstances under which subsurface contamination is found or suspected and investigated (e.g., brownfield redevelopment, citizen reports/complaints, reported release)

- The variety of sources that may contribute to vapor concentrations in ambient air and may serve as indoor vapor sources unrelated to vapor intrusion.

A few of the possible scenarios are illustrated in Figure 2-1. Many more can be inferred from the conceptual model of vapor intrusion discussed in Section 2. Some of the common scenarios where vapor intrusion has been documented to occur include:

- Groundwater contaminant plumes in shallow aquifers underlying residential and nonresidential buildings. Many well-known vapor intrusion sites are in this category, in part because there is generally a greater opportunity to have multiple buildings overlying the vapor source. Specific sites and buildings normally can be prioritized and distinguished based upon their potential for vapor intrusion, which generally would depend upon a number of site-specific factors, such as:

    - strength, proximity, and extent of the vapor source emanating from shallow groundwater (see Sections 2.1 and 5.4);

    - the potential for significant attenuation of vapor migration due to geologic, hydrologic, or biochemical conditions in the vadose zone (see Sections 2.2 and 5.4);

    - the potential for significant attenuation of the contaminant plume due to geologic, hydrologic, or biochemical conditions in the saturated zone; and

    - type(s), characteristics and structural condition of the overlying building(s) (see Sections 2.3, 2.4, and 5.4).

- Soil contamination in the vadose zone underlying commercial or industrial buildings. Typically, one or a few buildings may be threatened by potential vapor intrusion. Specific buildings and sites normally can be prioritized and distinguished based upon their potential for vapor intrusion, which generally would depend upon a number of site-specific factors, such as:

    - strength, proximity, and extent of the vadose zone source (see Sections 2.1 and 5.4);

    - the potential for attenuation of vapor migration due to geologic, hydrologic, or biochemical conditions in the vadose zone (see Sections 2.2 and 5.4); and

    - type(s), characteristics and structural condition of the overlying building(s) (see Sections 2.3, 2.4, and 5.4).

- Sites with residual wastes (e.g., landfills, former manufactured gas plants, former oil production fields) underlying or near buildings. The potential for methane formation may more frequently warrant additional consideration for sites with residual wastes than for contaminated groundwater plumes.

EPA's recommended approaches and practices for vapor intrusion investigations aim to be flexible and adaptable to a wide range of reasonably expected scenarios and are not intended to be prescriptive or exhaustive for any specific scenario.

6.2 Planning and Scoping

Before information or data are collected, EPA generally recommends conducting systematic and thorough planning during which performance or acceptance criteria are developed for the collection, evaluation, or use of these data (EPA 2006a).[99] EPA recommends the data quality objective (DQO) process as the appropriate systematic planning process for its decision-making and has issued guidance for its application to hazardous waste site investigations pursuant to CERCLA and RCRA (EPA 2000a).[100] When appropriately conducted, planning provides greater assurance that the data collected will fulfill specific project needs and that mitigation and subsurface remediation options will be considered early in the process.[101] A clear and logical plan will often facilitate communication with building owners, occupants, and other stakeholders.

Given these considerations, a thorough planning process, guided by a CSM, is usually advisable for detailed vapor intrusion investigations. Figure 6-1 provides a diagram to illustrate such planning and scoping. The initial stages of planning would typically entail gathering readily available existing information and formulating an initial CSM, as described in Section 5.4. The CSM portrays the current understanding of site-specific conditions, including the nature and extent of contamination, contaminant fate and transport routes, potential "receptors" and contaminant exposure pathways. The term "conceptual" merely reflects that the model need not be entirely quantitative and mathematical; it does not, however, denote a simplistic or incomplete understanding of site conditions. The CSM normally warrants updating as new information is developed and new investigatory questions are framed and answered.

Subsequent to formulating an initial CSM based on readily available information, the scope for an initial phase of vapor intrusion investigation would be developed, preferably along with a logical plan for future directions in response to the reasonably expected outcomes of the initial investigatory phases and in coordination with the objectives and phasing of the broader site

[99] In situations where imminent threats (see Section 5.2) are known or reasonably expected, the initial planning process may be more truncated and focused, but careful and thoughtful planning is still recommended.

[100] Appendix B provides additional information about EPA's quality system and DQO process.

[101] *Science and Decisions: Advancing Risk Assessment* was prepared by the National Academy of Sciences (NAS) Committee on Improving Risk Analysis Approaches Used by the U.S. EPA (NRC 2009) and is commonly referred to as the "Silver Book." Among other recommendations, the NAS Committee encouraged EPA to focus greater attention on design in the formative stages of risk assessment, specifically on planning and scoping and problem formulation, and to view risk assessments as a method for evaluating the relative merits of various options for managing risk, rather than as an end in itself. Consistent with these recommendations, plausible mitigation and subsurface remediation options (see Section 8) may warrant consideration during development of vapor intrusion investigation plans.

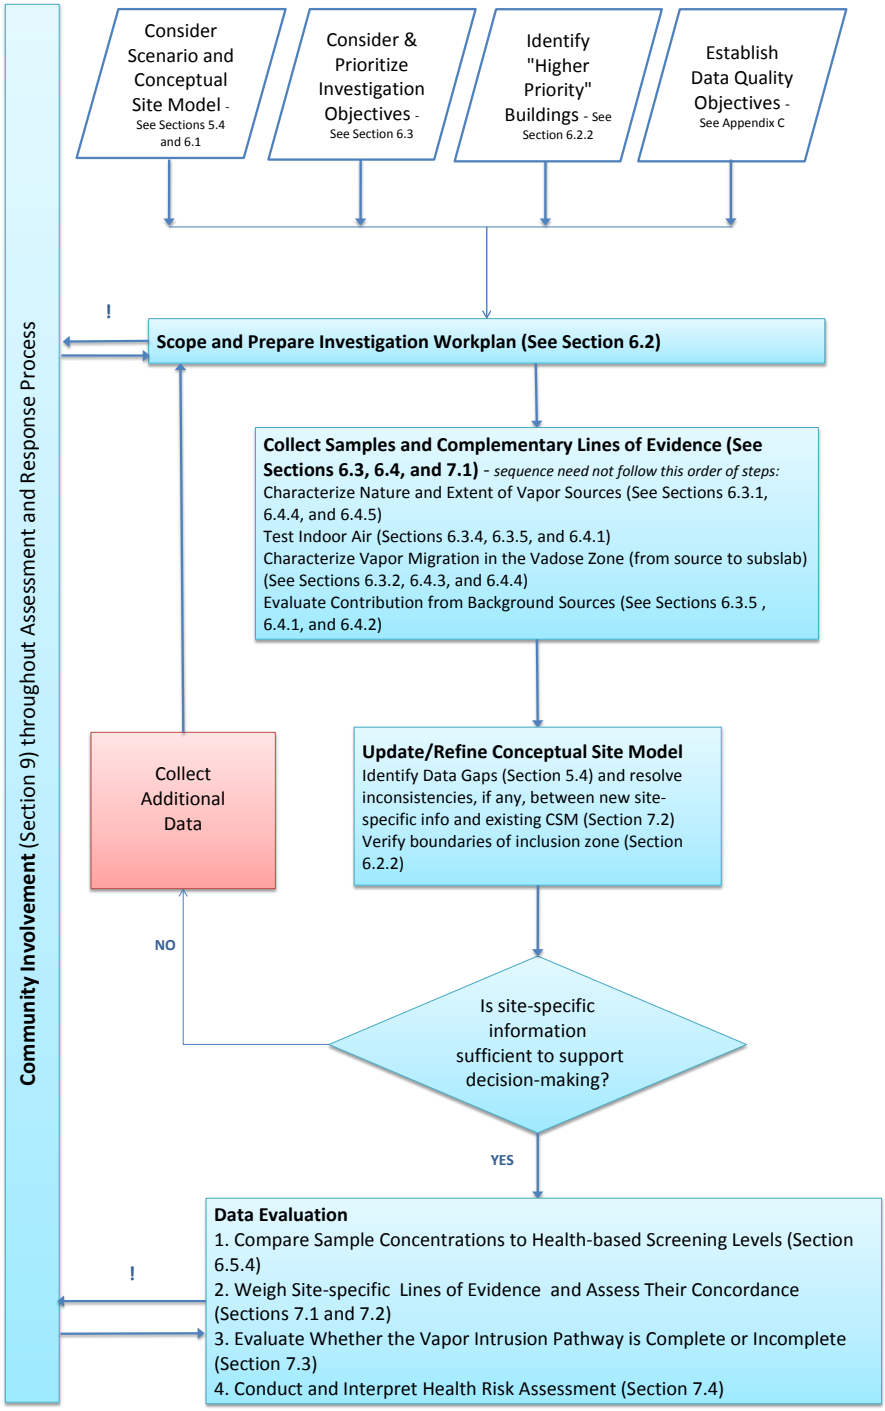

Figure 6-1 Overview of Planning, Scoping, and Conducting Vapor Intrusion Investigations

characterization. Initial plans may warrant periodic updates and refinements, particularly when data outcomes are unexpected and prompt the need to reevaluate the CSM. In each case, EPA recommends that the investigation work plan include the identification of and basis for the indoor air screening levels (such as the vapor intrusion screening levels (VISLs)) and/or indoor air action levels (i.e., level of each vapor-forming chemical of potential concern that would trigger a response action if exceeded), which would dictate the DQOs for the sampling and analysis methods. In general, EPA recommends the plan also include a rationale or logic for where and how the data will be collected and over what duration(s), how the data will be interpreted (e.g., weighed with other lines of evidence, compared to risk-based benchmarks), whether confirmatory sampling will be needed if all sample concentrations are less than the action levels, whether response action(s) would be triggered if sample concentrations exceed the target levels, and similar considerations. EPA recommends considering potential health effects and relevant exposure periods (e.g., chronic versus short-term effects and exposure durations and scenarios; see Section 7.4) for site-related, vapor-forming chemicals when developing DQOs and sampling plans for indoor air (see Section 6.4.1, for example). Sections 6.3 through 6.6 below provide additional information for planning and scoping site-specific investigations for vapor intrusion assessment.

EPA's fundamental approach to evaluating contaminated sites calls for proceeding in a stepwise fashion with early data collection efforts usually limited to developing a basic understanding of the site, as reflected in the CSM.[102] Subsequent data collection efforts focus on filling gaps in the understanding of the CSM and gathering information necessary to evaluate the relative merits of various options for managing risk. Therefore, EPA generally recommends developing and implementing an overall vapor intrusion investigation plan in multiple stages or phases. Such a phased approach encourages the identification of key data needs early in the process to better ensure that data collection provides information relevant to decision-making (e.g., interim action to mitigate vapor intrusion and selection of a cleanup plan for subsurface contamination). In this way, the overall site characterization effort can be scoped to prioritize data collection and minimize the collection of unnecessary data and maximize data quality.

EPA recommends that the objectives and methods of the investigation be documented, preferably in a vapor intrusion work plan. An individual work plan may address a single phase or stage or may address the overall investigation. The vapor intrusion work plan(s) may be

[102] Investigations under CERCLA and RCRA corrective action (CA) explicitly recognize phasing. In these cleanup programs, the first investigatory phase is an *initial site assessment.* The purpose of this activity is to gather information on site conditions (current and historical), releases, potential releases, and exposure pathways. Investigators use this information to determine whether a response action (e.g., removal action or interim cleanup measure) may be needed or to identify areas of concern for further study. Information collected during this phase usually forms the basis for determining whether the next stage, site investigation, is warranted. In the RCRA CA program, the initial site assessment is called the RCRA facility assessment. Under CERCLA, this phase is called the preliminary assessment/site inspection. The purpose of the second phase, site investigation, is to determine the nature and extent of contamination at a site, quantify risks posed to human health and the environment, and gather information to support the selection and implementation of appropriate remedies. In the RCRA CA program, this phase is known as the RCRA facility investigation. Under the CERCLA remedial program, this phase is referred to as the remedial investigation. In addition, the site investigation may itself be conducted in multiple stages (or phases).

incorporated as part of a comprehensive site investigation work plan or as a stand-alone document, depending upon site-specific circumstances.[103]

At a minimum, EPA recommends that the components of the work plan(s) include or reference:

- Narrative description of the rationale, objective(s), and scope of the investigation.
- Summary of the CSM, based upon the current understanding of site conditions.
- Scaled map(s) illustrating known extent of subsurface contamination and readily identifiable landmarks (e.g., streets and buildings).
- Media to be sampled.
- Number, type, and location of and rationale for proposed sampling locations.
- Sampling methods and procedures for each medium.
- Analytic method(s) to be used to obtain chemical concentrations and a statement about whether a stationary or mobile laboratory will be used.
- Standard operating procedures of the laboratory and for field instruments.
- Quality assurance project plan (QAPP).
- Health and safety plan.[104]

EPA recommends that planning for vapor intrusion investigations also consider site and building access agreements, equipment security, and locations of underground utilities.

EPA recommends that the planning, data collection, and data review team(s) for vapor intrusion investigations generally include:

- Individuals with expertise in characterizing subsurface environmental conditions and interpreting and communicating environmental data.
- On-site (field) personnel with appropriate training and experience in hazard identification, workplace practices to foster health and safety, and recommended sampling protocols.

[103] EPA recommends that monitoring programs (see Section 8.4) that assess the performance and effectiveness of remediation and mitigation systems (see Sections 8.1 and 8.2, respectively) also be documented, preferably in work plans similar to those recommended herein for characterizing and assessing the vapor intrusion pathway.

[104] All governmental agencies and private employers are directly responsible for the health and safety of their employees. This general rule applies to many parties involved in the assessment and cleanup of Superfund sites, RCRA corrective action sites, and brownfield redevelopment sites. Standards established pursuant to the Occupational Safety and Health Act are found in Title 29 of the Code of Federal Regulations (29 CFR), which include standards for training, hazard communication, and site-specific health and safety plans.

- Individuals with expertise in human health risk assessment to characterize risks posed by the vapor intrusion pathway.

- Individuals with expertise in community involvement and outreach.

Depending upon the complexity of the CSM (see Section 5.4) and site-specific data evaluations, decision-makers may also find valuable input from individuals with expertise in hydrogeology, inferential statistics, laboratory analysis methods, and building construction, ventilation, and operations and individuals knowledgeable about land use planning, zoning, and land development.

EPA recommends that the scope of investigations within buildings and on individual properties be contemplated, planned, and implemented with the goal of limiting, to the extent practical, return visits, which can cause disruption and inconvenience for building occupants and owners. For example, it may be preferable to collect a comprehensive set of data (e.g., indoor air, sub-slab soil gas, and ambient air samples; pressure readings; see Section 6.4) and confirm information about building occupancy, building usage, heating, cooling, and ventilation (see Section 6.4.1) in a single mobilization, rather than over separate visits, when the investigation objectives include indoor air sampling (see Section 6.3.4) or evaluating contributions of 'background' sources on levels of vapor-forming chemicals in indoor air (see Section 6.3.5).

6.2.1 Vapor Intrusion Inclusion Zones

Soil gas concentrations generally decrease with increasing distance from a subsurface vapor source, and eventually at some distance the concentrations become negligible. The distance at which soil gas concentrations become negligible is a function of the strength and dimensions of the vapor source, the type of vapor source, the soil types and layering in the vadose zone, the presence of physical barriers (e.g., asphalt covers or ice) at the ground surface, and the presence of preferential migration routes, among other factors (see, for example, EPA 2012b). The extent of the site-specific "inclusion zone" for vapor intrusion may also expand in the future, depending upon:

- The age of the chemical release and whether sufficient time has elapsed to allow soil gas to migrate from the source to its maximum potential extent.[105]

- Whether the subsurface vapor source is expanding (i.e., is migrating) or rising in concentration, including hazardous byproducts of any biodegradation.

Because these factors vary among sites, the distance beyond which structures will not be affected by vapor intrusion should be a site-specific determination.

Recommended Distance for Initial Evaluation. There are limited published empirical data relating observed indoor air concentrations of subsurface contaminants to distance from a well-

[105] EPA (2012b, Section 6.1) presents some information about transient vapor migration after a subsurface vapor source is released. Sites with shallow vapor sources (e.g., less than one meter deep) may take only a few hours to a few days for soil gas to migrate to its maximum potential extent. Sites with deeper vapor sources (e.g., greater than 10 meters deep) may take months or years for soil gas to migrate to its maximum potential extent.

defined source boundary. However, a buffer zone of approximately 100 feet (laterally or vertically from the "boundary" of subsurface vapor concentrations of potential concern) generally has been used in determining which buildings to include in vapor intrusion investigations (i.e., which buildings are 'near' a subsurface vapor source for purposes of a preliminary analysis) when significant surface covers are not present, under the assumption that preferential vapor migration routes are absent.[106] Specifically, a buffer zone of 100 feet (or approximately two houses wide) has been suggested by several states for initial evaluation and is supported, in general, by:

- theoretical analyses that assume the absence of a preferential vapor migration route(s) and that diffusion is the predominant mechanism of vapor migration in the vadose zone (Lowell and Eklund 2004); and

- reports that vapor intrusion impacts generally have not been observed "at distances greater than one or two houses beyond the estimated extent of the groundwater plume", at sites where contaminated groundwater is the subsurface vapor source (Folkes et al. 2009).

However, we would note that vapor source types for which use of a 100-foot buffer would typically be inappropriate include:

- Landfills where methane is generated in sufficient quantities to induce advective transport in the vadose zone.[107]

- Commercial or industrial settings where a vapor-forming chemical(s) has been released within an enclosed space at a density that may result in significant advective transport of the vapor(s) downward through cracks or openings in floors and into the vadose zone.

- Leaking vapors from pressurized gas transmission lines.

In each of these cases, the diffusive transport of vapors may be overridden by advective transport and the vapors may be transported in the vadose zone several hundred feet from the source of contamination.[108]

Moreover, we would also note that anecdotal evidence indicates that in some settings buildings greater than 100 feet from a plume "boundary" are affected by vapor intrusion, even when

[106] Preferential migration routes are defined and discussed in Section 5.4. When present, they may facilitate subsurface vapor migration over distances greater than 100 feet.

[107] EPA has also published *Guidance for Evaluating Landfill Gas Emissions from Closed or Abandoned Facilities* (EPA 2005), which provides procedures and a set of tools for evaluating landfill gas emissions to ambient air and soil gas migration due to pressure gradients.

[108] For example, Little et al (1992) describe a landfill in southern California, where methane was detected in enclosed spaces in nearby homes at concentrations approaching 1% by volume and chlorinated hydrocarbons had migrated into a house 180 meters from the landfill.

diffusion is the presumed mechanism of vapor migration.[109] Furthermore, the presence of conduits (e.g., sewer and drain lines that intercept and carry subsurface contamination (Vroblesky et al. 2011), as well as permeable bedding for sewer lines or other utilities) or preferential hydrogeologic pathways that facilitate unattenuated vapor migration in the vadose zone, and other factors (e.g., presence of extensive surface covers, uncertainties in delineating the boundaries) may extend the recommended inclusion distance for a vapor intrusion investigation. For these reasons, EPA recommends investigating soil vapor migration distance on a site-specific basis. That is, larger or smaller distances may need to be considered when developing objectives for detailed vapor intrusion investigations and interpreting the resulting data. Data from sub-slab and exterior soil gas sampling (see, for example, Sections 6.4.3, and 6.4.4, respectively)[110] and indoor air testing (see, for example, Sections 6.3.4 and 6.4.1) can be collected and evaluated to delineate or confirm areas at specific sites within which buildings are potentially subject to vapor intrusion.

Criteria for Establishing "Boundaries" of the Plumes that Contain Vapor-forming Chemicals. This Technical Guide is intended to be applied to existing groundwater plumes as they are currently defined (e.g., Maximum Contaminant Levels, state standards, or risk-based concentrations). However, it is important to recognize that some non-potable aquifers may have plumes that have been defined by threshold concentrations significantly higher than drinking-water concentrations. In these cases, contamination that is not technically considered part of the plume may still have the potential to pose unacceptable human health risk via the vapor intrusion pathway. Consequently, the plume definition may need to be expanded for purposes of defining an inclusion zone for a vapor intrusion investigation. When groundwater is the subsurface vapor source, EPA generally recommends comparing groundwater concentrations to the VISLs to estimate the boundaries of the plume, when contaminated groundwater is a subsurface vapor source, for purposes of establishing the boundaries of the vapor intrusion inclusion zone.

Criteria for Establishing "Boundaries" of NAPL Plumes that Contain Vapor-forming Chemicals. EPA generally recommends comparing soil gas concentrations to the respective VISLs to estimate the boundaries of the vapor plume, when residual or free-phase NAPL is a subsurface vapor source, for purposes of establishing the boundaries of the vapor intrusion inclusion zone.

6.2.2 Prioritizing Investigations with Multiple Buildings

At sites where numerous buildings are potentially subject to vapor intrusion (e.g., developed areas with an extensive plume of contaminated groundwater), it may not be feasible or practical at the outset to sample indoor air in each building or soil gas underneath or near each building. In such circumstances, EPA generally recommends a "worst first" approach to prioritize

[109] Among other possibilities, vapor intrusion impacts observed to occur at distances greater than 100 feet in the absence of a preferential migration route(s) may reflect imprecision in the interpolated edge of a plume, based upon sampling data from sparse monitoring wells, and/or use of screening levels for drinking water, rather than for vapor intrusion (i.e., VISLs), to delineate a plume's extent.

[110] For assessing the extent of soil gas migration from the subsurface vapor source, EPA generally recommends measuring soil gas concentrations, either sub-slab soil gas (preferably) or exterior soil gas, with a sufficient density to characterize and understand spatial variability (Section 6.3.2).

buildings for investigation. Factors that, if known, may warrant consideration in prioritizing buildings for investigation include:

- Source strength and proximity. Buildings overlying and near a source of vapors in the vadose zone would generally be expected to have a greater potential for vapor intrusion than buildings that do not overlie this same vapor source. Where the subsurface vapor source is groundwater, buildings located over higher concentrations or shallower water levels would generally be expected to have a greater potential for vapor intrusion than buildings located over lower concentrations and deeper groundwater plumes.

- Building types and conditions. Buildings that are continuously occupied may pose a more immediate concern than buildings that are not currently occupied, if all other factors (e.g., source strength and proximity) are equivalent. Nonresidential buildings with bay-style doors that are routinely open may be better ventilated than other types of nonresidential buildings, providing greater potential for dilution of vapor-forming chemicals that enter the building via vapor intrusion.

- Vapor migration ease. Buildings overlying vadose zones comprised of coarse geological materials (e.g., gravel, boulders) generally would be expected to have a greater potential for vapor intrusion than buildings overlying vadose zones comprised of fine-grained materials (e.g., silts, clays), provided significant preferential migration routes (e.g., geologic fractures, utility corridors) are not present in the fine-grained layers.

Interviews and building surveys during development of the investigation work plan (or during the preliminary analysis – see Section 5) also can provide useful information for prioritizing buildings, when phased testing is chosen or indicated. Sections 6.3 and 6.4 provide additional examples of survey information that can support planning, in addition to supporting data interpretation.

In situations where "higher-priority" buildings and locations are investigated initially, investigation of locations of other buildings may still be warranted, for example, to ensure that the CSM is complete and accurate and that variability in the subsurface conditions and building conditions is understood. There usually is substantial spatial variability in the concentrations of subsurface vapors, caused by heterogeneities in the subsurface materials and other factors, that can result in variability among buildings in vapor flux and indoor air concentrations arising from vapor intrusion. Additionally, building construction, building age and maintenance, and occupants' activities that affect soil gas entry and air exchange rate will vary from building to building, further adding to the variability in indoor air concentrations between buildings. Therefore, it may be difficult to identify *a priori* either a "representative" or "reasonable worst case"[111] building or group of buildings, when it is determined that sampling all buildings is not practical.

[111] For purposes of this Technical Guide, "reasonable worst case" is intended to be a semi-quantitative phrase, referring to the upper portion of the high end of the exposure distribution, but less than the absolute maximum exposure (see Glossary). Because EPA generally recommends a "worst first" approach to prioritize buildings for investigation of the vapor intrusion pathway, "reasonable worst case" buildings would warrant a "higher priority" than "representative" or typical buildings.

When sampling all buildings is not practical, but other lines of evidence suggest that vapor intrusion may be occurring, the site management team may wish to consider installing engineered exposure controls for vapor intrusion mitigation in buildings without baseline indoor air data (i.e., building mitigation as an early action – see Sections 3.3 and 7.8).

6.2.3 Planning for Community Involvement

Community involvement is an important component of any vapor intrusion investigation. EPA recommends that a community involvement or public participation plan (see Section 9.1) be developed or refined while planning a vapor intrusion investigation. Proper and sustained community outreach and engagement efforts are critical to effectively implementing work plans for vapor intrusion investigations, particularly when they involve sampling in a home or workplace or on private property. Resuming and conducting community involvement at legacy sites (i.e., sites that have a past history of agency involvement; see Section 9.6) can be particularly complex. The site planning team is encouraged to consult with appropriate EPA colleagues experienced in community outreach and involvement efforts and utilize available EPA planning resources, including those discussed in Section 9.

6.3 Characterize the Vapor Intrusion Pathway

As discussed in Section 2, the vapor intrusion pathway entails emanation of volatile chemicals from a subsurface source(s) in a vapor form that migrates in the vadose zone, gradually increases in amount underneath buildings as time passes, and enters buildings through openings and conduits. As a result, detailed vapor intrusion investigations designed to develop or enhance the CSM for a specific site will typically address one or more of the following objectives, often in phases:[112]

- Characterize the nature and extent of subsurface sources of vapors.
- Characterize the subsurface migration paths between vapor sources and buildings (potential “receptors”).
- Assess building(s) for their susceptibility to soil gas entry.
- Evaluate the presence and concentration of a site-related subsurface contaminant(s) in indoor air.
- Identify and evaluate contributions of indoor and ambient air sources to concentrations of hazardous vapors in indoor air.

[112] The order of presentation is not intended to convey a suggested sequencing of objectives; rather, it follows the presentation of the conceptual model of vapor intrusion in Section 2.

These objectives are described in the following subsections for purposes of identifying the primary lines of evidence typically developed and evaluated for each objective and describing how the objectives fit together in developing and enhancing the CSM for a specific site an characterizing vapor intrusion potential. This information is provided to assist the site planning team in selecting and sequencing objectives for vapor intrusion investigations.

6.3.1 Characterize Nature and Extent of Subsurface Vapor Sources

Where the preliminary analysis indicates that subsurface contamination with vapor-forming chemicals may be underlying or near buildings, EPA recommends that the nature and extent of such contamination be well characterized. Source characterization data are critical to developing a sound CSM and supporting confident, final decisions about the vapor intrusion pathway.

Investigations to characterize the nature and delineate the extent of potential sources of vapors may rely upon the results of groundwater sampling, soil sampling, or soil gas sampling, as dictated by the site-specific source(s) and subsurface conditions.

Groundwater Sources:

Where contaminated groundwater is a vapor source located near buildings, EPA recommends that groundwater observation wells (i.e., monitoring wells) be installed at strategic locations and used to assess groundwater flow and contaminant concentrations; i.e., verify the nature and extent of groundwater contamination through groundwater sampling and analysis.[113] Groundwater samples obtained from the uppermost portion of the aquifer[114] that underlies the study area of interest (i.e., where buildings are located) are recommended for characterizing representative vapor source concentrations for vapor intrusion assessment. For this purpose, wells (or multi-level samplers) that are screened across the water table interface are preferred and EPA recommends samples be collected as close as possible to the top of the water table using approved sampling methods designed to minimize loss of volatiles while sampling (EPA 2002a, EPA-ERT 2001a).[115] Ideally, the plume can be shown as stable or shrinking (i.e., is not migrating or rising in concentration, including hazardous byproducts of any biodegradation), through multiple rounds of sampling, so that vapor source concentrations can be confidently evaluated under reasonably expected future, as well as current, conditions. Otherwise, the inclusion zone for vapor intrusion (see Section 6.2.1) may expand over time and/or current sample concentrations in or beneath a given building may under-estimate the reasonable maximum vapor intrusion condition in the future.

For purposes of assessing vapor intrusion for specific buildings, groundwater samples from wells nearer to buildings are generally recommended over those from more distant wells. Interpolation of the results obtained from two or more wells in the uppermost portion of the aquifer may be warranted for these purposes when the spatial pattern suggests significant lateral gradients in contaminant concentrations within the area of interest. However, for purposes of determining whether contaminated groundwater poses acceptable human health risk from vapor intrusion on an area-wide basis, it may be more appropriate to utilize sampling results for the most greatly impacted well within the area of interest.

In addition, EPA generally recommends that a soil gas sample be collected immediately above the groundwater table (and above the capillary fringe) (i.e., "near-source" soil gas sample)[116] to help characterize the subsurface vapor source. The results of such "near

[113] Although a soil gas survey can also be employed as a screening tool to assist with the delineation of a plume of contaminated groundwater, EPA recommends that plume delineation ultimately be supported by the collection and analysis of confirmatory groundwater samples at appropriate locations.

[114] EPA recommends that, to the extent practical, groundwater samples be collected over a narrow interval (e.g., a few feet or less) just below the water table when the data are to be used for assessing the potential for vapor intrusion. Of course, the broader objectives of a site characterization will generally necessitate installation and sampling of additional wells, from other depth intervals, to accurately characterize the full nature and extent of groundwater contamination. Such wells and the broader topic of site characterization are not discussed in this Technical Guide, which is focused instead on recommended guidelines that are pertinent specifically to vapor intrusion.

[115] If available groundwater data do not meet these criteria, the site data review team may consider whether they are nevertheless representative of potential vapor source concentrations emanating from groundwater.

[116] In this context and for purposes of this Technical Guide, "near" means "within a practically short distance." Site- and location-specific circumstances and project-specific objectives typically will influence the quantitative definition of "near" for purposes of collecting "near-source" soil gas samples.

source" soil gas samples can be compared to calculations of the vapor concentration expected when the soil gas is in equilibrium with the concentrations measured in shallow groundwater (see Appendix C). A favorable comparison (i.e., the two concentrations are equivalent for each vapor-forming chemical in groundwater) would help to support the results of the groundwater characterization. On the other hand, a "fresh water lens" (or other site-specific conditions; see, for example, Section 6.3.2) could account for measured soil gas concentration(s) being significantly lower than the calculated equilibrium concentration(s).

Because fluctuations in water table elevation can lead to elevated vapor concentrations in the vadose zone, EPA also recommends that "near source" soil gas sampling (and possibly a soil gas survey) be considered in different seasons that coincide with groundwater fluctuations.

Vadose Zone Sources:

Where contaminated soil or non-aqueous-phase liquid (NAPL) in the vadose zone is a subsurface vapor source, soil sampling using coring techniques for sample retrieval or using sensors, such as a membrane interface probe, can be used to characterize the chemical composition and general location of contamination; that is, bulk soil concentration data can be used in a qualitative sense for this purpose. For example, high soil concentrations generally would indicate impacted soil. Unfortunately, the converse is not always true. Non-detect results for soil samples cannot be interpreted to indicate the absence of a subsurface vapor source, because of the potential for vapor loss due to volatilization during soil sampling, preservation, and chemical analysis.

Alternatively or in addition, a soil gas survey can be used to locate the primary source zone and delineate the areal and vertical extent of the vapor-affected area. Generally, EPA recommends that the soil gas survey include a soil gas sample collected immediately above each contaminant source in the vadose zone (i.e., "near-source" soil gas samples) to help characterize the vapor source.

Although a soil gas survey can generally be used to characterize many other subsurface vapor sources (e.g., sewer and drain lines; landfills and other land-based disposal units; impoundments and other land-based storage and/or treatment units, pressurized tanks and pipelines), additional approaches tailored to the specific source type may also warrant consideration.

These sampling options are generally coupled with an understanding of the site-specific subsurface conditions that control the location and extent of contamination (e.g., geologic properties, including stratigraphy and level of heterogeneity; hydrogeologic conditions; sewers, drains, and other conduits that lie underneath or intersect areas of groundwater and soil contamination). Such understanding is generally developed by interpreting the data obtained through borehole logging (i.e., visually inspecting soil cores and determining soil texture) or geophysical tools.

EPA generally recommends sample locations be of sufficient density to adequately account for spatial variability and heterogeneity in subsurface conditions. EPA generally recommends consulting with individuals who have expertise in characterizing subsurface environmental conditions (e.g., a geologist) when determining appropriate sampling locations and spacing.

When combined with the data demonstrating that the property reflects the conditions and assumptions of the generic model invoked in the VISLs (see Section 6.5.2), groundwater and "near-source" soil gas samples can be compared to medium-specific screening levels to develop an initial quantitative perspective about the potential level of exposure and human health risk posed by vapor intrusion. Section 6.5 provides additional information about risk-based screening of vapor source concentrations.

6.3.2 Characterize Vapor Migration in the Vadose Zone

As described in Section 2, geologic, hydrologic, biochemical factors in the vadose zone, as well as elapsed time since the environmental release, can influence vapor migration and attenuation in soil gas concentrations between subsurface vapor sources and nearby building(s).[117] As noted in Section 5.4, EPA recommends the CSM portray the current understanding of these vadose zone conditions in and around the subsurface vapor source(s) and nearby building(s). Furthermore, EPA recommends the CSM identify known or suspected preferential migration routes that could facilitate vapor migration to greater distances and at higher concentrations than otherwise expected. When these conditions are not well established from existing information, EPA recommends that a detailed investigation be scoped to address these data gaps.

When combined with other data, as discussed further in Section 7.3, information about subsurface vapor migration can support determinations that the vapor intrusion pathway is complete under current conditions or may be complete under future conditions. In some cases, vadose zone conditions may impose sufficient resistance to vapor migration to make the vapor intrusion pathway insignificant. In these circumstances, information about subsurface vapor migration, combined with other lines of evidence, can support determinations that the vapor intrusion pathway is incomplete under current conditions, as discussed further in Section 7.3.

Investigations seeking to characterize vapor migration in the vadose zone generally entail, at a minimum, a soil gas survey. Because soil gas concentrations can exhibit considerable spatial variability, due to a variety of factors,[118] EPA generally recommends that soil gas surveys collect soil gas samples at multiple locations and depth intervals between the vapor source and building(s) (potential "receptors"). As a result, the soil gas survey may include samples collected immediately outside the building ("exterior soil gas") at various depths or several depth intervals,

[117] The horizontal and vertical distance over which vapors may migrate in the subsurface depends on the source concentration, source depth, soil matrix properties (e.g., porosity and moisture content), and time since the release occurred. For example, months or years of volatilization and vapor migration may be required to fully develop vapor distributions in the vadose zone at sites with deep vapor sources or with impedances to vapor migration arising from hydrologic or geologic conditions (Section 2.5; EPA 2012b). Under such circumstances, soil gas surveys conducted soon after an environmental release may not yield data indicating the maximum extent of vapor migration.

[118] Modeling of idealized scenarios provides additional demonstrations about spatial variability of soil gas concentrations. For example, vertical profiles of soil gas concentration(s) can be very different underneath buildings compared to locations exterior to the building and soil gas concentrations may not be uniform laterally, particularly in the vicinity of the building, even when the vapor source is a laterally extensive plume of contaminated groundwater (EPA 2012b). These simulation results indicate why EPA recommends that soil gas generally be sampled in multiple sampling locations, when assessing subsurface vapor migration routes.

as well as immediately beneath it (e.g., sub-slab soil gas sampling).[119] If any shallow soil gas samples are collected, EPA recommends they be collected as close as possible to the building and at depths below the respective building foundation and no less than five feet below ground surface, depending on site-specific conditions. Where crawl spaces are present, crawl space air sampling may also be conducted.

Generally, EPA recommends that the soil gas survey include a "near-source" soil gas sample collected immediately above each source of contamination to help characterize the subsurface vapor source (see Section 6.3.1). The results of such "near source" soil gas samples can be compared to calculations of the vapor concentration expected when the soil gas is in equilibrium with the concentrations measured in shallow groundwater (see Appendix C), when the subsurface vapor source is in the groundwater. Geologic, hydrologic, or biologic impedances to vapor migration may be indicated if the measured "near source" soil gas concentrations are significantly lower than the calculated equilibrium concentrations.

To characterize subsurface migration in the vadose zone, soil gas survey data are generally coupled with an understanding of the site-specific subsurface conditions that influence vapor migration and attenuation (e.g., geologic properties, including stratigraphy and level of heterogeneity; hydrologic conditions, including groundwater elevation and soil moisture;[120] and biological properties, including availability of oxygen to support aerobic biodegradation).[121] Such geologic understanding is generally developed by interpreting the data obtained through borehole logging and geophysical tools. Soil permeability to air flow can be measured in the field (McHugh et al. 2013) and would be used to corroborate inferences based upon borehole logging data. Hydrologic conditions can be characterized by analyzing soil samples for porosity and moisture content and by hydrologic modeling. For potentially biodegradable contaminants, an intensive soil gas survey to establish current vertical profiles for contaminant vapors and oxygen (and, in some cases, biodegradation products, such as carbon dioxide or methane)[122] may be able to demonstrate that biodegradation is responsible for attenuating vapor migration

[119] EPA recommends that spacing of soil gas sampling locations generally consider the extent and location of the subsurface vapor source, distance between the building and the source, and other site-specific factors.

[120] Tillman and Weaver (2007) conducted hydrologic modeling and collected field data, which showed that moisture content determined from soil cores taken external to a building may over-estimate soil moisture underneath the building. They inferred that vapor intrusion assessments based upon moisture content in soil from open areas between buildings may under-estimate vapor intrusion potential.

[121] As noted in Section 2, vapor migration in the vadose zone can be impeded by several factors, including soil moisture, low-permeability (generally fine-grained) soils, and biodegradation. Significant characterization of the vadose zone may be needed to demonstrate that such geologic, hydrologic, and biologic features are laterally extensive over distances that are large compared to the footprint of the building and the extent of the subsurface vapor source at a specific site.

[122] Interpretation of profiles for carbon dioxide and methane can be challenging, due to the presence of natural sources unrelated to contaminant biodegradation (Holden and Fierer 2005).

to a greater extent than can be attributed to advection and diffusion in the vadose zone.[123, 124] For both purposes, samples collected directly underneath the building will tend to be more representative of conditions influencing vapor intrusion potential than samples collected outside the building footprint, all else being equal.

When conducted contemporaneously for multiple buildings, a soil gas survey and characterization of the vadose zone can help identify distances from subsurface vapor sources beyond which threats from vapor intrusion are not reasonably expected, as mentioned in Section 6.2.1. At sites with a limited number of potentially affected buildings, it may be feasible to characterize the subsurface vapor migration near and surrounding all of them. However, at sites where a large number of buildings may be affected, this approach is not likely to be feasible; in these cases, EPA generally recommends that the site manager seek the advice of an individual familiar with the site-specific subsurface conditions (typically a geologist) to help guide selection of appropriate sampling locations and assess whether "representative" or "reasonable worst case" locations can be identified, as appropriate to the objectives of the investigation. Because there usually is substantial spatial variability in the concentrations of subsurface vapors, caused partially by heterogeneities in the subsurface materials, it may be difficult to identify *a priori* locations that are either "representative" or are "reasonable worst case" subsurface conditions.

Subsurface investigations of vapor intrusion also generally warrant an evaluation of utility corridors, which can facilitate unattenuated vapor transport over longer-than-anticipated distances and/or vapor migration towards and into buildings that are serviced by the utility. EPA also recommends subsurface investigations of vapor intrusion consider whether sewers and other man-made conduits have the potential to transport NAPLs, contaminated groundwater, and/or vapors (through soil) towards and/or directly into buildings. Public and facility records may be useful sources of information about utility and sewer locations, which may provide maps, "as built diagrams," or construction specifications. Depending upon the CSM, sampling of vapors within the utility corridor (or within a sewer, if present) may be warranted to characterize vapor migration in the subsurface (or characterize a secondary source of vapors – see Sections 6.3.1 and Section 2.1).

Reasonably expected future risks posed by the subsurface vapor source(s) warrant consideration, in addition to risks posed under current conditions, "in order to demonstrate that a site does not present an unacceptable risk to human health and the environment" (EPA 1991a). For example, when evaluating subsurface vapor migration and attenuation in locations where buildings do not exist, it is important to recognize that the conditions in the vadose zone and soil

[123] At sites where aerobic biodegradation is limiting the upward migration of petroleum hydrocarbon vapors, for example, the vertical concentration profile will typically show higher concentrations of petroleum hydrocarbons and lower (or non-detect) concentrations of oxygen in deeper soil gas samples. At these same sites, the vertical concentration profile will typically show lower (or non-detect) concentrations of petroleum hydrocarbons and higher concentrations of oxygen in shallower soil gas samples. Because weather events can affect rates of oxygen replenishment in the vadose zone (Lundegard et al. 2008), multiple rounds of such sampling are recommended to demonstrate that biodegradation consistently poses a significant impedance to upward vapor migration. This recommendation is particularly apt where the subsurface vapor source is strong (e.g., unweathered NAPL in the vadose zone) relative to time-variable processes supplying oxygen to the vadose zone.

[124] In this context, mathematical modeling (see Section 6.6) can be employed to characterize vapor migration attributable to advection and diffusion in the vadose zone.

gas concentrations may be changed as a result of constructing a new building and/or supporting infrastructure. The moisture content may decrease and the moisture profile change in the vadose zone as a result of reduced infiltration of rainwater below a building footprint (Tilman and Weaver 2007). The permeability to vapor flow in the vadose zone may be altered in the foundation vicinity due to construction. Finally, the future presence of extensive surface covers and/or utility corridors may also modify the vertical and horizontal profile of soil gas concentrations in the subsurface (EPA 2012b). As a result, EPA recommends that appropriate lines of evidence in addition to a soil gas survey (e.g., mathematical modeling, where parameters are chosen to represent conditions that give a high-impact case – Section 6.6) be developed and considered to support any determination that a future building will not be subject to vapor intrusion or will not pose unacceptable human health risk for occupants. Owing to the potentially unpredictable plans for building construction and site redevelopment, as well as potentially unpredictable changes in the transitory soil characteristics (e.g., soil moisture) and soil gas concentrations, institutional controls may be warranted (e.g., to inform the need for a confirmatory evaluation of the vapor intrusion pathway) when new buildings are constructed in areas where the subsurface vapor source(s) has(have) significant potential to pose a vapor intrusion threat.

6.3.3 Assess Building Susceptibility to Soil Gas Entry

When elevated concentrations of vapor-forming chemicals accumulate in the soil gas immediately underneath the foundation, surrounding the basement, or within the crawl space of a vulnerable building, then soil gas entry (i.e., vapor intrusion) can lead to unacceptable levels of subsurface contaminants in indoor air, depending upon building- and site-specific circumstances. As discussed in Section 2.3, soil gas can enter a building when openings are present and driving ‘forces’ exist to draw the vapors from the subsurface through the openings into the indoor environment.

Single-family detached homes can generally be presumed to have openings for soil gas entry; as such, they will generally be susceptible to soil gas entry unless a mitigation system (e.g., radon mitigation system) is present and operating as intended. Some buildings are more susceptible to soil gas entry than others. For example, buildings with significant openings, such as:

- buildings with deteriorating basements or dirt floors, which generally provide poor barriers to vapor (soil gas) entry; and
- buildings with sumps (or other openings to the subsurface) that can facilitate transport of vapors via soil gas entry.

EPA recommends that appropriate lines of evidence be employed to assess susceptibility to soil gas entry, when this objective is selected as part of a site-specific investigation plan for vapor intrusion assessment. Vulnerability to soil gas entry can be assessed for a specific building by using any of several methods, including:

- Concurrently monitoring indoor air samples for presence of radon and finding radon in indoor air at levels greater than in ambient air.[125]

- Concurrently monitoring indoor air and ambient air (see Section 6.3.5) and finding cis-1,2-dichloroethylene, vinyl chloride, 1,1-dichloroethylene, or 1,1-dichloroethane in indoor air at levels greater than in ambient air, when and where they are present in the subsurface vapor source(s), but are not used indoors.[126]

- Employing a photoionization detector (PID) or other real-time in-field device, capable of detecting parts per billion by volume (ppbv) levels, to directly survey suspected locations of soil gas entry (e.g., utility penetrations, sumps) and finding elevated readings of vapors.

- Conducting a visual inspection for cracks and holes in concrete foundation slabs, basement walls, or any floor drain(s). (Openings for soil gas entry will not necessarily be visible or accessible for inspection, so the absence of visible openings, by itself, is insufficient to demonstrate that a building is not susceptible to soil gas entry.)

- Monitoring pressure differences between the building and subsurface environment to characterize the 'driving force' for soil gas entry and the effects of the heating, ventilation, and air-conditioning (HVAC) systems.

- Injecting tracers into the subsurface at selected concentrations and subsequently finding it in indoor air samples.

Certain complementary information obtained for the building, as identified in Section 6.4.1, can also support such assessments. Relevant information includes the operating characteristics of HVAC systems.

In many commercial buildings, the HVAC system brings outdoor air into the building, potentially creating building over-pressurization relative to the outdoor environment. When the building is

[125] Because vapor intrusion and radon intrusion entail similar mechanisms for subsurface vapor migration and gas entry into buildings and structures (Section 2.3), naturally occurring radon may serve as a tracer to help identify those buildings that are more susceptible to soil gas entry than others. Buildings with radon concentrations greater than levels in ambient air are likely susceptible to soil gas intrusion and would likely be susceptible to intrusion of any chemical vapors in the subsurface. On the other hand, the radon concentration in a building is not generally expected to be a good quantitative indicator of indoor air exposure concentrations of vapor-forming chemicals arising from sub-surface contamination. Hence, radon measurement is not generally recommended as a proxy for directly measuring vapor-forming chemicals in indoor air. Among other factors, the distribution of radon-emanating rock and soil and the spatial and temporal variability of their source strength are generally expected to be very different (e.g., tending to be broader and more uniform) than the distribution and source strength variability for subsurface sources of chemical vapors.

[126] EPA (2011a) reports that "vinyl chloride, 1,1-dichoroethylene, cis-1,2-dichloroethylene, and 1,1-dichloroethane are rarely detected in background indoor air." DoN (2011a) also reports that vinyl chloride and cis-1,2-dichloroethylene "are rarely detected in background indoor air." When they are subsurface contaminants, volatile chemicals that are rarely or never present in indoor sources can be inferred to arise in indoor air via vapor intrusion "without further explanation" (DoN 2011a). Brenner (2010), for example, employed this principle (and cis-1,2-dichloroethylene) to identify buildings susceptible to vapor intrusion and to diagnose the relative contributions of vapor intrusion and infiltration to indoor air concentrations.

over-pressurized sufficiently to eliminate the driving force for soil gas entry over at least a portion of the building foundation, vapor intrusion potential is diminished.[127]

Reasonably expected future risks posed by subsurface contamination warrant consideration, in addition to risks posed under current conditions, "in order to demonstrate that a site does not present an unacceptable risk to human health and the environment" (EPA 1991a). For example, current building use and HVAC systems might not be sustained perpetually. Therefore, when the subsurface vapor source(s) underneath or near a building with an over-pressurizing HVAC system has(have) significant potential to pose a vapor intrusion threat, it may be useful to assess susceptibility to soil gas entry and diagnose vapor intrusion (also see Sections 6.3.4 and 6.4.1) in such buildings under conditions when the HVAC system is not operating. (In addition, indoor air testing could be conducted during periods when the HVAC system operates with diminished flows, such as weekends or evenings.) The results of such testing can be used to support determinations about whether the vapor intrusion pathway is "potentially complete" and is reasonably expected to pose unacceptable human health risk (see Section 7.4) in the future,[128] in which case a response action(s) may be warranted (see Section 7.7). For example, if the results indicate susceptibility to soil gas entry when the HVAC system is not in operation and vapor intrusion under these conditions has the potential to pose a health concern, then the building may warrant future monitoring (e.g., continuous monitoring of the pressure gradient across the foundation or indoor air testing) and/or engineered exposure controls, which may be enforceable through an institutional control (IC) (see Section 8.6).

Likewise, well-designed and operated radon mitigation systems generally should diminish vapor intrusion via soil gas entry under current conditions. Therefore, buildings with pre-existing radon mitigation systems, which overlie or are near subsurface vapor sources, could be tested under conditions where the radon mitigation system is temporarily not operated to support decisions about monitoring and ICs as part of a vapor intrusion remedy.[129]

6.3.4 Evaluate Presence and Concentration of Subsurface Contaminants in Indoor Air

Indoor air sampling (see Section 6.4.1) using time-integrated sampling methods or grab samples can confirm the presence, if any, of a site-related vapor-forming chemical (i.e., one comprising the subsurface vapor source(s)) in the indoor environment. When combined with data characterizing subsurface vapor migration and demonstrating the building is (or is not) susceptible to soil gas entry, indoor air sampling data can support determinations that the vapor intrusion pathway is (or is not) complete for a given building, as discussed further in Section 7.3. When conducted contemporaneously in multiple buildings, indoor air sampling can, in concert with soil gas survey data and data delineating subsurface vapor sources, help identify the boundaries of the land area(s) within which buildings are known or suspected to have indoor air concentrations of subsurface contaminants arising from vapor intrusion (also see Section 6.2.1).

---

[127] Over-pressurization may not be uniform throughout a building, particularly in large buildings. Over-pressurization in portions of a building will not necessarily mitigate all openings for soil gas entry.

[128] "Both current and reasonably likely future risks need to be considered in order to demonstrate that a site does not present an unacceptable risk to human health and the environment." (EPA 1991a).

[129] EPA recommends that state and local laws be researched before any such testing is conducted. Some areas have local ordinances governing operation and maintenance of radon mitigation systems.

Indoor air sampling is most commonly conducted using time-integrated sampling methods, when characterizing exposure concentrations for building occupants (see Section 6.4.1), which may include contributions from "indoor" or ambient air sources of these chemicals (see Section 2.7). For example, time-integrated concentrations of hazardous vapors in samples of indoor air can be compared to appropriate, risk-based screening criteria (see Section 6.5) to obtain some preliminary insights about the potential level of exposure and risk posed by vapor intrusion or can be used to support a human health risk assessment (Section 7.4) about vapor-forming chemicals found in the subsurface environment.[130]

When sampling indoor air (or sub-slab soil gas) to characterize exposure concentrations arising from vapor intrusion, EPA recommends removing potential indoor sources of vapor-forming chemicals (see Section 2.7 and 6.4.1) from the building to strive to ensure that the concentrations measured in the indoor air samples are attributable to the vapor intrusion pathway. However, even after removing indoor sources, their effects may linger depending on source strength, relative humidity in the building, the extent to which the contaminants have been absorbed by carpets and other fabrics or "sinks," and air exchange rate. In addition, field experience suggests that it may not be possible to remove all indoor sources. It may be particularly impractical to do so in industrial settings where vapor-forming materials are used or stored.

6.3.5 Identify and Evaluate Contributions from Indoor and Ambient Air Sources

As noted in Section 2.7 herein, indoor air is likely to contain detectable levels of a number of vapor-forming chemicals regardless of whether the building overlies a subsurface vapor source, because indoor air can be impacted by a variety of indoor and outdoor vapor sources unrelated to site contamination. The contribution of indoor and outdoor vapor sources (or both) to indoor air concentrations is referred to as "background" throughout this Technical Guide, when they do not arise from site-related contamination (see Glossary). Information on 'background' contributions of site-related, vapor-forming chemicals in indoor air is important to risk managers because generally EPA does not clean up to concentrations below natural or anthropogenic background levels (EPA 2002e).

To determine if a subsurface vapor source(s) is (or are) responsible for indoor air contamination, EPA recommends that such background sources of site-specific analytes be identified and distinguished from vapor-forming chemicals arising from vapor intrusion. A comprehensive investigation of all background substances found in the environment is usually not recommended. For example, sub-slab soil gas and ambient air samples typically would not be analyzed for radon for purposes of characterizing 'background' exposures *per se*, whereas EPA would recommend analyzing for radon if its precursor was part of a regulated release to the subsurface environment (EPA 2002e).[131] Generally, EPA recommends the site planning and

[130] In certain cases, depending in part on the results (e.g., concentrations exceed risk-based screening levels), indoor air sampling data may be a sufficient basis for supporting decisions to undertake pre-emptive mitigation/early action (see Sections 3.3 and 7.8) in lieu of additional rounds of sampling and analysis or an evaluation of the contribution of background sources to indoor air concentrations.

[131] Sub-slab soil gas and indoor air samples might also be analyzed for radon, where its precursor was not part of a release to the subsurface environment, for purposes of diagnosing vulnerability to soil gas entry (see, for example, Section 6.3.3), depending upon the objectives of the vapor intrusion investigation.

data evaluation team limit chemical analyses to those vapor-forming chemicals known (based upon subsurface contaminant characterization) or reasonably expected (based upon site history) to be present as a result of a release to the subsurface environment.

To support evaluations of sources of indoor air concentrations, EPA recommends conducting a building survey (see Section 6.4.1) that identifies in individual buildings known or suspected indoor sources of the vapor-forming chemicals also found in the subsurface (see Section 2.7) and characterizing ambient air quality (see Section 6.4.2) in the site vicinity for these same chemicals. Key supporting information includes: (1) the locations and types of known or potential indoor vapor sources; (2) information about outdoor vapor sources related to the site (e.g., locations of chemical storage, use, and/or release to the environment); (3) information about outdoor vapor sources un-related to the site, such as nearby commercial or industrial facilities and mobile sources (e.g., cars, trucks, and other equipment); and (4) data on the local ambient air quality.

Interviews of building occupants and inspections of buildings can be helpful initial sources of information about indoor uses and storage of vapor-forming consumer and commercial products.[132] In addition, vapor-detecting field instruments and in-field gas chromatographs[133] can be used to locate indoor vapor sources. Grab (essentially short-duration) samples of indoor air, as described in Section 6.4.1, can be useful for identifying specific vapor-forming chemicals emanating from indoor vapor sources of consumer or commercial products. When the objective is to quantitatively distinguish contributions to indoor air concentrations from vapor intrusion versus contributions from indoor and ambient air sources, as described below, EPA recommends obtaining indoor air concentrations using time-integrated sampling methods (see Section 6.4.1) instead of grab samples.

If the subsurface vapor source(s) is (or are) comprised of multiple vapor-forming chemicals and the subsurface source medium (e.g., soil, groundwater) and location are identical for these chemicals, then contemporaneous samples of sub-slab soil gas (see Section 6.4.3) and indoor air (see Section 6.4.1) can be compared, potentially supporting one of the following conclusions:

> Results indicating vapor intrusion as solely responsible for vapor concentrations in indoor air. The predominant vapor-forming chemicals in the sub-slab soil gas and their relative proportions in indoor air and sub-slab vapor samples would be expected to be similar, whereas their concentrations in sub-slab soil gas would be expected to be substantially higher than in indoor air,[134] if vapor intrusion is solely responsible for indoor air

[132] Information about the chemical composition of commonly encountered products is provided by the U.S. Navy (DoN 2011a, Appendix A) in its guidance for background analysis for the vapor intrusion pathway.

[133] Gorder and Dettenmaier (2011) reported on the use of a field-portable gas chromatograph and mass spectrometer to identify specific sources of vapor-forming chemicals and estimate their mass emission rate(s). EPA's Environmental Response Team has employed the Trace Atmospheric Gas Analyzer (TAGA) mobile laboratory for similar purposes.

[134] Based upon the generic sub-slab attenuation factor identified in Section 6.5.3 herein, sub-slab soil gas concentrations can be expected to typically exceed indoor air concentrations by 33 times or more in residences that are impacted by vapor intrusion (i.e., 33 is the inverse of an attenuation factor of 0.03), when background sources are negligible and the building is under-pressurized relative to the subsurface during indoor air sampling.

concentrations.[135] If recalcitrant (i.e., not subject to biodegradation in the vadose zone), the predominant vapor-forming chemicals and their relative proportions in the subsurface vapor source would likewise tend to be similar to those in indoor air if vapor intrusion is solely responsible for indoor air concentrations.[136]

Results indicating indoor vapor sources as primarily responsible for indoor air concentrations. If a vapor-forming chemical is present with an elevated concentration in indoor air, but is not present or is negligibly present in sub-slab soil gas samples (or representative samples of the subsurface vapor source), then the presence of this contaminant in indoor air may not arise from the vapor intrusion pathway, but rather from indoor sources or other background sources (e.g., ambient air). In these circumstances, EPA recommends considering additional attempts to identify and temporarily eliminate indoor sources, where practical, and re-sample indoor air and sub-slab soil gas after doing so.

Likewise, outdoor (ambient) air samples can be collected (see Section 6.4.2) contemporaneously with indoor air (see Section 6.4.1) and sub-slab soil gas (see Section 6.4.3) samples, as recommended in Section 6.4.

Results indicating outdoor vapor sources as primarily responsible for indoor air concentrations. If a vapor-forming chemical(s) is(are) detected in outdoor air and indoor air at similar concentrations, but is(are) not present in sub-slab soil gas samples (or representative samples of the subsurface vapor source) or is present in the subsurface samples at concentration(s) similar to indoor air),[137] then the presence of this contaminant(s) in indoor air may not arise from the vapor intrusion pathway, but rather from outdoor sources (i.e., ambient air).

Concentrations of vapor-forming chemicals in indoor air, sub-slab soil gas, and ambient air can be compared, as described above, using an individual time-integrated sample for each medium. Recognizing that weather conditions and building operations can lead to variable contributions from vapor intrusion and ambient air infiltration over time, EPA recommends, however, that such

[135] Conversely, if there is an interior source of a vapor-forming chemical in indoor air samples, the relative proportion of this chemical in indoor air will be greater than its respective proportion in the sub-slab soil gas, even where vapor intrusion is occurring, assuming that the other vapor-forming chemicals in the sub-slab soil gas do not have 'background' sources.

[136] Conversely, if there is an interior source of a vapor-forming chemical in indoor air samples, the relative proportion of this chemical in indoor air will be greater than its respective proportion in the subsurface vapor source or in "near-source" soil gas samples (see Section 6.3.1), even where vapor intrusion is occurring, assuming that the other vapor-forming chemicals in the sub-surface do not have 'background' sources.

[137] Sample concentrations of vapor-forming chemicals in indoor air and sub-slab soil gas can be compared to conservative, risk-based screening levels to provide a complementary line of evidence. Generally, vapor-forming chemicals with concentrations that consistently fall below screening levels (see Section 6.5) through multiple sampling events (see Section 6.4) warrant no further action or study, so long as the exposure assumptions match those taken into account by the calculations and the site fulfills the conditions and assumptions of the generic conceptual model underlying the screening levels (see Section 6.5.2).

comparisons be made for multiple sets of paired samples, collected in different seasons,[138] to support any conclusion that vapor intrusion is not a significant contributor to indoor air concentrations, which can instead be attributed to indoor and outdoor sources unrelated to the subject site. Even with a few sets of such samples, rigorous statistical tests may not be feasible. Nevertheless, comparing contemporaneously measured concentrations and proportions of vapor-forming chemicals in indoor air, subsurface media, and ambient air can be effective for this investigation objective, particularly when one (or more) of the analytes is known to be present only in the subsurface or in ambient air.

The following hypothetical example illustrates how site-specific sampling data might inform conclusions about the relative contributions of indoor versus subsurface vapor sources in a building overlying contaminated groundwater:

Example: Time-integrated samples of indoor air, outdoor air, and subslab soil gas were collected contemporaneously for a building that overlies shallow groundwater that is contaminated with a suite of vapor-forming chemicals (designated as VFCA, VFCB, VFCC, and VFCD). The sampling results are summarized as follows:

Vapor-forming Chemical in Groundwater	Time-weighted Sample Concentrations ($\mu g/m^3$)			Ratio of Subslab Concentration to Indoor Air Concentration
	Subslab Soil Gas	Indoor Air	Outdoor Air	
VFCA	*1*	*0.65*	*0.75*	*3*
VFCB	*33,000*	*26*	*0.18*	*1,300*
VFCC	*5,200*	*5.8*	*0.14*	*900*
VFCD	*15,000*	*15*	*0.51*	*1,000*

Based upon the conceptual site model, the presence of these vapor-forming chemicals in outdoor (ambient) air is believed to be due to anthropogenic sources that are not associated with the environmental release responsible for the subsurface contamination. The building is presumed to be susceptible to vapor intrusion, as indicated by pressure monitoring data that indicate building under-pressurization, relative to the subsurface environment, during the sampling event (as discussed further in Section 6.4.1).

Based upon these findings, the presence of VFCB, VFCC, and VFCD in indoor air appears to be solely or primarily attributable to vapor intrusion. The relative proportions

[138] A goal of collecting multiple samples is to observe and characterize a reasonable maximum vapor intrusion condition for the respective building. Because weather conditions and building operations can lead to time-variable contributions from vapor intrusion (e.g., driving forces for vapor intrusion; see Section 2.3) and ambient air infiltration (see Sections 2.4), indoor air concentrations of vapor-forming chemicals can be expected to vary over time. An individual sample, collected at a randomly chosen time, may under-estimate or over-estimate average and reasonable maximum exposure conditions (see Section 6.4.1) to different degrees, depending upon the season of sample collection and other factors.

of these subsurface contaminants in indoor air and sub-slab vapor samples are similar, as indicated by a similar ratio of subslab to indoor air concentration, considering analytical uncertainty. In addition, their indoor air concentrations exceed those found in the paired sample of ambient air.

By contrast, the presence of VFCA in indoor air may be entirely attributable to infiltration of ambient air, as the sample concentrations in indoor air and outdoor are similar, considering analytical uncertainty.

Recommended next steps in the investigation might include a human health risk assessment (see Section 7.4) and a review of the conceptual site model (see Section 5.4) to evaluate whether the different conclusion for VFCA can be reasonably explained (e.g., by vapor attenuation in the vadose zone that is expected to be substantially greater than for VFCB, VFCC, and VFCD).

EPA has compiled and published an evaluation of studies pertaining to indoor air concentrations of volatile organic compounds in North American residences in 1990-2005 (EPA 2011a), which can be employed to identify whether measured indoor air concentrations in residences exceed the historical range of background concentrations. Specifically, if measured indoor air concentrations are found to greatly exceed the historical range of background levels, there is a greater likelihood that the indoor air concentrations are the result of vapor intrusion. This conclusion is supported by the expectation that current levels of vapor-forming chemicals in ambient air and in indoor air due to indoor and ambient air sources are likely to be lower than those observed historically,[139] due to regulations and business practices fostering less use of toxic chemicals in consumer products and industrial processes and reduced emissions from mobile and stationary sources. As a result of this expectation, EPA does not recommend the use of generic values of historical background concentrations, even those cited in peer-reviewed publications or available from databases maintained by regulatory agencies, to characterize current levels in any building, for purposes of supporting conclusions that indoor air concentrations are due to 'background' sources. Rather, EPA recommends that site-specific data (e.g., sub-slab, indoor air and ambient air sampling data) be obtained (as described in Sections 6.4.1, 6.4.2, and 6.4.3), and evaluated, as described above, when the investigation objectives include determining whether indoor air concentrations arise from indoor or ambient air sources.

The following additional approaches for identifying and characterizing 'background' sources may warrant consideration in special situations:

- McHugh et al. (2012) have demonstrated the principle that building over-pressurization can be employed temporarily to minimize vapor intrusion and facilitate measuring indoor

[139] McCarthy et al. (2007), for example, analyzed ambient air data for 25 toxic substances collected in the United States from 1990 through 2005 and found that concentrations of many halogenated volatile organic compounds were declining at most sites and evaluation periods (i.e., 1990-2005, 1995-2005, and 2000-2005). They found that concentrations of petroleum hydrocarbons, such as benzene, associated with mobile sources were all consistently decreasing over the three evaluation periods at most sites.

air concentrations under conditions where only indoor sources may be contributing.[140] At this time, however, there are no standard practices for using over-pressurization to assess 'background' contributions, which is a research and development need (SERDP-ESTCP 2014).

- Forensic and multi-variate statistical methods have been described and illustrated by the U.S. Navy (DoN 2011a) in its guidance for background analysis for the vapor intrusion pathway.

6.3.6 Select, Prioritize, and Sequence Investigation Objectives

Site-specific investigations of potential vapor intrusion frequently begin with pursuing one or more of the objectives presented in Sections 6.3.1 through 6.3.5. Criteria potentially warranting consideration by the site planning team when making decisions about prioritizing and sequencing investigation objectives include, but are not limited to: site scenario (see Section 6.1); building occupants who may be particularly sensitive to the potentially toxic effects of vapors; buildings that are more susceptible to soil gas entry (e.g., buildings with deteriorating basements or dirt floors; whether there are any significant data gaps in the CSM (see Section 5.4); and relationships with and perspectives of the owners and occupants of potentially impacted buildings.

Characterizing subsurface vapor sources (Section 6.3.1), characterizing subsurface vapor migration (Section 6.3.2), and evaluating the presence of subsurface contaminants in indoor air (Section 6.3.4) – are frequently candidates for an initial objective and each can be pursued separately. For example, characterizing subsurface vapor sources (Section 6.3.1) may be a useful initial choice when responding to an initial report about a release of hazardous, vapor-forming chemicals to the subsurface from a commercial or industrial operation or when buildings do not exist currently, but are expected in the future. Characterizing subsurface vapor sources may also be a useful initial choice when building owners or occupants are reluctant to grant access for indoor air testing. In this situation, the site planning team may need to pursue subsurface investigations more intensely to characterize vapor intrusion potential before being granted building access. On the other hand, testing indoor air is recommended as an initial objective when responding to reports of odors in buildings or clusters of inhalation-related symptoms and there is credible information to suggest that a subsurface environmental release may be a contributing factor (see Section 5.2).

In a different scenario, characterizing subsurface vapor migration (Section 6.3.2) may be a useful starting point when addressing sources that are comprised of potentially biodegradable chemicals or that are suspected to occur below an extensive geologic layer that might impede upward diffusive migration. For large buildings with HVAC systems that may over-pressurize the interior relative to the subsurface environment, EPA generally recommends: a building assessment early in the investigation, which obtains and weighs the complementary information

[140] Indoor air concentrations measured after sufficient periods of over-pressurization may be indicative of 'background' levels, whereas indoor air concentrations detected before and after a sufficient period of "rebound" from temporary over-pressurization may be indicative of joint contributions from 'background' sources and any vapor intrusion from the subsurface.

identified in Section 6.4.1, to support investigation planning; and an evaluation of susceptibility to soil gas entry under conditions when the HVAC system is not operating (see Section 6.3.3).

Each of the investigation objectives described in Sections 6.3.1 through 6.3.5 may, in some cases, be conducted iteratively with increasing complexity as the investigation proceeds and the CSM is refined. For example, field instruments can be useful for locating potential background sources (e.g., household or commercial cleaning products) (see Section 6.3.5) and grab (essentially short-duration) samples of indoor air, as described in Section 6.4.1, can be useful for characterizing the chemical composition of identified indoor sources of vapors during an initial building reconnaissance while potential background sources are surveyed. These activities might be followed by indoor air and sub-slab soil gas sampling, using time-integrated sampling methods as described in Section 6.4.1 and 6.4.2, to distinguish subsurface contributions from indoor sources. More advanced methods of distinguishing the various potential contributions to indoor air might be utilized, if warranted, in intermediate phases of the investigation under such an iterative approach.

6.4 General Principles and Recommendations for Sampling

Sampling of indoor air, outdoor air, soil gas, and groundwater and analysis for vapor-forming chemicals can play an important role in vapor intrusion investigations for one or more of the objectives identified in Section 6.3. This subsection summarizes for indoor air, outdoor air, sub-slab soil gas, exterior soil gas, and groundwater the following:

- Principal methods for collecting samples.
- Potential uses of the resulting sampling data.
- Recommended practices for sample collection.
- Unique or frequently encountered logistical issues.

We would note that soil and NAPL sampling has been and may be used to characterize the nature (e.g., chemical composition) and general location of subsurface vapor sources (see Section 6.3.1). Information about soil sampling can be found in *Standard Operating Procedures, Soil Sampling* (EPA-ERT 2001b). However, bulk soil (as opposed to soil gas) sampling and analysis is not currently recommended for estimating the potential for vapor intrusion to pose unacceptable human health risk in indoor air, because of the potential for vapor loss due to volatilization during soil sampling, preservation, and chemical analysis. In addition, there are uncertainties associated with soil partitioning calculations.

To ensure that the sampling data will meet the site-specific data quality needs, EPA recommends that the sampling and analytical methods selected by the site planning team be capable of obtaining reliable analytical detections of concentrations less than project-appropriate, risk-based screening levels (e.g., VISLs). Towards that end, EPA recommends that, as part of establishing site-specific data quality objectives (DQOs), the planning and data collection team(s) consult with a laboratory skilled in the analysis of air and soil gas samples and choose sampling and analytical methods capable of routinely attaining the desired detection sensitivity for each medium.

EPA also recommends that the site planning team identify and utilize appropriate sampling locations and durations and address spatial and temporal variability to fulfill the specific objectives of the investigation, which may include obtaining data to characterize the potential human exposure in a building(s). EPA recommends the CSM, the objective(s) of the investigation, and other site-specific information be considered in determining the number and types of samples used at a specific site.

The sampling duration depends on the type of medium being sampled (for example, soil gas, sub-slab soil gas, and indoor or outdoor air) and analytical methods (for example, Method TO-15). Some of the key recommended considerations are provided in the following subsections. Several rounds of sampling are recommended to develop an understanding of temporal variability[141] to ensure that final risk management decisions are based upon a consideration of a reasonable maximum vapor intrusion condition.[142]

6.4.1 Indoor Air Sampling

Indoor air sampling results are used to assess the presence of and level of human health risk posed by vapor-forming chemicals in indoor air (see Sections 6.3.4 and 7.4), and to diagnose whether vapor intrusion is occurring (see Sections 6.3.3, 6.3.5, and 7.3). These two uses of indoor air sampling in vapor intrusion investigations are discussed further below with recommended methods for each. As discussed further in Sections 8.4 and 8.7, indoor air sampling may also be useful for supporting performance evaluations of vapor intrusion mitigation systems and verifying the health protectiveness of subsurface remediation systems.

EPA recommends that the decision to collect indoor air data be supported by lines of site- or building-specific evidence (e.g., characterization of subsurface vapor source(s) strength and proximity to building(s), vadose zone conditions, and building conditions) that demonstrate that vapor intrusion has the potential to pose a significant human exposure. Confidence in the assessment is expected to be higher when multiple lines of site- or building-specific evidence, in addition to indoor air data, come together to provide mutually supporting evidence for a common understanding of the site conditions/scenarios and the potential for vapor intrusion (i.e., the various lines of evidence are in agreement with each other).

A potential shortcoming of indoor air testing is that indoor sources and outdoor sources unrelated to subsurface contamination and to releases from the subject site – “background” (see Glossary) – may contribute to the presence of volatile chemicals in occupied buildings (see Section 2.7), particularly if these sources cannot be removed from the building prior to and throughout the duration of sampling indoors. This shortcoming of indoor air testing is

[141] Seasonally variable conditions (e.g., moisture levels, depth to groundwater) can lead to seasonally variable concentrations and distributions of vapors in the vadose zone. Likewise, weather conditions and building operations can lead to time-variable contributions from vapor intrusion (e.g., driving forces for vapor intrusion; see Section 2.3) and ambient air infiltration (see Sections 2.4). Collectively, these processes cause indoor air concentrations of vapor-forming chemicals to vary over time (see Section 2.6). An individual sample (or single round of sampling) would be insufficient to characterize seasonal variability, or variability at any other time scale.

[142] EPA recommends basing the decision about whether to undertake response action for vapor intrusion (i.e., a component of risk management; see Section 7.4) on a consideration of a reasonable maximum exposure (e.g., EPA 1989, 1991a), which is intended to be a semi-quantitative phrase, referring to the lower portion of the high end of the exposure distribution (see Glossary).

unavoidable when the subsurface environment contains the very same volatile chemicals that contemporaneously arise in indoor air due to background sources, which is common for some chemicals and relatively rare for others (EPA 2011a). In this circumstance, additional lines of evidence, possibly including special procedures and analyses, may warrant evaluation to distinguish background contributions from those originating from vapor intrusion (see Section 6.3.5).

After discussing recommended sampling methods and practices for the primary uses of indoor air sampling data, this sub-section concludes by discussing:

- Recommended measures to reduce the impact of indoor sources of vapor-forming chemicals.
- Recommended approach to establishing analyte lists for indoor air samples.
- Complementary, building-specific data (i.e., additional lines of evidence) that can be collected contemporaneously while indoors.

Characterize Human Exposure Levels. Indoor air sampling and analysis provide a direct approach to obtaining concentrations of vapor-forming chemicals in indoor air to which building occupants can be exposed. For this purpose, EPA generally recommends time-integrated sampling methods, since indoor air concentrations can be temporally variable[143] and time-integrated exposure estimates over appropriate exposure durations (e.g., chronic typically; less-than-chronic in some cases) are generally most useful for assessing human exposure and human health risk (see Section 7.4).

Because of variability, a single indoor air sample, collected at a randomly chosen time, is insufficient information to estimate an average exposure. On the other hand, it is impractical to collect indoor air samples continuously over a chronic exposure period (i.e., up to 30 years for a reasonable maximum exposure duration in a residence (EPA 2014a)), which would also entail deferring risk management decisions for a prolonged period while human exposures from vapor intrusion could occur unabated. Hence, current and past practice has generally relied upon collecting multiple indoor air samples for purposes of estimating long-term average (i.e., chronic) exposures and assessing human health risk (see Section 7.4). All else being equal, a longer collection period for each individual sample would be expected to yield a more reliable basis for estimating long-term, time-average exposure than would a one-day sample collection period.

When investigating short-term exposure conditions that might warrant prompt response action to protect human health (see, for example, Sections 5.2 and 7.5.2), time-integrated indoor air samples can provide useful estimates of exposure for the location and time period of sample collection. (A short-term exposure is defined as a “repeated exposure for more than 24 hours,

[143] Because weather conditions and building operations can lead to time-variable contributions from vapor intrusion (e.g., driving forces for vapor intrusion; see Section 2.3) and ambient air infiltration (see Sections 2.4), indoor air concentrations of vapor-forming chemicals can be expected to vary over time (see Section 2.6). Field observations indicate that indoor air concentrations arising from vapor intrusion can be temporally variable within a day and between days and seasons in an individual residential building (EPA 2012f; Holton et al., 2013ab).

up to 30 days" – see Glossary.) All else being equal, a longer collection period for an individual sample would be expected to yield a more reliable basis for estimating time-average short-term exposure than a one-day sample.

As noted above, EPA also recommends considering potential health effects and relevant exposure periods for site-related, vapor-forming chemicals when developing DQOs and sampling plans for indoor air.

Variability in laboratory analyses can be considered when evaluating these data in support of risk management decisions.[144]

Time-integrated samples provide a direct measurement of the average chemical concentration over a fixed period of time (e.g., ranging from 8 hours to several weeks, depending upon the sampling method, its capabilities, and its deployment). Time-integrated samples can be collected using either evacuated canisters, which collect gas in a container, or sorbent samplers, which collect vapor-forming chemicals on a sorbent material.

Evacuated canisters

Evacuated canisters are spherical- or cylindrical-shaped stainless steel or silica-lined containers that are prepared to be under negative pressure relative to the environment and certified by the laboratory to be clean and leak-free.[145] As described in EPA Method TO-14A (EPA 1999c), evacuated canisters can be used as passive (sub-atmospheric pressure sampling) or active (pressurized sampling) samplers. In both cases, the canister is initially evacuated to a standard vacuum in preparation for sampling. For sub-atmospheric sampling, when the canister is opened for sample collection, the differential pressure causes air to flow into the canister without use of a pump. In this case, sampling must end before the vacuum is fully dissipated, else the sample collection period will be unknown. For pressurized sampling, a pump is used to pass air into the canister until a specified pressure (up to two atmospheres) is reached. In both cases, a flow-control device is used to maintain a constant flow into the canister over the desired sample period. To ensure that the canisters are filling at the proper rate, EPA recommends checking the flow rate periodically during sample collection. EPA Methods TO-14A and TO-15 provide further information on measuring and controlling flow rates into canister-type samplers.

[144] For a recently published study, EPA's ORD determined "The acceptance criterion to demonstrate equivalency is ±30% … based on what is defined as acceptable reproducibility in vapor intrusion field studies" (EPA 2012f).

[145] Canisters are cleaned and re-used because they are too expensive to dispose routinely. The certification process entails cleaning the interior of the container using a combination of dilution, heat, and high vacuum. Canisters are then analyzed for a large suite of vapor-forming chemicals to establish that they are free of detectable chemicals at a suitably low (sensitive) detection level. The cleanliness of canisters can be certified individually (i.e., direct testing of each canister, or 100% certification), which is generally desirable in instances where the data are to be used for exposure/risk assessment purposes. Alternatively, canisters can be certified by batch (or lot), in which a subset of the canisters are tested directly (e.g., 10%) and results are extrapolated to the remainder of the batch. Batch-certified canisters may be sufficient when concentrations of target analytes are expected to be high, relative to potential levels of residual contamination in the canister after cleaning. EPA recommends that flow controllers also be cleaned between uses to avoid artificial contamination.

Typically, for vapor intrusion investigations, indoor air samples are collected using six-liter canisters using sub-atmospheric pressure sampling over a 24-hour period in residences or over an 8-hour period (or workday equivalent) in commercial and industrial settings, when using these devices. Larger canisters (i.e., 15-liter) allow higher flow rates and may be preferable for longer sampling events or to collect a larger volume of sample.[146] A capillary flow controller has been developed and demonstrated for use in industrial hygiene applications (Rossner et al. 2002; Rossner and Wick 2005), which may hold promise for extending sampling time periods for indoor air with standard-sized canisters.

Details for selecting and utilizing sampling canisters are provided in EPA Methods TO-14A (EPA 1999c) and TO-15 (EPA 1999d). EPA's Environmental Response Team has developed a standard operating procedure for sampling air with evacuated canisters (EPA-ERT 1995).

An advantage of using evacuated canisters for sample collection is the capability of analyzing multiple sub-samples from the same canister (because these canisters obtain a "whole air" sample). They are also reasonably easy to deploy and retrieve. However, sample recovery and representativeness can be affected by ambient conditions; for example, low humidity conditions in the sample may lead to losses of certain volatile compounds on the canister walls (EPA 1999c).

Fourteen days is the most commonly cited hold time for air samples in canisters. Some analytes, however, may be stable in canisters for up to 30 days.

Sorbent Samplers

Sorbent sampling devices are hollow containers that hold one or more adsorbent media that can bind vapor-forming chemicals. They have been developed and tested over several decades for industrial hygiene monitoring and have more recently been employed for other purposes, including vapor intrusion investigations. Sorbent samplers can be used in an active or passive mode.

In the active mode, a pump is used to draw air at a known rate through the device. The flow rate and sampling volume are determined based on the type of sorbent used, the target constituent(s), and the amount of sorbent contained in the device. Care must be taken to ensure that the volume of air drawn through the tube does not exceed the "breakthrough" volume[147] (i.e., the volume of air which may be passed through the sorbent tube before a detectable level of the analyte concentration elutes from the non-sampling end), else the time-weighted average concentration will be biased low by an unknown amount.

In the passive mode, no pump is used, and vapor-forming chemicals enter the device due to diffusion. Consequently, passive (diffusion) samplers may be placed in locations of interest without consideration of power availability.

[146] Alternatively, two (or more) large canisters can be connected together to allow collection of time-integrated samples over longer durations, which is generally desirable for characterizing long-term average exposure levels.

[147] For this reason, sample volumes in the one- to four-liter range are generally recommended for this method (EPA 1999e).

Although passive (diffusion) samplers have been less commonly used to quantify indoor air concentrations, their use may grow as a result of recent demonstrations that they can yield results comparable to those obtained using evacuated canisters (EPA-Region 9 2010; EPA 2012f; Odencrantz et al. 2009; Odencrantz et al. 2008),[148] and a recognition that they may be less intrusive for some building owners and occupants and more convenient for field staff (EPA-Region 9 2010). Passive samplers are also capable of being deployed for longer durations than evacuated canisters, thereby providing a more economic means of obtaining average indoor air concentrations over longer periods of exposure. Time-integrated samples of indoor air over longer periods than one day are also indicated by field observations demonstrating that indoor air concentrations arising from vapor intrusion can be temporally variable within a day and between days and seasons (EPA 2012f; Holton et al., 2013a).

The basic configuration of a passive sampler is a solid, typically granular, sorbent contained in a metal, glass of plastic container with openings of known dimensions. Several different containers and a wide range of adsorptive media are commercially available, which function similarly. After sample collection, adsorbed mass is measured in a laboratory for each analyte; the two most common analytical methods involve thermal desorption or solvent extraction combined with gas chromatography/mass spectrometry. The air concentration for each analyte is calculated from the adsorbed mass, the duration of sampling, and the uptake rate.

The uptake rate is dependent upon the geometry of the sampling device and the diffusion coefficient of the analyte. The uptake rate is the most critical variable for accurately measuring air concentrations with passive samplers, since the sampling duration and adsorbed mass can generally be measured very accurately. Fortunately, most commercially available passive samplers have published uptake rates for several compounds, which collectively address many of the vapor-forming chemicals described in Section 3.1.[149] Once the target analyte(s) and uptake rate(s) are known, the sample duration needed to attain data quality objectives (i.e., reporting limit equal to or lower than the risk-based screening level or risk-based action level) can be calculated for each analyte.

Uptake rates of deployed samplers can be affected by ambient conditions (e.g., temperature, because chemical-specific diffusion rates are temperature-dependent; and humidity, which influences the uptake of water vapor, which may interfere with retention and stability of the analyte and/or with laboratory analysis). EPA, therefore, recommends that ambient conditions be recorded during deployment of passive samplers.

One potential advantage of passive samplers is that they can be left unattended for relatively longer durations, thereby conveniently providing estimates of longer-term time-

[148] For example, EPA's National Exposure Research Laboratory found that Radiello™ charcoal passive samplers performed well for sampling periods up to 28 days for TCE (EPA 2012f). In that study, one-week (7-day) Radiello™ passive samplers were utilized as a primary measurement tool and the resulting data were used as a basis of comparison to longer-duration samples (e.g., two-week, four-week (monthly), and 13-week (quarterly) samples).

[149] Standard methods for determining uptake rates have been published by a few organizations. Ideally, the selected passive sampling device will have vendor-supplied uptake rates supported by controlled chamber tests or a considerable body of field-calibrated uptake rates for most, if not all, of the target compounds.

weighted average concentrations. However, similar to active sorbent sampling, the duration of passive sampling must be such that the adsorptive capacity of the media is not approached or exceeded, else the time-weighted average concentration will be biased low by an unknown amount.

One potential disadvantage of sorbent sampling, compared to canister sampling, is that only one analysis is possible from an individual device, because it does not collect a "whole air" sample. Thus, if an error occurs in laboratory handling or there is an instrument malfunction, the sample is lost. Such errors generally are not common. Therefore, this potential disadvantage will not generally offset the benefits of sorbent sampling, the foremost of which is the ability to obtain time-integrated samples over longer periods (i.e., up to a few months for some compounds) than with evacuated canisters.

For a typical-size residential building or a commercial building less than 1,500 square feet, EPA recommends that the site teams generally collect one time-integrated sample in the area directly above the foundation floor (basement or crawl space) and one from the first floor living or occupied area, at least for the initial sampling round.[150] In general, EPA recommends samples be collected at the breathing zone level for the most sensitive exposed population.[151]

EPA recommends the site planning and data evaluation team discuss the number of sample locations per building for atypical situations, which include: (1) very large homes or buildings;[152] (2) multi-use buildings, particularly ones with segmented areas that are occupied by different populations (e.g., day care with young children versus office with adult workers) or have different occupancy patterns over time. Additional samples may also be warranted, depending on internal building partitions, HVAC layout, contaminant distribution in the subsurface, and occurrence of observable locations of potential soil gas entry (e.g., basement sumps or drains, relatively large holes or spaces in the foundation floor, entry points for utilities). Closed rooms located below ground may have appreciably higher contaminant concentrations originating from vapor intrusion. Closed rooms may warrant sampling to characterize the reasonably maximum exposure levels, if occupied, or to diagnose vapor intrusion (e.g., see below), even if not occupied.

[150] Placement of indoor air sampling devices may entail compromises. Whereas the ideal location may be a central location that is unobstructed and representative of the actual used area of a room, placement at breathing zone height in a heavily used area well away from any wall is likely to interfere with normal occupant activities.

[151] The "most sensitive" exposed population may be identifiable by combining information about the types of human occupants in a given building and the types of potential toxic effects for vapor-forming chemicals found in the subsurface environment. For example, the 'most sensitive' exposed population could be children, pregnant women, or elderly adults, depending upon building- and chemical-specific characteristics.

[152] Larger commercial and residential buildings (e.g., multi-family residences) may warrant additional discussion with the site planning team and perhaps a statistician to select the appropriate number and placement of indoor air samples to meet DQOs.

Indoor air concentrations vary over time, due to time-dependent changes in soil gas entry rates, exchange rates, intra-building mixing, among other factors (see Section 2).[153] Therefore, multiple rounds (and often several rounds) of indoor air sampling is generally recommended in order to reduce the chance of reaching a false-negative conclusion (i.e., concluding exposure is at an acceptable risk level when it is not) or reaching a false-positive conclusion (i.e., concluding exposure is at an unacceptable risk level when it is not).[154] Also, multiple sampling events generally are considered necessary to account for seasonal variations in climate and the habits of building occupants and ensure that related risk management decisions are based upon a consideration of a reasonable maximum vapor intrusion condition.[155] In many geographic areas in the continental United States, indoor air sampling during the heating season may yield higher indoor air concentrations than at other periods, because stack effects are generally more significant and, therefore, higher rates of soil gas entry are reasonably expected. Another scenario that may yield higher indoor air concentrations is when a building is sealed and the ventilation system is not operating.

When sampling indoor air (or sub-slab soil gas), EPA generally recommends removing potential indoor sources of vapor-forming chemicals (see Section 2.7) from the building to strive to ensure that the concentrations measured in the indoor air samples are attributable to the vapor intrusion pathway.[156] After removal of indoor sources, their effects may linger longer depending on source strength, relative humidity inside the building, the extent to which the contaminants have been absorbed by carpets and other fabrics or "sinks," and air exchange rate of the building. In residential settings, EPA generally recommends that potential indoor sources be removed from the structure and stored in a secure location at least 24 to 72 hours prior to the start of sampling, based on an approximate air exchange rate of 0.25 to 1.0 per hour in

[153] Because weather conditions and building operations can lead to time-variable contributions from vapor intrusion (e.g., driving forces for vapor intrusion; see Section 2.3) and ambient air infiltration (see Sections 2.4), indoor air concentrations of vapor-forming chemicals can be expected to vary over time. Holton et al. (2013ab) obtained and reported a set of long-term, high-frequency, indoor air data for an unoccupied house (except for periodic visits by researchers) in Utah overlying a plume of chlorinated hydrocarbons. TCE concentrations in indoor air varied by approximately two to three orders of magnitude, exceeding variations in measured air exchange rate.

[154] An individual sample, collected at a randomly chosen time, may under-estimate average and reasonable maximum exposure conditions. From their high-frequency, measured data, Holton et al. formulated a synthetic data set (simulating one-day-average concentrations), which they used to estimate that a single, randomly drawn, one-day sample had a forty percent chance of being less than the true mean (Holton et al. 2013b; see Table 1 therein). When the true mean was assumed to exceed the risk-based action level ("target concentration" in their parlance) by two or five times, they estimated that a single, randomly drawn, one-day sample had a twenty percent or six percent chance, respectively, of not detecting the exceedance. These data support EPA's recommendation to collect multiple rounds of indoor air sampling to reduce the chance of reaching a false-negative conclusion. Collecting multiple rounds of indoor air sampling can also reduce the chance of reaching a false-positive conclusion (i.e., concluding that vapor intrusion poses unacceptable human health risk when it does not), because an individual sample, collected at a randomly chosen time, may over-estimate the average exposure condition.

[155] Given EPA's over-arching duty to protect human health and recognizing the disruption to building owners and occupants caused by indoor air sampling, risk managers may choose to pursue pre-emptive mitigation (i.e., early action) at some buildings (see Sections 3.3 and 7.8) rather than, for example, conduct multiple rounds of sampling over a few years to establish an estimate of long-term average exposure concentration and characterize temporal variability.

[156] Vapor-detecting field instruments and in-field gas chromatographs can be used to locate indoor sources of vapors. For example, Gorder and Dettenmaier (2011) reported on the use of a field-portable gas chromatograph and mass spectrometer to identify specific sources of vapor-forming chemicals. EPA's Environmental Response Team has employed the Trace Atmospheric Gas Analyzer (TAGA) mobile laboratory for similar purposes.

residential buildings. In residences with attached garages, keeping the door(s) between the garage and the living space closed prior to and during indoor air sampling may also be warranted, in situations where the site-specific chemicals of potential concern include petroleum hydrocarbons or are components of products stored in the garage.

Diagnose Vapor Intrusion and Background Sources. When access is granted for indoor air sampling, EPA generally recommends concurrently collecting samples of sub-slab soil gas (see Section 6.4.3) and outdoor (ambient) air (see Section 6.4.4) over similar durations using the same methods. Comparing these results to each other and to results for subsurface vapor sources can foster insights and support findings about the relative contribution of vapor intrusion and background sources to indoor air concentrations (as described in Section 6.3.5). In this case, time-integrated sampling methods are recommended for indoor air, because concentrations of vapor-forming chemicals can vary significantly over time (see Section 2.6).

Grab (essentially short-duration) samples can, however, be useful for:

- confirming the presence of a subsurface contaminant in indoor air[157] (see Section 6.3.4) or in gas in a drain line or sewer lateral that enters a building,
- identifying specific vapor-forming chemicals emanating from indoor sources of consumer or commercial products[158] (see Section 6.3.5), and
- identifying specific vapor-forming chemicals emanating from suspected openings for soil gas entry into buildings (see Section 6.3.3).

Grab samples can provide a convenient and less intrusive means of confirming the presence, if any, of a site-related subsurface contaminant(s) in the indoor environment. However, an individual grab sample is not reliable for purposes of demonstrating that vapor intrusion is not occurring in a specific building; among other considerations, vapor intrusion and indoor air concentrations can exhibit significant temporal variability (EPA 2012f, Holton et al., 2013ab). Consequently, EPA recommends collecting multiple time-integrated samples to support any such building-specific determination.

Indoor air samples can also be concurrently collected for radon testing, which may be useful in evaluating building susceptibility to soil gas entry (see Section 6.3.3).

Evaluate and Develop Analyte Lists. EPA recommends the site planning and data evaluation team generally limit chemical analyses to those vapor-forming chemicals known (based upon subsurface contaminant characterization) or reasonably expected (based upon site history) to be present in the subsurface environment. For example, if the site history and reliable subsurface sampling data do not identify benzene as a subsurface contaminant, it would be appropriate for site managers to exclude benzene as a target analyte for indoor air samples. Benzene could originate indoors as a result of a car, lawnmower, or snow blower in a garage. In

[157] For this purpose, EPA generally recommends collecting one sample directly above the foundation floor (e.g., basement or crawlspace) and one from the first floor living or occupied area.

[158] For characterizing indoor sources or openings for soil gas entry, one round of grab sampling of indoor air may be sufficient.

this hypothetical case, benzene would not typically be amenable to reduction by vapor mitigation systems or subsurface remediation efforts. In fact, requesting an extensive list of analytes that are not related to subsurface contamination may unnecessarily complicate risk communication if indoor air testing reveals volatile chemicals unrelated to vapor intrusion.

Collect Complementary Data While Indoors. A variety of useful information can be gathered during a building survey conducted in advance of or during indoor air sampling. EPA recommends that the following complementary data be gathered by observation, interviews, or reports (e.g., mechanical test-and-balance reports) when buildings are to be sampled to analyze indoor air:

- Building Occupancy
    - Characteristics and locations of building occupants (e.g., residents, including children or other sensitive populations; expectations for presence of general public in commercial or industrial settings; presence of multiple exposure units – due to different uses or activities and occupants – within a building other than a single-family residence).
    - Hours of building occupancy under current conditions (and reasonably expected future conditions, as appropriate), particularly for a nonresidential setting. Because this information is pertinent to the human health risk assessment and data evaluation, EPA recommends considering hours of building occupancy when establishing the sampling duration for characterizing indoor air exposure levels.
- Susceptibility to Soil Gas Entry Under Current Conditions
    - EPA recommends that the pressure difference between the indoors and the subsurface be measured whenever indoor air samples are collected. Ideally, differential pressure data would be collected continuously starting several days before sampling and throughout the sample collection period.[159] The magnitude and direction of the pressure difference during sampling can support insights about whether a 'driving force' for vapor intrusion is present during indoor air sampling; if not, then the resulting sampling data are unlikely to characterize a reasonable maximum vapor intrusion exposure condition. Differences in driving forces (direction or magnitude) among indoor air sampling events may help to explain any significant differences in observed indoor air concentrations over time.[160] Measuring pressure difference between the indoors and the subsurface

[159] These data can be collected using portable pressure monitors installed in a dedicated sub-slab probe at one or more locations. Pressure transducers were employed for this purpose during high-frequency sampling as part of a research study in Indianapolis (EPA 2012f, see Section 3.6.6 therein); readings were recorded every 15 minutes. Technical information about pressure-measuring instruments (e.g., description, operation, and calibration) can be found in Section 4 of *Technical Guidance Document: Compliance Assurance Monitoring* (EPA 1998).

[160] Pre-mitigation measurements of the pressure difference between indoors and the subsurface may also be useful for supporting design of active depressurization technologies to reduce vapor intrusion (EPA 1993a, see Section 3 therein).

is a more direct means of assessing building under-pressurization than is monitoring weather/climate factors (e.g., air temperature, wind speed). Pressure difference monitoring in large buildings can help identify any areas with significant under-pressurization.

- Presence and operation of a mitigation system, which would generally be expected to mitigate intrusion of vapor-forming chemicals even if designed for radon.

- Physical conditions that indicate potential openings to soil gas entry (e.g., potential conduits, such as cracks or floor drains; presence of structures such as utility pits, sumps, and elevators; basements or crawl spaces; modifications to the original foundation).

- Building Heating, Ventilation, and Cooling

  - Building ventilation, including zones of mechanical influence and stagnation. As noted in Section 2.4, greater ventilation is intended to result in smaller vapor concentrations in indoor air. Any non-ventilated or passively ventilated rooms (such as mechanical rooms) may be subject to greater accumulation of vapors. For commercial and industrial buildings, each distinct zone of influence may warrant sampling, when indoor air testing is selected as part of a site-specific investigation plan for vapor intrusion assessment.

  - Operating characteristics of HVAC systems. In many commercial buildings, the HVAC system brings outdoor air into the building, potentially creating building over-pressurization relative to the outdoor environment. EPA recommends noting any areas with significant over-pressurization, relative to the outdoors.

- Indoor and Outdoor Sources of Vapor-Forming Chemicals

  - Chemicals and consumer products used or stored within the building that can act as potential sources of toxic vapors. Vapor-forming chemicals are used in many commercial and most industrial buildings.[161] As noted in Section 2.7, consumer products that can emit vapors may be common in residential buildings. In some circumstances, a photoionization detector (PID) can be used to directly screen the building for locations with vapor-forming chemicals and materials; however, the PID may not be sensitive enough for very low concentration sources. More sensitive options include use of the HAPSITE gas chromatograph/mass spectrometer (Gorder and Dettenmaier 2011) or the TAGA Mobile Laboratory (EPA-ERT 2012).

  - HVAC systems that bring outdoor air into the building potentially bring contaminated outdoor air into the building, depending on the location of the vent and exhaust with regard to other spaces. For example, HVAC intakes adjacent to

[161] Depending upon it history of uses and operations, buildings undergoing renovation, redevelopment or reuse may have lingering presence of vapor-forming chemicals due to a past release(s) also.

or near a dry-cleaning facility may introduce vapors of the dry-cleaning solvent into the building.

- In some cases, contaminated groundwater seeps into or actively collects in the building (for example, in sumps), possibly serving as a direct source of vapors. It may be appropriate to collect water samples concurrently with indoor air (and any sub-slab) samples in these circumstances.

- Presence and operation of any indoor air treatment system (e.g., in-line carbon adsorption) that can reduce indoor exposure levels of vapor-forming chemicals.

In general, EPA recommends that the foregoing complementary information be collected during investigation planning and scoping to help determine where to sample and prioritize or sequence buildings for testing. Then, the information can be confirmed during indoor sampling.

Field experience in residential settings suggests that it may not be possible to remove all indoor sources of vapor-forming chemicals. It may be particularly impractical to do so in industrial settings where vapor-forming materials are used or stored. It may also be impractical when deploying passive samplers, owing to their longer deployment period. Therefore, EPA recommends asking building occupants to document indoor sources (and relevant building operations) during indoor air sampling, using an activity log or questionnaire.

6.4.2 Outdoor Air Sampling

Outdoor air concentration data can be useful in identifying potential contributions to indoor air concentrations from ambient air sources (see Section 6.3.5). Therefore, EPA generally recommends collecting ambient air samples using similar sampling and analysis methods, whenever indoor air samples are collected. Normally, EPA recommends one or two outdoor air sample locations to characterize the conditions surrounding a single or a few buildings.[162] Additional outdoor air samples may be warranted if the investigation is assessing multiple buildings over a wide area. EPA also recommends that sample locations be designed to characterize representative conditions in the absence of site-related subsurface contamination (e.g., avoid collecting ambient air samples near locations of known or suspected chemical release(s), including any atmospheric releases from remediation equipment). It also is suggested that observable potential outdoor sources of pollutants (e.g., air emissions from nearby commercial or industrial facilities) be recorded during all building surveys.

Because concentrations of vapor-forming chemicals in ambient air can vary with time, EPA recommends that ambient air samples generally be collected over the same sampling period as indoor air, which will facilitate data evaluations when contaminant concentrations are compared between media. For residential buildings, EPA generally recommends beginning ambient air sampling at least one hour, but preferably two hours, before indoor air monitoring begins and continuing to sample until at least 30 minutes before indoor monitoring is complete. EPA recommends this practice because most residential buildings have an hourly air exchange rate in the range of 0.25 to 1.0, causing air that enters the building before indoor air sampling to

[162] For buildings where outdoor air is mechanically brought into the building, an outdoor sample may be co-located near the HVAC intake.

remain in the building for a long time (for example, see Section D.10, ITRC 2007a). Recommended lag times may warrant adjusting for nonresidential buildings.

Evaluate and Develop Analyte Lists. To characterize potential concentrations entering a building via ambient air, EPA generally recommends that chemical analyses for ambient air samples be limited to those vapor-forming chemicals known (based upon subsurface testing) or suspected (based upon site history) to be present in the subsurface environment. Requesting an extensive list of analytes that are not related to subsurface contamination, as discussed previously, may unnecessarily complicate risk communication.

Consider Collecting Complementary Data. Monitoring air exchange during ambient air sampling events can provide useful complementary data. Ideally, these data would be collected continuously starting before sampling and throughout the sample collection period. Information about air exchange can support insights about the amount of ambient air infiltration during sampling.

6.4.3 Sub-slab Soil Gas Sampling

Sub-slab sampling is intended to draw soil gas from the air space immediately below the floor slab of a building. Depending upon building construction and condition, this air space may be an air gap that forms beneath a concrete foundation due to differential settlement over time or a pore space within a granular layer that may have been placed below the concrete slab. Access to this air space is generally provided by drilling or coring through the concrete and inserting a probe, which is sealed into the floor. EPA's Environmental Response Team has developed a standard operating procedure for constructing and installing sub-slab soil gas sampling probes (EPA-ERT 2007).

Sub-slab soil gas samples can provide useful data for characterizing the levels of hazardous, vapor-forming chemicals that can enter a building via soil gas intrusion. When combined with other soil gas data, sub-slab soil gas data can be used to assess whether the subsurface vapor migration route is complete (i.e., subsurface vapor migration is capable of transporting hazardous vapors from the source to building; see Section 6.3.2). When combined with an appropriate attenuation factor (e.g., a conservative generic value – see Section 6.5.3), sub-slab soil gas data can be used to estimate a potential upper-bound indoor air concentration[163] that may arise from vapor intrusion. In this way, sub-slab data can be used to assess the potential for the vapor intrusion pathway to pose a health concern.[164]

---

[163] For purposes of this Technical Guide, the term "upper bound indoor air concentration" is intended to be a semi-quantitative phrase, referring to the high end of the exposure distribution. EPA recommends basing the decision about whether to undertake response action for vapor intrusion (i.e., a component of risk management) on a consideration of a "reasonable maximum exposure" (e.g., EPA 1989, 1991a), which is intended to be a semi-quantitative phrase, referring to the lower portion of the high end of the exposure distribution (see Glossary). Alternatively, a "worst case" or "reasonable worst case" (see Glossary) indoor air concentration would refer to the upper portion of the exposure distribution. Section 6.6, which discusses mathematical modeling of vapor intrusion, notes that consideration of a "worst case" exposure condition may be particularly useful where the predicted "worst case" indoor air concentrations can be shown to pose acceptable human health risk.

[164] The sub-slab soil gas concentration provides only half of the information for estimating vapor flux into a building. The other information needed is the soil gas flow rate (Q_{soil}), which is embodied in the attenuation factor. The soil gas flow rate can also be explicitly calculated using a model.

Field experience indicates there may be substantial spatial variability in sub-slab soil gas concentrations even over an average-sized footprint of a residential building. EPA, therefore, recommends site planning and data review teams consider collecting multiple samples per building when sub-slab soil gas sampling is conducted.[165] Three sub-slab samples have been collected in a number of EPA investigations of a typical size residential building or commercial building less than 1,500 square feet in area. EPA recommends the site planning and data evaluation team discuss the number of sample locations per building for atypical situations, which include: (1) very large or small homes or buildings;[166] (2) buildings with more than one foundation floor type;[167] (3) subsurface structures or conditions that might facilitate or mitigate vapor intrusion; and 4) multi-use buildings with distinct segmented areas that differ significantly by occupying population or exposure frequency. In addition, EPA recommends multi-point sub-slab samples be considered to support data interpretation and resolve uncertainties that may arise when:

- There are fewer surrounding buildings that are being sampled (that could have helped the understanding of typical sub-slab values and variability).[168]

- The indoor and sub-slab concentrations for a specific building(s) are out of line with expectations based on data from neighboring homes and other information.

EPA generally recommends that sub-slab sampling include centrally located sub-slab samples in buildings identified for testing when the subsurface vapor source is laterally extensive relative to the building footprint (e.g., a broad plume of contaminated groundwater).[169] In addition, EPA recommends that site teams consider internal building partitions, HVAC layout, contaminant distribution, utility conduits, and openings for preferential soil gas entry in selecting any additional locations for collecting sub-slab samples.

Several rounds of sampling are generally recommended to develop an understanding of temporal variability of sub-slab soil gas concentrations, particularly when these data are used with the recommended attenuation factor (see Section 6.5.3) to estimate a potential upper-bound indoor air concentration that may arise from vapor intrusion.

[165] An individual sample, collected at a randomly chosen time, may under-estimate or over-estimate average subslab conditions. Collecting multiple subslab soil gas samples can, therefore, reduce the chance of reaching a false-negative conclusion (i.e., concluding subsurface vapor source strength is limited, when vapor intrusion actually poses an unacceptable human health risk) or a false-positive conclusion (i.e., concluding subsurface vapor source strength is unacceptably elevated, when vapor intrusion actually poses an acceptable human health risk).

[166] For larger structures, a statistician may assist in identifying the number and placement of sampling ports to meet the desired DQOs.

[167] In basements with a partial slab, but one large enough to allow vapors to accumulate (for example, if the slab covers more than 50 percent of the building footprint), EPA generally recommends that one sub-slab port be installed on the slab portion and an indoor air sample be collected directly over the dirt portion.

[168] In these cases, EPA recommends multiple ports be installed in a specific percentage (e.g., more than 10 percent) of the buildings sampled to provide a check for variability in the study area.

[169] Based on work conducted in New York as of the spring of 2010, it appears that the sub-slab concentrations beneath the central area of a home are usually (75 percent of the time) higher than (or as high as) the concentrations closer to the perimeter of the home. This field observation is supported by modeling results for idealized scenarios, which show greater sub-slab soil gas concentrations near foundation centers in under-pressurized residential buildings when the vapor source is laterally extensive relative to the building footprint (EPA 2012b).

If a site team decides to proceed with sub-slab sampling, EPA recommends that leak-testing be performed to ensure the hole is properly sealed, for example through the use of a helium tracer gas shroud. Because installing soil gas probes can disturb subsurface conditions, EPA recommends that the site team allow some time after the sampling probe has been installed for the subsurface to return to equilibrium conditions. An EPA study of the time needed for the subsurface conditions to come back to equilibrium (equilibration rate) after they have been disturbed by installation of the soil gas probes found that an equilibration time of two hours generally was sufficient because most sub-slab material consists of sand or a sand-gravel mixture—even for buildings built directly on clay (Section 5.0, EPA 2006b).

There also may be special considerations for sub-slab soil gas samples because of either a unique construction (for example, pretension concrete slab) or environmental situation. Key EPA recommendations include, but are not limited to:

- Identify the location of cables in post-tensioned concrete (e.g., using ground-penetrating radar) before sub-slab sampling, as drilling through a cable poses a significant health and safety concern and may damage the slab.

- Avoid locating sub-slab samples in areas where groundwater might intersect the slab.

- Identify and avoid the location(s) of underground utilities and structures (for example, electric, gas, water, or sewer lines) to prevent damage to these lines; however, sample collection in close proximity to these lines may be warranted as building penetrations for these lines may pose openings for soil gas entry.

- Consider whether to augment sub-slab samples with samples through the basement walls, as the primary entry points for vapors in basements might be through the sidewalls rather than from below the floor slab.

Evaluate and Develop Analyte Lists. To characterize potential concentrations entering a building via soil gas, EPA generally recommends that chemical analyses for sub-slab soil gas samples be limited to those vapor-forming chemicals known (based upon subsurface testing) or suspected (based upon site history) to be present in the subsurface environment. Requesting an extensive list of analytes that are not related to subsurface contamination, as discussed previously, may unnecessarily complicate risk communication.

Collect Complementary Data While Indoors. When sub-slab soil gas samples are collected, EPA recommends that the following complementary information be gathered by observation or interviews:

- Physical conditions and characteristics that are pertinent to assessing the building's susceptibility to soil gas entry, if any (e.g., potential conduits, such as cracks or floor drains; presence of structures, such as utility pits and elevators; basements or crawl spaces). Such information may help interpret spatial differences in sub-slab or indoor air concentrations within a building.

- Areas with potentially significant over- or under-pressurization relative to the outdoors. Such information may assist in interpreting spatial differences in sub-slab or indoor air concentrations within a building.

- Where outdoor air is mechanically brought into the building by the HVAC system and building(s) interiors are over-pressurized, it may be helpful to also collect ambient air samples to support interpretations of the sub-slab sampling results. If the predominant vapor-forming substances and their respective concentrations in sub-slab soil gas and outdoor air samples are similar, then ambient air may be influencing sub-slab soil gas conditions.

EPA recommends that the pressure difference between the indoors and the subsurface be measured whenever sub-slab soil gas samples are collected. Ideally, differential pressure data would be collected continuously starting several days before sampling and throughout the sample collection period.[170] EPA recommends measuring pressure at locations away from where sub-slab sampling probes are installed to avoid any pressure artifacts caused during purging and sampling. The magnitude and direction of the pressure difference during sampling can support insights about whether a driving force for vapor intrusion is present during sampling.

When any sub-slab soil gas sample is collected, EPA recommends that relevant meteorological data that can influence soil gas concentration patterns at the time of sampling, such as wind speed, snow or ice cover, significant recent precipitation, and changes in barometric pressure, be recorded, using direct observation (e.g., for snow or ice cover) or readily available data sources (e.g., regional weather stations). These data may be helpful qualitatively in data interpretation; for example, in reconciling soil gas data collected on multiple occasions.

A potential shortcoming of sub-slab soil gas testing is that gaining access may be difficult (or, in some cases, infeasible). This difficulty can often be overcome by implementing a program of community outreach and engagement that fosters trust and good relationships (see Section 9.0).

When access is granted for indoor sampling, EPA recommends collecting sub-slab and indoor air samples contemporaneously using similar sampling and analysis methods and sampling durations to allow for data comparison. The sub-slab sampling ports can be installed after the indoor air sample is deployed and collected (8 - 24 hours later) to avoid biasing the indoor air concentrations with potentially higher sub-slab gas infiltration rates during port installation. Alternatively, the sub-slab ports may be installed prior to indoor air sampling and sampled concurrently with the indoor air samples, provided sufficient time is allowed for the indoor air concentrations to return to “normal” after installation of the sub-slab port.[171]

[170] These data can be collected using portable pressure monitors installed in a dedicated sub-slab probe at one or more locations. Pressure transducers were employed for this purpose during high-frequency sampling as part of a research study in Indianapolis (EPA 2012f, see Section 3.6.6 therein); readings were recorded every 15 minutes. Technical information about pressure-measuring instruments (e.g., description, operation, and calibration) can be found in Section 4 of *Technical Guidance Document: Compliance Assurance Monitoring* (EPA 1998).

[171] EPA generally recommends delaying indoor air testing for at least 24 to 72 hours based on an approximate air exchange rate of 0.25 to 1.0 per hour. Note that the effects of any ‘spike’ in indoor air concentration may linger depending on source strength, relative humidity inside the building, and the extent to which the contaminants have been absorbed by carpets and other fabrics or “sinks.”

6.4.4 Soil Gas Sampling

Data obtained from a soil gas survey can be used to identify, locate, and characterize subsurface vapor sources (see Section 6.3.1) and characterize subsurface vapor migration routes, including any impedances from geologic, hydrologic, or biochemical conditions (see Section 6.3.2). Soil gas survey data can also be useful in supporting the design of soil vapor extraction systems and other subsurface remediation systems and the performance assessment of these systems (see Section 8.1). For each of these purposes, EPA recommends that soil gas survey data be supported by site-specific geologic information (i.e., site geology and subsurface lithology).

Soil gas sampling generally consists of installing a probe into the ground, drawing gas out of the probe, and collecting the gas for transport to a location for analysis. Inert materials (e.g., stainless steel, copper, brass, polyvinyl chloride, high-density polyethylene) are recommended for constructing soil gas probes. To ensure that data collected are representative of conditions *in situ* (e.g., are not adversely impacted by artificial infiltration of ambient air), a reliable seal of the annulus between the probe and the probe housing and leak testing for the seal are generally recommended. In addition, purging of the probe before collecting the soil gas sample is recommended, analogous to purging of monitoring wells before collecting groundwater samples. EPA's Environmental Response Team has developed a standard operating procedure for soil gas sampling, including constructing and installing sampling probes (EPA-ERT 2001c).

Typically, grab (rather than time-integrated) samples are collected when sampling soil gas. EPA recommends that the site team allow some time after the sampler has been installed for the subsurface to return to equilibrium conditions because installing temporary or permanent soil gas probes can disturb subsurface conditions. The equilibration time may depend on the degree of soil disturbance during installation, which is influenced by the type of drilling techniques used to install the soil gas probes (e.g., with more time needed for auger drilling compared with hand drilling). For example, the California Environmental Protection Agency recommends an equilibration time of two hours for temporary driven probes and 48 hours for probes installed using augered borings (CalEPA 2012).

EPA recommends documenting wind direction, precipitation information, temperature, and other site-specific information that can influence soil gas concentration patterns at the time of sampling, using readily available data sources. These data may be helpful qualitatively in data interpretation; for example, in reconciling soil gas data collected on multiple occasions or assessing concordance of sampling data from various media, when not collected contemporaneously.

EPA recommends that soil gas samples be taken as close to the areas of interest as possible and preferably from directly beneath the building structure. As vapors are likely to migrate upward through the coarsest or driest material in the vadose zone, EPA recommends that soil gas samples be collected from these materials.

Using vertical boring or drilling techniques, it is generally practical to collect soil gas samples only in locations exterior or adjacent to a building's footprint ("exterior" soil gas samples). Modeling results for idealized scenarios show that, in homogeneous soil, soil gas concentrations tend to be greater beneath the building than at the same depth in adjacent open areas when the vapor source is underneath the building, even if the source is laterally extensive relative to the building footprint (e.g., broad plume of contaminated groundwater) (EPA 2012b). Given these

predictions and supporting field evidence (EPA 2012a, see Figure 6; Luo et al. 2009; Patterson and Davis 2009, see Figure 1), individual exterior soil gas samples cannot generally be expected to accurately estimate sub-slab or indoor air concentrations. This potential limitation may be particularly valid for shallow soil gas samples collected exterior or adjacent to a building footprint. On the other hand, when the subsurface vapor source is not underneath the building, "exterior" soil gas samples collected from depths below a building's foundation and along the side of the building closest to the source may be useful for characterizing a reasonable worst case condition underneath the building in the absence of routes for preferential vapor migration or soil gas entry.

Deeper soil gas samples collected in the vadose zone immediately above the source of vapor contamination (i.e., "near-source" soil gas samples; see Section 6.3.1) can reasonably be expected to be less susceptible to the diluting effects of ambient air, compared to shallow soil gas samples. On this basis, deeper soil gas samples collected in the vadose zone immediately above the source of vapor contamination will tend to be more suitable than will be shallow soil gas samples for assessing vapor concentrations that may be in contact with the building's sub-slab.[172] Several rounds of sampling are generally recommended to develop an understanding of temporal variability of "near-source" soil gas concentrations, particularly when these data are used with the recommended attenuation factor (e.g., a conservative generic value – see Section 6.5.3) to estimate a potential upper-bound indoor air concentration that may arise from vapor intrusion.[173]

6.4.5 Groundwater Sampling

Groundwater sampling and analysis also feature prominently in many vapor intrusion investigations, for example, to help characterize plumes that can serve as vapor sources. Groundwater sampling methods are not discussed here because practitioners typically are relatively experienced and trained to collect samples that meet site-specific data quality needs (see, for example, EPA-ERT 2001a). However, Section 6.3.1 provides a few recommended guidelines for groundwater sampling that are pertinent for characterizing representative vapor source concentrations for vapor intrusion assessment. One key consideration in sampling groundwater for vapor intrusion investigations is focusing on characterizing water table

[172] Luo et al. (2009) also point to the shortcomings of relying on exterior sampling data, citing significant differences in vapor concentrations and soil gas composition between interior and exterior sampling locations at a maintenance warehouse located at a former refinery. They also observed that the spatial variability in the soil-gas distribution was smaller for soil-gas samples drawn from the source zone, suggesting greater confidence in the assessment of source zone or "near source" vapor concentrations.

[173] For purposes of this Technical Guide, the term "upper bound indoor air concentration" is intended to be a semi-quantitative phrase, referring to the high end of the exposure distribution. EPA recommends basing decisions about whether to undertake response action for vapor intrusion (i.e., a component of risk management) on a consideration of a reasonable maximum exposure (e.g., EPA 1989, 1991a), which is intended to be a semi-quantitative phrase, referring to the lower portion of the high end of the exposure distribution (see Glossary). Alternatively, a "worst case" or "reasonable worst case" (see Glossary) indoor air concentration would refer to the upper portion of the exposure distribution. Section 6.6, which discusses mathematical modeling of vapor intrusion, notes that consideration of a "worst case" exposure condition may be particularly useful where the predicted "worst case" indoor air concentrations can be shown to pose acceptable human health risk.

concentrations. EPA recommends that groundwater samples be taken from wells screened (preferably over short intervals) across the top of the water table.[174]

Groundwater data can be compared to the groundwater VISLs (see Section 6.5).[175] When combined with an appropriate attenuation factor (see Section 6.5.3), groundwater data can be used to estimate a potential upper-bound indoor air concentration that may arise from vapor intrusion.[176] In these ways, groundwater data can be used to assess the potential for vapor intrusion from groundwater sources to pose a health concern.

6.4.6 Planning for Building and Property Access

Vapor intrusion investigations generally entail gaining legal access to buildings and properties to conduct sampling. To address this practical and logistical concern during the planning stage, EPA recommends that an access agreement be executed between the property owner, any occupants, and the investigating entity. Section 9.3 provides additional information for addressing building and property access for sampling.

Obtaining and scheduling access to a property and building can be difficult, whether the structure is a commercial or institutional building or a private residence. This potential difficulty can often be overcome by implementing a program of community outreach and engagement that fosters trust and good relationships. EPA recommends conducting public outreach and communication for this purpose considering the site-specific community involvement plan (See Section 9.1).

6.5 Overview of Risk-Based Screening

Risk screening for vapor intrusion generally is performed using site-specific data collected via appropriate methods, as described in Section 6.4. In some cases, pre-existing data identified during a preliminary analysis can be deemed reliable and adequate for use in risk-based screening (see Section 5.5).

6.5.1 Objectives of Screening

The primary objective of risk-based screening is to identify sites or buildings unlikely to pose a health concern through the vapor intrusion pathway. Generally, at properties where subsurface concentrations of vapor-forming chemicals (e.g., groundwater or "near source" soil gas concentrations) fall below screening levels (i.e., VISLs), no further action or study is warranted, so long as the exposure assumptions match those taken into account by the calculations and the site fulfills the conditions and assumptions of the generic conceptual model underlying the

[174] EPA recommends that, to the extent practical, groundwater samples be collected over a narrow interval (e.g., a few feet or less) just below the water table when the data are to be used for assessing the potential for vapor intrusion.

[175] If available groundwater data do not meet the criteria set forth in Section 6.4.5, the site data review team may judge whether they are nevertheless representative of potential vapor source concentrations emanating from groundwater.

[176] EPA recommends basing decisions about whether to undertake response action for vapor intrusion (i.e., a component of risk management) on a consideration of a reasonable maximum exposure (e.g., EPA 1989, 1991a).

screening levels. In a similar fashion, the results of risk-based screening can help the data review team identify areas, buildings, and/or chemicals that can be eliminated from further assessment.

Subsurface concentrations of vapor-forming chemicals that exceed the VISL for the respective medium (e.g., groundwater, soil gas, subslab soil gas) would not automatically trigger mitigation or subsurface remediation (i.e., they are not offered as response action levels or cleanup levels). Exceeding a subsurface screening level generally suggests, however, that further evaluation of the vapor intrusion pathway is appropriate. In this way, risk-based screening, along with other lines of evidence, can help focus a subsequent site-specific investigation, the results of which would provide support for considering building mitigation and other risk management options (see Section 8.0). For example, the results of vapor source strength screening can help identify and prioritize buildings for indoor testing.

Finally, risk-based screening can also support:

- a preliminary evaluation of human health risk using individual building data (e.g., indoor air concentrations), which would consider the magnitude of the concentration exceedance of the indoor air screening level and site-specific risk management benchmarks (see Section 7.4.1); and

- identification of buildings and structures that may warrant prompt action due to potential explosion threats (see Section 7.5.1).

6.5.2 Scope and Basis for Health-based, Vapor Intrusion Screening Levels

EPA developed VISLs for human health protection that are generally recommended, medium-specific, risk-based screening-level concentrations intended for use in identifying areas or buildings that may warrant further investigation of the vapor intrusion pathway. These VISLs are calculated and documented in the VISL Calculator and are based on:

- Current toxicity values selected considering OSWER's hierarchy of sources for toxicity values (EPA 2003).

- Physical-chemical parameters for vapor-forming chemicals.

- EPA-recommended approaches for human health risk assessment (e.g., EPA 2009c, 2014a).

The VISLs for human health protection include indoor air screening levels for long-term (i.e., chronic) exposures, which consider the potential for cancer and noncancer effects of vapor-forming chemicals.[177] The VISLs for human health protection also include subsurface screening levels for comparison to sub-slab soil gas, "near-source" soil gas, and groundwater sampling

[177] The VISL Calculator does not include information about radon. Information about characterizing the human health risk posed by radon can be found on-line at: http://epa-prgs.ornl.gov/radionuclides/

results. These screening levels are derived from the indoor air screening levels for chronic exposures using medium-specific, generic attenuation factors described further in Section 6.5.3 and Appendix A. The user's guide for the VISL Calculator provides additional information about derivation of the indoor air and subsurface screening levels (EPA 2015a).

The medium-specific VISLs for human health protection are intended to be compared to:

- Building-specific data, such as results from sub-slab soil gas samples, crawl space samples, or indoor air samples; or
- Site- or building-specific data that characterize subsurface vapor sources (e.g., groundwater samples, "near-source" soil gas concentrations)

to determine if there is a potential for the vapor intrusion pathway to pose a health concern to building occupants.

The medium-specific VISLs for health protection are developed considering a generic conceptual model for vapor intrusion consisting of:

- A source of vapors underneath the building(s) either in the vadose zone or in the uppermost, continuous zone of groundwater.
- Vapor migration via diffusion upwards through unsaturated soils from these sources toward the ground surface and overlying buildings.
- Buildings with poured concrete foundations (e.g., basement or slab-on-grade foundations) that are susceptible to soil gas entry.

A critical assumption for this generic model is that site-specific subsurface characteristics will tend to reduce or attenuate soil gas concentrations as vapors migrate upward from the source and into overlying structures. Specific factors that may result in relatively unattenuated or enhanced transport of vapors into a building include the following:

- Significant openings to the subsurface that facilitate soil gas entry into the building (e.g., sumps, unlined crawl spaces, earthen floors) other than typical utility penetrations. [178]
- Very shallow groundwater sources (e.g., depths to water less than five feet below foundation level) (see, for example, EPA (2012a), Section 5.2).
- Significant routes for preferential, subsurface vapor migration whether naturally-occurring (e.g., fractured bedrock) or anthropogenic (see Sections 5.4 and 6.3.2).

[178] For purposes of this Technical Guide, the term "significant openings" is intended to refer to forms and amounts of openings, other than adventitious and intentional openings in a building that are expected to typically be present in all buildings (e.g., cracks, seams, interstices, and gaps in basement floors and walls or foundations; perforations due to utility conduits). Such an atypical opening would be "significant" when it is of sufficient volume and proximity to a building that it may be reasonably anticipated to influence vapor migration towards or soil gas entry into the building.

These specific factors are likely to render inappropriate the use of the recommended attenuation factors and the sub-slab, groundwater, and soil gas VISLs for purposes of identifying sites or buildings unlikely to pose a health concern through the vapor intrusion pathway. On the other hand, further evaluation of the vapor intrusion pathway is still appropriate when the sub-slab, groundwater, and soil gas VISLs are exceeded for samples from a building or site where these specific factors are present.

Vapor source types that typically make the use of the recommended attenuation factors and health-based VISLs for groundwater and soil gas inappropriate include:

- Those originating in landfills where methane is generated in sufficient quantities to induce advective transport in the vadose zone.

- Those originating in commercial or industrial settings where vapor-forming chemicals can be released within an enclosed space and the density of the chemicals' vapor may result in significant advective transport of the vapors downward through cracks and openings in floors and into the vadose zone.

- Leaking vapors from pressurized gas transmission lines.

In each case, the diffusive transport of vapors may be overridden by advective transport, and the vapors may be transported in the vadose zone several hundred feet from the source of contamination with little attenuation in concentration.

In general, EPA recommends considering whether the assumptions underlying the generic conceptual model are attained at a given site. If they are not attained, then EPA recommends that the medium-specific VISLs not be relied upon as a line of evidence for identifying sites or buildings unlikely to pose a health concern through the vapor intrusion pathway. Where the assumptions regarding the subsurface attenuation factors do not or may not apply, EPA generally recommends collecting indoor air samples.

As noted in Section 6.5.1, these VISLs are not automatically response action levels, although EPA recommends that similar calculation algorithms be employed to derive cleanup levels (see Section 7.6)**.** Comparison of sample concentrations to the VISLs is only one factor recommended for use in determining the need for a response action at a site. As discussed further in Section 6.5.4, an individual subsurface sampling result that exceeds the respective, chronic screening level does not establish that vapor intrusion will pose an unacceptable human health risk to building occupants. Conversely, these generic, single-chemical VISLs do not account for the cumulative effect of all vapor-forming chemicals that may be present. Thus, if multiple chemicals that have a common, non-cancer toxic effect are present, a significant health threat may exist at a specific building or site even if none of the individual substances exceeds its VISL (see discussion of non-cancer hazard index in Section 7.4.1).

6.5.3 Recommended Attenuation Factors for Health-based Screening

Vapor attenuation refers to the reduction in volatile chemical concentrations that occurs during vapor migration in the subsurface, coupled with the dilution that can occur when the vapors enter a building and mix with indoor air (Johnson and Ettinger 1991). The aggregate effect of these physical and chemical attenuation mechanisms can be quantified through the use of a vapor intrusion attenuation factor, which is defined as the ratio of the indoor air concentration

arising from vapor intrusion to the soil gas concentration at the source or a depth of interest in the vapor migration route (EPA 2012a).[179]

EPA compiled a database of empirical attenuation factors for chlorinated VOCs and residential buildings through review of data from 913 buildings at 41 sites with indoor air concentrations paired with sub-slab soil gas, groundwater, exterior soil gas, or crawl space concentrations (EPA 2012a). After removing data that do not meet quality criteria and data likely to be influenced by background sources, the distributions of the remaining attenuation factors were analyzed graphically and statistically.[180] Based upon these analyses, the attenuation factors in Table 6-1 are recommended by EPA to derive the VISLs for health protection.

With the exception of the "near-source" exterior soil gas attenuation factor, the recommended values for residential buildings are the estimated 95th percentile values, rounded to one significant figure.[181] The rationale for these recommendations and related analyses are provided in Appendix A. These recommended values are proposed to apply to all vapor-forming chemicals for use in estimating potential upper-bound concentrations in indoor air that may arise from vapor intrusion.[182] The recommended groundwater and "near-source" soil gas attenuation factors do not, however, include the effects of biodegradation.[183] On the other hand, because biodegradation is not expected to occur indoors (i.e., in indoor air in the absence of an air treatment system), the sub-slab soil gas and crawl space attenuation factors are expected to apply equally to vapor-forming chemicals that biodegrade in the vadose zone and those that do not.

As with the medium-specific VISLs, EPA recommends considering whether there are site- or building-specific factors that may result in unattenuated or enhanced transport of vapors toward and into a building, such as the presence of preferential migration route(s) as described in Sections 5.4 and 6.3.2. The presence of such factors is likely to render inappropriate the use of any of these generic attenuation factors.

[179] As defined here, the vapor attenuation factor is an inverse measurement of the overall dilution that occurs as vapors migrate from a subsurface vapor source into a building; i.e., lower attenuation factor values indicate lower vapor intrusion impacts and greater dilution; higher values indicate greater vapor intrusion impacts and less dilution (EPA 2012a, b). Johnson and Ettinger (1991) utilized the symbol α for the vapor intrusion attenuation factor. For example, the subslab soil gas attenuation factor is intended to account for concentration dilution arising during migration through openings in the foundation and from mixing of subsurface contaminants inside the building. The groundwater attenuation factor is intended to account for concentration dilution arising during vapor migration from the groundwater table through the vadose zone, in addition to concentration dilution arising during migration through openings in the foundation and from mixing of subsurface contaminants inside the building.

[180] A summary of the resulting distributions is provided in Appendix A of this document.

[181] The recommended "near-source" exterior soil gas attenuation factor corresponds to approximately the estimated 75th percentile value.

[182] EPA recommends basing decisions about whether to undertake response action for vapor intrusion (i.e., a component of risk management) on a consideration of a reasonable maximum exposure (e.g., EPA 1989, 1991a).

[183] Appropriate data can be collected and evaluated, as described in Section 6.3.2, to characterize and document the occurrence of biodegradation in the vadose zone and its effects in attenuating vapor concentrations of biodegradable vapor-forming chemicals.

TABLE 6-1
RECOMMENDED VAPOR ATTENUATION FACTORS FOR RISK-BASED SCREENING OF THE VAPOR INTRUSION PATHWAY[184]

Sampling Medium	Medium-specific Attenuation Factor for Residential Buildings
Groundwater, generic value, except for shallow water tables (less than five feet below foundation) or presence of preferential vapor migration routes in vadose zone soils	1E-03 (0.001)
Groundwater, specific value for fine-grained vadose zone soils, when laterally extensive layers are present[185]	5E-04 (0.0005)
Sub-slab soil gas, generic value	3E-02 (0.03)
"Near-source" exterior soil gas, generic value except for sources in the vadose zone (less than five feet below foundation) or presence of routes for preferential vapor migration in vadose zone soils	3E-02 (0.03)
Crawl space air, generic value	1E-00 (1.0)

The VISL Calculator (http://www.epa.gov/oswer/vaporintrusion/guidance.html) also facilitates calculation of groundwater screening levels based on the recommended attenuation factor for fine-grained soil. EPA recommends that any use and application of this semi-site-specific groundwater attenuation factor be supported by site-specific geologic information (i.e., site geology and subsurface lithology). Significant characterization of the vadose zone may be needed to demonstrate that fine-grained layers are laterally extensive over distances that are large compared to the size of the building(s) or the extent of vapor contamination at a specific site, which is the recommended support for using the semi-site-specific attenuation factor for

[184] Use of these attenuation factors for estimating indoor air concentrations is contingent upon site conditions fitting the generic model of vapor intrusion described in Section 6.5.2 and subsurface conditions being characterized considering the recommendations in Sections 6.3 and 6.4.

[185] The Draft VI Guidance allowed for the modification of VISLs for groundwater by incorporating a lower attenuation factor, based upon "some site-specific inputs", which estimates a greater reduction in vapor concentrations in the vadose zone than the generic value (EPA 2002c, 2010b). In the Draft VI Guidance, graphs were provided from which such "semi-site-specific" attenuation factors could be selected and justified based upon site-specific soil type and depth to the water table. Based upon analysis of EPA's expanded database, a single groundwater attenuation factor is provided in this Technical Guide for fine-grained soils.

fine-grained soil.[186] For purposes of applying the groundwater attenuation factors, EPA recommends the depth to groundwater be estimated relative to the bottom of the building foundation and be based upon the seasonal high groundwater table.

6.5.4 Comparing Sample Concentrations to Health-based Screening Levels

When evaluating environmental sampling results to assess the vapor intrusion pathway, it is important to first determine that the samples were collected appropriately. Section 6.4 provides information about recommended sampling locations and procedures for vapor intrusion investigations. In addition, EPA recommends collecting and evaluating appropriate site-specific information to demonstrate that the property fulfills the conditions and assumptions of the generic conceptual model underlying the VISLs, as described in Section 6.5.2.

After verifying that the CSM justifies the use of the VISLs, the individual sample concentrations may be compared to the appropriate medium-specific screening levels. In order to select the appropriate target media concentrations for comparison, it generally is important to identify whether a source of vapors for a building or a developed area occurs in the unsaturated zone, which is an important aspect of the CSM. This allows the site data to be segregated into two categories:

- Data representing areas where contaminated groundwater is the only source of contaminant vapors.

  In this first case, groundwater VISLs are generally appropriate to use to evaluate groundwater concentrations (also see sampling recommendations in Sections 6.3.1 and 6.4.5). Under these circumstances, EPA recommends that the plume be shown to be stable or shrinking (i.e., is not migrating or rising in concentration, including hazardous byproducts of any biodegradation) to establish that the potential for vapor intrusion to pose a human health risk from vapor intrusion will not increase in the future. "Near-source" soil gas data (i.e., soil gas samples collected immediately above the water table) could also be compared to the soil gas VISLs to obtain a corroborating line of evidence (see recommendations in Section 6.3.1).

  When the anticipated outcome of the screening is a finding that groundwater poses acceptable human health risk from vapor intrusion on an area-wide basis, it may be appropriate to compare sampling results for the most greatly impacted well within the area of interest and show that these results are less than the groundwater VISLs.

- Data representing areas where the underlying vadose zone soil contains a source of vapors (e.g., residual NAPL).

  In this second case, EPA recommends that only soil gas VISLs be used and compared to results from "near-source" soil gas samples collected near the vapor source zone

[186] The general soil type assigned to paired vapor intrusion data in the EPA's database "generally represents the coarsest soil described in the vadose zone near the sample location" unless "sufficient stratigraphic information was available to indicate finer sediments are laterally continuous" (EPA 2012a). EPA recommends that similar criteria be applied to justifying the use of the semi-site-specific attenuation factor for groundwater (or selection of soil-related parameters for modeling); see Section 6.6. For these purposes, soil classified as clay, silty clay, silty clay loam, or silt consistent with the U.S. Soil Conservation Service classification system can be considered to be "fine-grained."

(also see sampling recommendations in Sections 6.3.1 and 6.4.4). In this situation, the groundwater VISLs (and vapor attenuation factors for groundwater) are not recommended for estimating potential upper-bound indoor air concentrations, because they have been derived assuming no other vapor sources exist between the water table and the building foundation.

In both cases, because of the complexity of the vapor intrusion pathway, EPA recommends that professional judgment be used when applying the VISLs.

Generally, if all subsurface sample concentrations for a given building or area are less than the respective medium-specific screening level, then vapor intrusion is less likely to pose an unacceptable human health risk to building occupants. On the other hand, when individual sample concentrations exceed the respective screening level, additional assessments may be warranted. So, for example, if a groundwater or "near-source" soil gas concentration exceeds the respective screening level, it is recommended that sub-slab soil gas testing and indoor air testing be conducted.

However, we would note that any individual subsurface sampling result that exceeds the respective, chronic screening level does not establish that vapor intrusion will pose an unacceptable human health risk to building occupants. For one, the subsurface screening levels are expected to be conservative (i.e., are likely to over-estimate the contribution to indoor air levels arising from vapor intrusion) for many buildings due to the use of a high-end attenuation factor (see Section 6.5.3). In many cases, indoor air concentrations arising from vapor intrusion would be expected to be lower than those estimated using the recommended generic attenuation factors. For carcinogens, the screening levels are set using a one-per-million lifetime cancer risk (i.e., 10^{-6}), whereas EPA recommends consideration of a cancer risk range when making risk management decisions (see Section 7.4.1). Finally, sampling results can be expected to be variable spatially and temporally and these screening levels assume a long period of exposure at the stated concentration.

Owing to the temporal variability in building-specific data and the potential temporal and spatial variability in soil gas vapor concentrations, EPA generally recommends multiple samples be collected (see Section 6.4) and compared to the respective medium-specific screening level. In addition, the results of risk-based screening are generally most useful when they can be evaluated for indoor air and subsurface vapor sources concurrently and in the context of the CSM. EPA, therefore, generally recommends that multiple lines of evidence be developed and their results weighed together when evaluating and making risk-informed decisions pertaining to vapor intrusion. EPA generally recommends that concordance among the multiple lines of evidence be obtained, particularly when considering a determination that the vapor intrusion pathway is incomplete or does not pose an unacceptable human health risk. Sections 7.1, 7.2, and 7.3 provide additional information and recommendations about developing and using multiple lines of evidence and risk management decision-making.

6.5.5 Planning for Communication of Sampling Results

EPA recommends the community involvement or public participation plan (See Section 9.1) describe and address community questions, concerns, and preferences for participation regarding sampling results. Generally, EPA recommends that the site planning team provide validated results to property owners and occupants. These results can be transmitted to relevant parties in a letter, along with a description of what future actions, if any, may be

warranted. In addition, the site planning team may choose to hold a community meeting to discuss the sampling results in general terms and EPA's plans, if any, for response actions. Section 9.4 provides additional information for communicating sampling results.

6.6 General Principles and Recommendations for Mathematical Modeling

When suitably constructed, documented, and verified, mathematical models can provide an acceptable line of evidence supporting risk management decisions pertaining to vapor intrusion. In certain situations (e.g., for future construction on vacant properties), it is particularly useful to employ mathematical modeling to predict reasonable maximum indoor air concentrations, because indoor air testing is not possible.

Mathematical modeling is most appropriately used in conjunction with other lines of evidence. For example, in the brownfield development case (i.e., yet-to-be-constructed building), EPA generally recommends these additional lines of evidence include, at a minimum, data that characterize potential subsurface vapor sources and associated geologic and hydrologic conditions in the vadose zone (see Sections 6.3.1 and 6.3.2).

Generally, mathematical models transform empirical values of input parameters into predictions of chemical concentrations in environmental media. The model input parameters are equally as important to the results as the mathematical components of the model (i.e., governing equations and solution algorithms). As a consequence, the results critically depend on the choices for the inputs.

Historically, to assure confidence in predictions of mathematical models, they have been compared to measured, site-specific values. When measured and predicted values do not reasonably match, model input parameters are adjusted through calibration. For example, calibration is commonly used in groundwater flow modeling, in which model-predicted groundwater levels are matched to measured groundwater levels for a baseline condition to gain insight into hydrogeologic properties. The calibrated input parameters must reasonably represent the underlying phenomena and the characteristics of the model must reasonably match the field situation. Calibration of mathematical models is known to be non-unique, so that different sets of parameters can be used to fit the same observed data. This means that calibration does not produce a theoretically correct set of parameters. Because various values of input parameters could be used in the calibrated model, there will always be uncertainty as to the actual values.

Three approaches exist for applying mathematical models in these circumstances:

1) Calibrating the mathematical model to the measured indoor air concentration (and, possibly, the sub-slab soil gas concentration) considered to be representative of vapor intrusion (i.e., background vapor sources have been identified and removed prior to sampling and data evaluation indicates that the concentration is reasonably attributable to vapor intrusion). Calibration entails adjusting the input parameters within plausible and realistic ranges so that the predicted indoor air concentrations (or sub-slab soil gas concentrations) are similar to the measured vapor concentrations. The adjusted input parameters can then be compared to site-specific conditions and data to verify that the CSM and calibrated model are coherent and sound.

2) Conducting an uncertainty analysis (perhaps using an automated uncertainty analysis (see http://www.epa.gov/athens/learn2model/part-two/onsite/uncertainty-vi.html as only one example)) to understand where, within the probability distribution of results, model results with pre-selected default parameters lie. This approach may be particularly useful where indoor air concentrations have not been measured or non-site-specific inputs have been used.

3) Using a bounding case analysis, where parameters are chosen to represent conditions that give a high-impact (e.g., "reasonable worst") case – see Glossary – or "worst" (maximum plausible)[187] case. This approach may be particularly useful where the predicted indoor air concentrations for the bounding case can be shown to pose acceptable human health risk.[188] The range of predicted indoor air concentrations can be established if the analysis also includes a low-impact ("best") case.

Unless site-specific parameter values are obtained for input parameters and the mathematical model is calibrated to field data, use of default input parameter values will generate model results that lie at an unknown point within an uncertainty band of the model outcomes. Because the combined effect of parameter uncertainty is large, a one- or two-order of magnitude error might be made unknowingly. To reduce these errors, sub-slab vapor sampling could be used to characterize the vapor concentration(s) beneath a building. Model results (i.e., predicted sub-slab soil gas concentrations) that match measured values would have increased confidence. Alternately, using bounding estimates of parameter values could provide a conservative model result that would be expected to represent the reasonable worst case of potential exposure.

Three examples follow where differing applications of mathematical models would be useful in vapor intrusion assessment:

- Verify General Magnitude. Modeling using site-specific inputs can be useful for verifying the general magnitude of measured indoor air sample concentrations, which may allow risk managers to reach supportable conclusions not to conduct additional indoor air testing. In this situation, the model could be calibrated to indoor air measurements and the plausibility of the calibrated input parameters evaluated. If the calibrated model input parameters are plausible, then they can be considered an additional line of evidence supporting risk management decisions.

- Explore Range of Outcomes through Uncertainty Analysis. In certain situations, indoor air testing is not possible (e.g., for future construction on vacant properties) or feasible.

[187] For purposes of this Technical Guide, the phrase "worst case indoor air concentration" is intended to be a semi-quantitative phrase, referring to the high end of the exposure distribution. "No-further-action" decisions can normally be supported more confidently when the "worst case indoor air concentration" can be shown to pose acceptable health risks. Under these conditions, the "reasonable maximum exposure" (see Glossary) typically would also pose acceptable health risks.

[188] "Bounding estimates" purposely overestimate the exposure or dose in an actual population for the purpose of developing a statement that the risk is "not greater than..." (EPA 1992c).

Here the range of possible outcomes could be explored with the model through an uncertainty analysis. For example, model input parameters, including building and vadose zone soil properties, could be varied within plausible ranges to determine the parameters to which the model is most sensitive to guide field investigations. Uncertainty analyses can also be used to ascertain whether the subsurface vapor source concentrations are such that indoor air samples would not be expected to contain detectable levels of vapor-forming chemicals arising from vapor intrusion.

- Generate Bounding Estimates. If the range of parameter values is known with confidence for the site, then parameters can be chosen to represent the bounding case of maximum plausible vapor intrusion (i.e., worst case).

In each of these examples, model parameters might vary in space and time because of subsurface heterogeneity, transient hydrologic conditions, or variation in building operation. Thus, there is a need for characterizing spatial and temporal variability.

Mathematical models provide opportunities to predict conditions that cannot be observed directly, but the reliability of the results need to be confirmed, especially when limited site-specific data are available and the model is not calibrated to observed indoor air concentrations. Use of a generic, conservative attenuation factor (see Section 6.5.3) to predict potential, upper-bound indoor air concentrations (based upon soil gas concentrations – see Sections 6.4.3 and 6.4.4) implicitly represents use of a mathematical model, even when the attenuation factor is selected from an empirical data set. Whether the mathematical model is implicit (e.g., generic, conservative attenuation factor) or explicit (e.g., mathematical model that generates a bounding estimate), both analytic approaches make the assumption that site-specific attenuation is likely to be greater and the indoor air concentration(s) is (are) likely to be lower than predicted value(s).

The use of extreme and non-representative assumptions or parameter values is the most common weakness of mathematical modeling for environmental assessments. Mathematical modeling typically yields more reliable results when used with high-quality, site-specific data inputs (that is, representative groundwater or soil gas concentrations, depth to groundwater, soil type and moisture content underneath the building, and the building conditions (e.g., air exchange rate, building mixing height), for example); in these cases, the site-specific data inputs and CSM provide additional lines of evidence supporting the use of mathematical modeling as a line of evidence.

Whenever mathematical modeling is used to make predictions pertaining to vapor intrusion, EPA recommends that the site planning and data team:

- Identify the underlying mathematical model and include appropriate references to document that it has been peer-reviewed.
- Verify that the selected model fits the CSM and is appropriate for the chosen purpose.
- Document all inputs and outputs in a readily recognizable and understandable format.
- Identify the critical parameters and conduct a sensitivity analysis for the most critical parameters.

- Determine and document the appropriate modeling approach (e.g., calibration, uncertainty analysis, bounding case analysis).

- Perform new individual measurements (i.e., field sampling) to confirm one or more results of the modeling.

A critical assumption underlying almost all mathematical models of vapor intrusion is that site-specific subsurface characteristics will tend to reduce or attenuate soil gas concentrations as vapors migrate upward from the source and into overlying structures. Mathematical modeling of vapor intrusion is, therefore, not generally recommended for sites and buildings where unattenuated or enhanced transport of vapors toward and into a building is reasonably expected. Sections 5.4, 6.3.2, and 6.5.2 identify several factors that may result in unattenuated or enhanced transport of vapors toward and into a building.

7.0 RISK ASSESSMENT AND MANAGEMENT FRAMEWORK

This section provides general recommendations about risk-informed decision-making pertaining to vapor intrusion. The risk management information described herein presumes that a sound CSM has been developed (see Sections 5.4 and 6.3), which is supported by multiple lines of evidence, and that subsurface vapor sources have been characterized (see Section 6.3.1) sufficiently to support the risk management decisions for the site. EPA also notes that temporal and spatial variability of sampling data can span at least an order of magnitude and often more.

Site-specific decisions potentially supported by the information described in this section include:

- Whether to install engineered exposure controls to prevent or reduce the impacts of vapor intrusion in specific buildings.
- Whether to remediate subsurface vapor sources for the site to reduce risks posed by vapor intrusion.
- Whether the vapor intrusion pathway is incomplete and there is no potential for unacceptable human exposure under current or future conditions.
- Whether to collect additional information as part of the detailed vapor intrusion investigation or monitor indoor air as part of an overall vapor intrusion remedy.

As conditions warrant and resources allow, EPA generally recommends that officials responsible for overseeing cleanups pursuant to RCRA and CERCLA ensure that past decisions pertaining to vapor intrusion continue to be supported by current conditions (EPA 2002b).

Finally, EPA encourages systematic approaches to decision-making, which can foster scientific rigor, consistency, and transparency.

7.1 Collect Site-specific Lines of Evidence

Current practice suggests that the vapor intrusion pathway generally be assessed using multiple lines of evidence. As discussed in Sections 5.1, 5.4, 5.5.2, 6.3, 6.4, and 6.5, appropriate lines of evidence to support development of the CSM and evaluate the vapor intrusion pathway may include, but are not limited to:

Subsurface Vapor Sources

- Site history and source of the contaminants to demonstrate that vapor-forming chemicals have been or may have been released to the underlying and surrounding subsurface environment and identify the type of vapor source (e.g., vapor-forming chemicals dissolved in groundwater or present in a NAPL).
- Groundwater data (generally recommended from more than one sampling event), as appropriate, to confirm the presence of a water-table aquifer, if present, as a source of vapors and establish its chemical and hydrogeologic characteristics.

- Soil gas data, bulk soil sampling data,[189] and/or NAPL sampling data to confirm the presence of contamination in the vadose zone, if present, as a source of vapors and establish its chemical and physical characteristics.

- Sub-slab (or crawl space) soil gas data to assess concentrations potentially available for entry with any intruding soil gas (generally recommended from multiple sampling events and in multiple locations to reduce the chance of reaching a false-negative conclusion (i.e., concluding subsurface vapor source strength is limited when vapor intrusion actually poses an unacceptable human health risk) or a false-positive conclusion.

- Comparison of groundwater and/or soil gas concentrations to VISLs to evaluate source strength and potential for a health concern if the vapor intrusion pathway is complete.

Vapor Migration and Attenuation in the Vadose Zone

- Soil gas survey data, including some level of vertical and spatial profiling, as appropriate, to confirm soil gas migration and attenuation along anticipated routes in the vadose zone between sources and buildings.

- Data on site geology and hydrology (e.g., soil moisture and porosity) to support the interpretation of soil gas profiles, the characterization of gas permeability, and the identification of anticipated soil gas migration routes in the vadose zone or the identification and characterization of impeded migration.

- Vertical profiles of chemical vapors, electron acceptors for microbial transformations (e.g., oxygen), and degradation products (e.g., methane, vinyl chloride) to characterize attenuation due to biochemical (e.g., biodegradation) processes.

- Utility corridor assessment to identify preferential migration routes, if any, that facilitate subsurface vapor migration between sources and towards and into buildings

Building Foundation Assessment, Including Susceptibility to Soil Gas Entry

- Building construction and current conditions, including utility conduits or other preferential routes or openings for soil gas entry, heating and cooling systems in use, and any segmentation of ventilation and air handling.

- Instrumental (e.g., PID) readings to locate and identify potential openings for soil gas entry into buildings.

[189] As noted in Section 6.4, bulk soil sampling and analysis can be used to characterize the chemical composition and general location of contamination; for example, high soil concentrations generally would indicate impacted soil. On the other hand, non-detect results for soil samples cannot be interpreted to indicate the absence of a subsurface vapor source, because of the potential for vapor loss due to volatilization during soil sampling, preservation, and chemical analysis. Therefore, bulk soil (as opposed to soil gas) sampling and analysis is not currently recommended for estimating the potential for vapor intrusion to pose unacceptable human health risk in indoor air.

- Grab samples of soil gas or indoor air near openings to characterize the composition of presumptive soil gas entering buildings.

- Pressure data to assess the driving force for soil gas entry into building(s) via advection.

- Tracer-release data to verify openings in building foundations for soil gas entry or assess fresh air exchange within buildings.

Interior Assessment

- Indoor air sampling data (Section 6.4.1) to assess the presence of subsurface contaminants in indoor air (Section 6.3.4), estimate potential exposure levels to building occupants to support site-specific human exposure and human health risk assessments (see Section 7.4), and otherwise diagnose vapor intrusion and characterize background concentrations (Section 6.3.5).[190]

Indoor and Outdoor Sources of Vapor-forming Chemicals Found in the Subsurface

- Building-specific indoor sources of volatile chemicals (Section 2.7).

- Concurrent outdoor air data to assess potential contributions of ambient air to indoor air concentrations (Sections 6.3.5 and 6.4.2).

- Comparative evaluations of indoor air and sub-slab soil gas data (e.g., Section 6.3.5), including calculation and comparison of building-specific, empirical attenuation factors (EPA 2012a, Section 3.0) (e.g., to assess their consistency among subsurface contaminants to assist in identifying indoor vapors arising from vapor intrusion).

Additional Supporting Lines

- Results of statistical analyses (e.g., data trends, contaminant ratios) to support data interpretation.

- Results of mathematical modeling that rely upon site-specific inputs (Section 6.6).

The relative utility of these and other individual lines of evidence will depend on site-specific factors, as described and documented in the CSM (Section 5.4), and the objectives of the investigation (Section 6.3). For example:

- When the primary subsurface vapor source is residual NAPL in the vadose zone, bulk soil data would typically be collected to characterize the chemical composition and general location of contamination; for example, high soil concentrations generally would

[190] In certain cases, depending in part on the results (e.g., concentrations exceed risk-based screening levels), indoor air sampling data may be a sufficient basis for supporting decisions and recommendations to undertake pre-emptive mitigation (see Sections 3.3 and 7.8) in lieu of additional rounds of sampling and analysis or an evaluation of the contribution of background sources to indoor air concentrations.

indicate impacted soil in the vadose zone, as discussed in Sections 6.3.1 and 6.4.[191] In this situation, "near source" soil gas data, rather than groundwater data, would be recommended for assessing the potential for vapor intrusion to pose an unacceptable human health risk to occupants of any building overlying the NAPL zone. On the other hand, when the subsurface vapor source underneath a building is shallow groundwater, groundwater sampling data from the uppermost hydrogeologic unit would be an appropriate line of evidence for purposes of assessing the potential for vapor intrusion to pose an unacceptable human health risk, unlike the previous example.

- In both of the preceding cases, information about the soil conditions (e.g., soil type and moisture) *underlying the buildings* would be useful for characterizing the subsurface vapor migration route between the subsurface vapor source and the building. Sub-slab soil gas samples and indoor air samples (if background sources are removed or accounted for), in concert with other lines of evidence, can provide a strong line of evidence regarding whether the vapor intrusion pathway is complete.

- For an industrial building, indoor air testing while the HVAC system is not operating (see Section 6.3.3) could be useful for diagnosing vapor intrusion. On the other hand, single-family detached homes can generally be presumed susceptible to soil gas entry when heating or cooling systems are operating.

7.2 Weigh and Assess Concordance Among the Lines of Evidence

To the risk manager, the ideal outcome from collecting multiple lines of appropriate evidence is a concordant set of site-specific information that unambiguously supports decisions that can be made confidently. However, based upon observations at many buildings and sites, the vapor intrusion site where all available information is in agreement and is unambiguous may be the exception rather than the rule. Some lines of evidence may not be definitive (e.g., indoor air and subsurface concentrations can be greatly variable temporally and spatially). At worse, some individual lines of evidence may be inconsistent with other lines of evidence. In general, when lines of evidence are not concordant and the weight of evidence does not support a confident decision, EPA recommends re-evaluating the CSM, which may warrant adjusting the CSM to better represent the weight of the available evidence.

For example, a building overlying contaminated shallow groundwater may have high concentrations of vapor-forming chemicals in the sub-slab soil gas samples, but lower concentrations in soil gas samples collected exterior to the building at intermediate depths. In this example, the exterior soil gas data suggest there may not be a connected vapor migration path between the groundwater source and the building that exhibits continuous attenuation along the path. Nevertheless, the data review team may conclude that vapor migration is capable of transporting hazardous vapors from the source to building(s) if the groundwater and sub-slab soil gas samples share common contaminants that are known or suspected to have been released at the site (for example, samples of both groundwater and

[191] Because of the large uncertainties associated with measuring concentrations of volatile contaminants introduced during soil sampling, preservation, and chemical analysis, bulk soil (as opposed to soil gas) sampling and analysis is not currently recommended for estimating the potential for vapor intrusion to pose unacceptable human health risk in indoor air. In addition, there are uncertainties associated with soil partitioning calculations.

the sub-slab soil gas contain TCE). In this circumstance, the data review team may wish to consider whether the occurrence of a higher TCE concentration in the sub-slab soil gas than in the exterior soil gas sample(s) can be explained by: (1) a previously unknown or unrecognized utility corridor or other preferential migration route that provides relatively unattenuated vapor transport between the groundwater and the building; (2) a previously unknown or unrecognized source of TCE in the vadose zone; or (3) the possibility that the exterior soil gas samples were not well located for purposes of characterizing subsurface vapor migration. This example also underscores the importance of developing an adequate CSM (e.g., identify all sources and preferential routes of subsurface vapor migration) and illustrates why EPA generally recommends that the vapor intrusion pathway not be deemed incomplete based upon any single line of evidence (EPA 2010b), such as exterior soil gas in this example.

When lines of evidence are not concordant and the weight of evidence does not support a confident decision, it may also be appropriate to collect additional lines of evidence, possibly including additional samples, depending upon the CSM. For example:

- Appropriate site-specific testing (see Section 6.3.5) can be conducted to assess the contribution of background sources of vapor-forming chemicals, including comparisons among chemicals of their relative concentrations in indoor air, outdoor air, and soil gas. Background sources of vapor-forming chemicals may help to explain situations where the indoor air concentration is higher than can be accounted for by the subsurface vapor source or the sub-slab soil gas data.

- Diagnostic testing of indoor air (see Section 6.4.1), building condition assessments or utility surveys, or supplemental hydrogeologic characterization (see Section 6.3.2) can be used to investigate the suspected presence of preferential migration routes, such as those described in Sections 5.4 and 6.3.2. Such investigations may help to explain situations where the sub-slab or indoor air concentration appears to reflect unattenuated vapor transport from the subsurface vapor source.

- Building susceptibility to vapor intrusion can be tested (see Section 6.3.3), which may help to explain situations where the indoor air concentration is significantly lower than expected based upon the sub-slab soil gas data.

- Vapor migration in the vadose zone can be further characterized to identify impedances to vapor migration (see Section 6.3.2), appropriate semi-site specific attenuation factors can be considered (see Section 6.5.3), and appropriate modeling can be conducted (see Section 6.6) to investigate site-specific vapor attenuation. Such data and analyses may help to explain situations where the sub-slab soil gas concentration is significantly lower than expected based upon groundwater source or “near-source” soil gas concentrations and the respective medium-specific attenuation factor (Section 6.5.2 and Appendix A). In some of these situations, the vapor intrusion pathway may be impeded, or perhaps even incomplete, due to geologic, hydrologic, or microbial characteristics in the vadose zone (see Sections 6.3.2 and 7.3).

Recognizing the temporal and spatial variability of indoor air and subsurface concentrations and the potentially episodic nature of vapor intrusion at some sites (Section 2), EPA generally recommends collecting multiple rounds of sampling in the respective media from multiple locations (see Section 6.4) to reduce the chance of reaching a false-negative or false-positive

conclusion. Considerable judgment may be necessary when evaluating multiple data sets from individual sampling events to support decision-making.

In summary, EPA recommends the appropriate use and evaluation ("weighing") of multiple lines of evidence for determining whether the vapor intrusion pathway is complete or not, whether any elevated levels of contaminants in indoor air are likely caused by subsurface vapor intrusion versus an indoor source or an ambient (outdoor) air source, whether concentrations of subsurface contaminants in indoor air may pose a health concern, and whether interim response measures to mitigate vapor intrusion are warranted.

7.3 Evaluate Whether the Vapor Intrusion Pathway is Complete or Incomplete

For purposes of this Technical Guide, and as reflected in the conceptual model of vapor intrusion (see Section 2), the vapor intrusion pathway is referred to as "complete" for a specific building or collection of buildings when the following five conditions are met under current conditions:

1) A subsurface source of vapor-forming chemicals is present underneath or near the building(s) (see Sections 2.1, 5.3, 6.2.1, and 6.3.1);

2) Vapors form and have a route along which to migrate (be transported) toward the building(s) (see Sections 2.2 and 6.3.2);

3) The buildings are susceptible to soil gas entry, which means openings exist for the vapors to enter the building and driving 'forces' exist to draw the vapors from the subsurface through the openings into the building(s) (see Sections 2.3 and 6.3.3);

4) One or more vapor-forming chemicals comprising the subsurface vapor source(s) is (or are) present in the indoor environment (see Sections 6.3.4 and 6.4.1); and

5) The building is occupied by one or more individuals when the vapor-forming chemical(s) is (or are) present indoors.

Considerable scientific and professional judgment will likely be needed when weighing lines of evidence to determine whether the vapor intrusion pathway is complete or incomplete. Each of the first four conditions generally entails obtaining and weighing multiple lines of evidence, whereas the fifth condition generally can be confidently determined by direct observation. EPA recommends considering and evaluating together the various lines of evidence in determining completeness of the vapor intrusion pathway under current conditions.

As noted previously (e.g., Section 3.2), EPA recommends that risk management decisions also consider whether the vapor intrusion pathway is 'potentially complete' under reasonably expected future conditions. The vapor intrusion pathway is referred to as 'potentially complete' for a building when:

- a subsurface source of vapor-forming chemicals is present underneath or near an existing building or a building that is reasonably expected to be constructed in the future;

- vapors can form from this source(s) and have a route along which to migrate (be transported) toward the building; and

- three additional conditions are reasonably expected to all be met in the future, which may not all be met currently; i.e.,

    - the building is susceptible to soil gas entry, which means openings exist for the vapors to enter the building and driving forces exist to draw the vapors from the subsurface through the openings into the building;

    - one or more vapor-forming chemicals comprising the subsurface vapor source(s) is (or will be) present in the indoor environment (see Sections 6.3.4 and 6.4.1); and

    - the building is or will be occupied by one or more individuals when the vapor-forming chemical(s) is (or are) present indoors.

This determination also generally entails obtaining and weighing multiple lines of evidence.

A complete pathway indicates that there is an opportunity for human exposure, which warrants further analysis to determine whether there is a basis for undertaking a response action(s). Specifically, a complete exposure pathway does not necessarily mean that an unacceptable human health risk exists due to vapor intrusion. Rather, specific exposure conditions, such as the magnitude, frequency, and duration of exposures, and the contribution from background concentrations warrant examination; hence, EPA recommends additional analyses be conducted to assess and characterize human health risk to building occupants where the vapor intrusion pathway is determined to be complete (see, for example, Sections 7.4 and 6.3.5). On the other hand, human exposure, and hence human health risk, from the vapor intrusion pathway would not exist if the pathway is incomplete.

The conceptual model described in Section 2 identifies the characteristics of the vadose zone that could render the vapor intrusion pathway incomplete under current and future conditions. These individual characteristics include, but are not limited to:

- Soil layers that significantly and persistently impede vapor transport due to geologic or hydrologic conditions (e.g., fine-grained soil, soil with high moisture content) and are laterally extensive over distances that are large compared to the size of the building(s) or the extent of subsurface contamination with vapor-forming chemicals; and

- A biologically active vadose zone that can significantly and persistently attenuate soil gas concentrations due to biodegradation, in which all appropriate conditions (e.g., nutrients, moisture, and electron acceptors, such as dissolved oxygen in the case of aerobic biodegradation) are readily available over a laterally extensive area.

EPA recommends demonstrating these characteristics, when present, by collecting, evaluating, and documenting multiple lines of evidence, as identified in Section 6.3.2. In addition, EPA recommends that any determination that the vapor intrusion pathway is incomplete be supported by site-specific evidence to demonstrate that:

- The nature and extent of vapor-forming chemical contamination in the subsurface has been well characterized, as discussed in Sections 6.3.1 and 6.4. Ideally, where groundwater is the source of vapors, the plume has been shown to be stable or

shrinking to establish that the potential for vapor intrusion to pose a health concern will not increase in the future.

- The types of vapor sources and the conditions of the vadose zone and surrounding infrastructure do not present opportunities for unattenuated or enhanced transport of vapors toward and into any building (e.g., via a preferential migration route(s)), as discussed in Sections 5.4, 6.2.1, 6.3.2, and 6.5.2.

When the vapor intrusion pathway is determined to be incomplete, then vapor intrusion mitigation is not generally warranted under current conditions. EPA recommends that site managers also evaluate whether subsurface vapor sources that remain have the potential to pose a complete vapor intrusion pathway and unacceptable human health risk due to vapor intrusion in the future if site conditions were to change. For example, potentially unpredictable changes in the transitory soil characteristics (e.g., soil moisture) and soil gas concentrations may occur as a result of constructing a new building or supporting infrastructure. Either type of change could result in the potential for unacceptable human health risk due to vapor intrusion in the future.

Response actions may, therefore, be warranted to protect human health wherever and as long as subsurface vapor sources remain that have the potential to pose unacceptable human health risk in the future due to vapor intrusion. These response actions (see Section 7.7) may include institutional controls (see Section 8.6) (e.g., to record and alert parties about the presence of subsurface vapor sources and/or to inform the need for a confirmatory vapor intrusion investigation in case infrastructure or geologic conditions are modified in the future). In addition, subsurface remediation may be warranted to protect human health or the environment via other exposure pathways (e.g., groundwater discharge to surface water bodies), consistent with applicable statutes and considering EPA guidance.

7.4 Conduct and Interpret Human Health Risk Assessment

EPA generally recommends that a human health risk assessment be conducted to determine whether the potential human health risk posed to building occupants by a complete or potentially complete vapor intrusion pathway are within or exceed acceptable levels, consistent with applicable statutes[192] and considering EPA guidance (EPA 1991a, 2009c). The primary purpose of this risk assessment is to provide risk managers with an understanding of the actual and potential risks to human health posed by vapor intrusion under current and reasonably expected future conditions. This information may be useful in determining whether a current or potential future threat to human health exists, as described in Sections 7.4.1, 7.4.2, and 7.5.2,[193] which warrants response action(s), as described in Sections 7.7 and 8.

[192] In the RCRA corrective action program, any human health risk assessment would typically be conducted during the RCRA facility investigation, if a release to the environment is identified. Under the CERCLA remedial program, a human health risk assessment would typically be conducted during the remedial investigation and is generally referred to as a baseline (i.e., pre-cleanup) risk assessment.

[193] In appropriate circumstances (e.g., where time is of the essence to ensure protection of human health; see, for example, Section 7.5.2), a formal human health risk assessment need not be completed and documented before taking a response action, but a preliminary evaluation of human health risk using individual building data or aggregated community data is generally recommended (also see Section 7.8).

The human health risk posed to building occupants by intrusion of a given vapor-forming chemical will depend upon its toxicity, its concentration in indoor air, the amount of time the occupants spend in the building, and other variables (e.g., human life stage (e.g., child) can matter for some chemicals (e.g., those with a mutagenic mode of action for carcinogenicity)). EPA recommends that its risk assessment guidance (e.g., EPA 2009c, EPA 2003) be used to identify, develop, and combine information about these variables and characterize human health risk due to vapor intrusion from subsurface contaminant sources.

For the vapor intrusion pathway, the inhalation route is the primary means of human exposure. Therefore, the human health risk assessment uses estimates of indoor air exposure concentrations, exposure duration and frequency for building occupants, and the potential toxicity of the vapor-forming chemicals found in the subsurface (e.g., inhalation unit risk and noncancer reference concentration) to characterize risks of cancer and noncancer effects (EPA 2009c). Generally, exposure concentrations in existing buildings can be estimated using direct measurements of indoor air (see Sections 6.3.4 and 6.4.1). EPA recommends that time-integrated measurements from multiple sampling events be used to estimate exposure concentrations appropriate for the exposure (occupancy) scenario being evaluated (e.g., residential versus commercial), when the risk assessment for an existing building would support a conclusion that the human health risk is acceptable (see Section 7.4.1).[194,195] Generally, modeling would be used to conservatively estimate exposure concentrations under future conditions in buildings yet to be constructed in areas with subsurface contamination by vapor-forming chemicals (see Section 6.6). EPA recommends the noncancer assessment consider the potential for adverse health effects from short-duration inhalation exposures (i.e., acute, short-term, or subchronic exposure durations),[196] as well as longer term inhalation exposure (i.e., chronic exposure) conditions. EPA recommends that inhalation toxicity values be selected

[194] An individual sample, collected at a randomly chosen time, may under-estimate (or over-estimate) average and reasonable maximum exposure conditions. From their high-frequency, measured data, Holton et al. formulated a synthetic data set (simulating one-day-average concentrations), which they used to estimate that a single, randomly drawn, one-day sample had a forty percent chance of being less than the true mean (Holton et al. 2013b; see Table 1 therein). When the true mean was assumed to exceed the risk-based action level ("target concentration" in their parlance) by two or five times, they estimated that a single, randomly drawn, one-day sample had a twenty percent or six percent chance, respectively, of not detecting the exceedance. These data support EPA's recommendation to collect multiple rounds of indoor air sampling data to reduce the chance of reaching a false-negative conclusion (i.e., concluding exposure is at an acceptable risk level when it is not). Collecting multiple rounds of indoor air sampling can also reduce the chance of reaching a false-positive conclusion (i.e., concluding that vapor intrusion poses unacceptable human health risk when it does not), because an individual sample, collected at a randomly chosen time, may over-estimate the average and reasonable maximum exposure conditions.

[195] Given EPA's assigned mission to protect human health from environmental contamination and recognizing the disruption to building owners and occupants caused by indoor air sampling, risk managers may choose to pursue pre-emptive mitigation (i.e., early action) at some buildings (see Sections 3.3 and 7.8) rather than, for example, conduct multiple rounds of sampling over a few years to establish an estimate of long-term average exposure concentration and characterize temporal variability.

[196] The inhalation reference concentration (RfC) (expressed in units of mass concentration in air) is defined as an estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. Reference values may be derived for acute (≤24 hours), short-term (>24 hours, up to 30 days), subchronic (>30 days, up to approximately 10% of the life span), and chronic (greater than 10% of the life span) exposure durations, all of which are derived based on an assumption of continuous exposure throughout the duration specified. See http://www.epa.gov/ncea/iris/help_ques.htm#whatiris

considering OSWER's hierarchy of sources (EPA 2003) and that relevant existing guidance (e.g., EPA 2009c) be followed in situations where a desired toxicity value is not available.

When a single vapor-forming chemical is present in the subsurface and intrudes as a vapor into occupied building spaces, the noncancer human health risk can be characterized by calculating the noncancer hazard quotient (HQ) (EPA 2009c,Chapter 8). When multiple vapor-forming chemicals are present in the subsurface and intrude as vapors into occupied building spaces, the HQ estimates for each chemical are aggregated (as a simple sum, which is the Hazard Index (HI)), based upon the assumption that each chemical acts independently (i.e., there are no synergistic or antagonistic toxicity interactions among the chemicals). If the HI exceeds one, there may be concern for potential adverse non-cancer effects and risk assessors should consider segregating the chemicals by target organ or toxic effect to derive separate hazard index (HI) values for each (EPA 2009c, Chapter 8). EPA recommends that noncancer HQ and HI values be estimated for each type of exposure period identified in the conceptual site model or indicated by measurements of indoor air levels of vapor-forming chemicals (e.g., chronic, subchronic, short-term, acute), evaluating inhalation reference concentrations that "match the characterization of the exposure scenario" (EPA 2009c, Chapter 4).[197]

The carcinogenic risks can be characterized by calculating the excess cancer risk over a lifetime (LCR) and, if multiple vapor-forming chemicals are present, aggregating the LCR estimates for each carcinogen (as a simple sum), based upon the assumption that each chemical acts independently (EPA 2009c, Chapter 8).

A well-crafted risk characterization section (EPA 1992c, 1995ab, 2000b, 2009c) puts risk calculations into context for risk managers, so that they may effectively weigh and interpret risk assessment results and recognize key uncertainties (e.g., in the exposure and dose-response assessments and risk estimation).[198] Additional recommendations for promoting and increasing the utility and transparency of human health risk assessments can be found in *Framework for Human Health Risk Assessment to Inform Decision Making* (EPA-RAF, 2014).

[197] For example, when evaluating situations in which vapor concentrations in indoor air exceed the chronic reference concentration (see Section 7.4.1), and there are shorter periods of significantly higher vapor intrusion exposure, EPA recommends that noncancer risks for the shorter periods also be characterized using toxicity values appropriate for the respective period(s). On the other hand, if vapor concentrations in indoor air are consistently less than benchmarks for acceptable chronic exposure, then exposures for less-than-chronic scenarios are unlikely to pose unacceptable human health risk.

[198] For example, EPA recommends that the risk characterization for existing buildings describe the uncertainty in the exposure assessment arising from: (i) inherent variability of indoor air exposures over time and space; (ii) the match between the sampling data [e.g., sampling frequency (i.e., number of samples and time intervals between samples); and time period over which each sample was collected] and the exposure period represented by the selected toxicity value (e.g., chronic); and (iii) the ability to distinguish and apportion the contribution to indoor air concentrations arising from vapor intrusion versus background sources. EPA recommends that the risk characterization for future buildings describe the principal uncertainties in the exposure assessment, which may be associated with the type(s) of building use, building construction and operations (e.g., HVAC system), frequency and duration of occupancy, vapor concentrations in indoor air, or other factors.

EPA recommends that any human health risk assessment be documented; a summary in a decision document is also generally warranted.[199] EPA also recommends that human health risk information for individual buildings be communicated to building occupant(s) and owners. Section 9.4 provides additional information for communicating sampling results.

7.4.1 Risk Management Benchmarks

EPA recommends that OSWER programs make the risk management determination to take response action consistent with their statutes and regulations and considering existing program guidance.[200] The carcinogenic risk and non-cancer HI values used in this determination generally are the "cumulative risks" that include all exposure pathways that a given population may consistently face.[201] In making such risk management determinations, EPA generally recommends reporting the HQ and HI to one significant figure.

EPA generally uses a cancer risk range of 10^{-6} to 10^{-4} as a "target range" within which to manage human health risk as part of site cleanup. For judging whether indoor air exposures may pose acceptable health risk based upon potential non-cancer effects, EPA generally recommends that the target HQ or HI not exceed 1.

Once a decision has been made to undertake a response action, EPA has expressed a preference for cleanups that are at the more protective end of the cancer risk range. Thus, EPA recommends using an individual lifetime cancer risk of 10^{-6} as a point of departure for establishing cleanup levels based upon potential cancer effects (see Section 7.6).[202] The EPA risk manager may determine that a response action achieving reductions in human health risk

---

[199] Devices that have been found to improve comprehension and retention of textual materials include a table of contents, clear section headings, and a summary (Morgan et al. 1992). It is most helpful to provide a summary that translates the risk assessment into relatively simple language that non-expert risk managers, stakeholders, and wider audiences can understand (Lundgren and McMakin, 2013). Hazards and risks posed by vapor intrusion are more likely to be misunderstood or misinterpreted if they are not explained in simple terms.

[200] See, for example: *The Role of the Baseline Risk Assessment in Superfund Remedy Selection Decisions*, OSWER Directive 9355.0-30, April 22, 1991 (EPA 1991a); *Rules of Thumb for Superfund Remedy Selection,* OSWER Directive 9355.0-69, August 1997 (EPA 1997); and Advanced Notice of Proposed Rulemaking: Corrective Action for Solid Waste Management Units at Hazardous Waste Management Facilities (61 *Federal Register* 19432, May 1, 1996). So, for example, EPA cited OSWER Directive 9355.0-30 (EPA 1991a) in its *Compilation of Information Relating to Early/Interim Actions at Superfund Sites and the TCE IRIS Assessment* (EPA 2014b).

[201] In some site-specific situations, a population might be exposed to a substance or combination of substances through several exposure pathways (i.e., not only the vapor intrusion pathway). For example, individuals might be exposed to substance(s) from a contaminated site by consuming contaminated drinking water from a groundwater supply, as well as from vapor intrusion. Once reasonably expected exposure pathways have been identified, EPA recommends examining whether it is likely that the same individuals would consistently face the reasonable maximum exposure for each pathway or a combination of some of these pathways. Under such circumstances, the total exposure to each chemical would equal the sum of the exposures by all consistently faced pathways (EPA 1989, Section 8.3) and EPA recommends that the risk assessor clearly identify those exposure pathway combinations for which a total risk estimate or hazard index is being developed. When characterizing human health risk arising from multiple pathways and posed by a vapor-forming chemical(s) with potential adverse noncancer effects, EPA recommends that the toxicity values for each pathway "match the characterization of the exposure scenario" (EPA 2009c, Chapter 4).

[202] See: National Oil and Hazardous Substances Pollution Contingency Plan (55 *Federal Register* 8717); and Advanced Notice of Proposed Rulemaking: Corrective Action for Solid Waste Management Units at Hazardous Waste Management Facilities (61 *Federal Register* 19432, May 1, 1996).

within the 10^{-6} to 10^{-4} cancer risk range is acceptable, however, depending on site-specific conditions or remedial factors.

For establishing cleanup levels based upon potential non-cancer effects, EPA generally recommends that the target HI not exceed 1 (see Section 7.6).

7.4.2 Accounting for Background Contributions

As noted previously, EPA recommends including in the human health risk assessment vapor-forming chemicals that are related to releases to the subsurface environment. Some of these vapor-forming chemicals may be present in indoor air due to 'background' sources (see Section 2.7). If data are available, EPA recommends that the contribution of 'background' to total exposure concentration(s) be distinguished in the human health risk assessment (EPA 2002e). If background vapor sources (see Glossary) are found to be primarily responsible for indoor air concentrations (see Section 6.3.5), then response actions for vapor intrusion would generally not be warranted for current conditions. In any event, EPA recommends that the risk characterization include a discussion of 'background' contributions to indoor air exposure and associated human health risk. With such information, EPA can help advise affected individuals about the environmental and public health risks they face that are within their control (e.g., indoor sources of vapor-forming chemicals in residences).[203] Other parties, including building owners and operators, may help with risk communication.

If 'background' contributions are unknown and such data are sought to support risk management decisions, EPA recommends that additional data be collected (see, for example, Section 6.3.5). Information on 'background' contributions of site-related, vapor-forming chemicals in indoor air is also important to risk managers because generally EPA does not clean up to concentrations below natural or anthropogenic background levels (EPA 2002e).

7.4.3 Occupational Exposure Limits

Permissible exposure limits (PELs) are enforceable occupational exposure standards developed by the Occupational Safety and Health Administration (OSHA) in the U.S. Department of Labor. Most of OSHA's PELs were adopted in 1971 from then-existing secondary guidance levels, such as Threshold Limit Values (TLVs) developed by the American Conference of Governmental Industrial Hygienists (ACGIH) to protect workers from adverse effects of occupational exposure to airborne chemicals. They were intended to protect workers against catastrophic effects (such as cardiovascular, liver, kidney, and lung damage), as well as more subtle effects (such as narcosis, central liver system damage, and sensory irritation).

PELs (and TLVs), however, are not intended to protect sensitive workers, may not incorporate the most recent toxicological data, and may differ from EPA derivations of toxicity values with respect to weight-of-evidence considerations and use of uncertainty factors. For these and other

[203] In cases where 'background' contamination (e.g., due to indoor use of a consumer product or household chemical in a residence) may pose a human health risk, but its remediation is beyond the authority of the applicable statute, risk communication to the public may be most effective when coordinated with public health agencies (EPA 2002e).

reasons, [204] EPA does not recommend using OSHA's PELs (or TLVs) for purposes of assessing human health risk posed to workers (EPA 1991c, Appendix C) by the vapor intrusion pathway or supporting final "no-further-action" determinations for vapor intrusion arising in nonresidential buildings. Rather, EPA's recommendations for assessing human health risk posed by vapor intrusion are set forth herein in Sections 7.4.1 and 7.4.2.

7.5 Concentration Levels Indicating Potential Need for Prompt Response Action

In some circumstances, human health risk arises from vapor intrusion, which warrants prompt response action. This Section provides some recommendations for identifying such circumstances.

7.5.1 Potential Explosion Hazards

EPA recommends using the chemical-specific LELs[205] to identify potential explosion hazards (e.g., for methane and other petroleum hydrocarbons). Whenever building-specific data (such as results from sub-slab soil gas samples and crawl space samples for any building type, indoor air samples from sheds or pump houses, or gas samples from confined or semi-confined spaces (e.g., sewers)) exceed one-tenth (10%) of the LEL for any chemical, a hazard is indicated that generally warrants prompt action.[206,207] EPA recommends to building owners and occupants the evacuation of buildings with potential explosion and fire hazards, along with immediate notification to the local fire department about the threat. Construction and operation of engineered systems that can reduce or eliminate intrusion of explosive vapors into existing buildings or unoccupied structures may also warrant consideration to reduce the potential for future explosion hazards.

7.5.2 Considering Short-term and Acute Exposures

EPA may identify health-protective concentration levels for vapor-forming chemicals based upon potential noncancer health effects that can be posed by air exposures over short-term or acute exposure durations, considering EPA guidance for human health risk assessment (e.g., EPA

---

[204] OSHA's website (May 2015) currently states: "OSHA recognizes that many of its permissible exposure limits (PELs) are outdated and inadequate for ensuring protection of worker health. Most of OSHA's PELs were issued shortly after adoption of the Occupational Safety and Health (OSH) Act in 1970, and have not been updated since that time. Since 1970, OSHA promulgated … new PELs for 16 agents, and standards without PELs for 13 carcinogens. Industrial experience, new developments in technology, and scientific data clearly indicate that in many instances these adopted limits are [also] not sufficiently protective of worker health. This has been demonstrated by the reduction in allowable exposure limits recommended by many technical, professional, industrial, and government organizations, both inside and outside the United States." [On-line source: https://www.osha.gov/dsg/annotated-pels/] On October 10, 2014, OSHA issued a Chemical Management Request for Information (79 FR 61384), in which it acknowledges many of its PELs are not sufficiently protective and seeks comment on strategies to address this problem; available on-line at: https://www.osha.gov/FedReg_osha_pdf/FED20141010.pdf

[205] The Vapor Intrusion Screening Level Calculator (EPA 2015a) provides LELs for vapor-forming chemicals to facilitate identification of potential explosion hazards.

[206] NIOSH has designated such concentrations as immediately dangerous to life or health (IDLH).

[207] Although the building-specific data may vary temporally, any short-term exceedance of one-tenth of the LEL indicates vapor concentrations that, given an ignition source and available oxygen, may be capable of causing an explosion.

2009c) and using sources of toxicity information considering OSWER's hierarchy (EPA 2003). For example, subchronic reference concentrations, developed by the EPA Office of Research and Development/National Center for Environmental Assessment/ Superfund Health Risk Technical Support Center (STSC), are currently available for some vapor-forming chemicals as Provisional Peer Reviewed Toxicity Values (PPRTVs), which are designated as a Tier 2 source of toxicity values by OSWER (EPA 2003). Acute and intermediate Minimal Risk Levels (MRLs)[208] adopted by the Agency for Toxic Substances and Disease Registry (ATSDR) are currently available for some vapor-forming chemicals and are designated as a Tier 3 source of toxicity values by OSWER (EPA 2003). PPRTVs and ATSDR MRLs are peer reviewed and are publicly available (see, http://hhpprtv.ornl.gov/ and http://www.atsdr.cdc.gov/mrls.html).

Historically, toxicity values for short-term or acute exposure durations have not been derived or published in EPA's IRIS, which otherwise is EPA's preferred source of toxicity values (EPA 2003). EPA, under its authority, will work to develop expanded science policy direction to address short-term exposures and develop and identify appropriate toxicity values for additional chemicals for consideration for vapor intrusion assessment and related OSWER regulatory frameworks. EPA recommends that relevant existing guidance (e.g., EPA 2009c) be followed in situations where a desired toxicity value is not available, using sources of toxicity information considering OSWER's hierarchy (EPA 2003).

Although the indoor air concentrations may vary temporally, an appropriate exposure concentration estimate (e.g., time-integrated or time-averaged indoor air concentration measurement in an occupied space – see Section 6.4.1) that exceeds the health-protective concentration levels for acute or short-term exposure (i.e., generally considered to be a hazard quotient (HQ) greater than one for an acute or short-term exposure period)[209] indicates vapor concentrations that are generally considered to pose an unacceptable human health risk.[210]

As noted in Section 7.4 of this Technical Guide, a well-crafted risk characterization section (EPA 1992c, 1995ab, 2000b, 2009c) puts risk calculations into context for risk managers, so that they may effectively weigh and interpret risk assessment results and recognize key uncertainties (e.g., in the exposure and dose-response assessments and risk estimation). Uncertainties include the derivation of an RfC, which is defined as "…an estimate (with uncertainty spanning perhaps an order of magnitude)…" (See http://www.epa.gov/ncea/iris/help_ques.htm#whatiris). Sections 3.3 and 7.7 identify other EPA-recommended considerations for risk managers.

When indoor air concentrations in an occupied space exceed health-protective concentration levels for short-term or acute inhalation exposures arising from a complete vapor intrusion

[208] Minimal Risk Levels (MRLs) published by ATSDR are estimates of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse non-cancer health effects over a specified duration of exposure. The ATSDR MRLs are peer reviewed and are publicly available (http://www.atsdr.cdc.gov/mrls.html).

[209] See Glossary for definitions of "acute" and "short-term" exposure durations.

[210] See, for example: *The Role of the Baseline Risk Assessment in Superfund Remedy Selection Decisions*, OSWER Directive 9355.0-30, April 22, 1991 (EPA 1991a); and *Rules of Thumb for Superfund Remedy Selection,* OSWER Directive 9355.0-69, August 1997 (EPA 1997). In addition, the NCP states "For systemic toxicants, acceptable exposure levels shall represent concentration levels to which the human population, including sensitive subgroups, may be exposed without adverse effect during a lifetime or part of a lifetime, incorporating an adequate margin of safety" [40 *CFR* 300.430(e)(2)(i)(1)].

pathway, ventilation, indoor air treatment, temporary relocation, and other response actions may be implemented to reduce or avoid these threats promptly (see Section 8.2.1). Construction and operation of engineered systems that can reduce or eliminate vapor intrusion into existing buildings (see Section 8.2) may also warrant consideration after urgent threats to human health have been addressed.

7.6 Risk-based Cleanup Levels

When response action is determined to be warranted to reduce or eliminate indoor air exposures from vapor intrusion (see Sections 7.4 and 7.5), EPA recommends that cleanup levels be established and documented consistent with statutes and regulations and considering guidance for the respective OSWER program.[211] These cleanup levels would be used to evaluate when building mitigation measures, subsurface remediation, and associated monitoring can be terminated and to assess cleanup progress in the meantime (see Section 8.7).

Candidate risk-based cleanup levels can be calculated using information from the risk assessment (Section 7.4). Results of the human health risk assessment indicate, for example, which site-related vapor-forming chemicals warrant building mitigation and subsurface remediation. The exposure factors and toxicity values used in the human health risk assessment can be used to calculate chemical-specific cleanup levels, considering EPA risk assessment methods (e.g., EPA 2009c, EPA 2003). Candidate cleanup levels are usually developed for potential cancer and non-cancer effects. The lower (or lowest if there are multiple potential non-cancer effects) of the candidate values, based upon cancer risk and non-cancer HQ/HI targets, is generally recommended for selection as the cleanup level (EPA 1991c, Section 3.4 therein).[212] The VISL Calculator (http://www.epa.gov/oswer/vaporintrusion/guidance.html) can be used to support these calculations, including input of alternative attenuation factor(s) based upon site- or building-specific information.

Calculating candidate cleanup levels based upon potential cancer effects entails selecting a target cancer risk. As noted above (Section 7.4.1), once a decision has been made to undertake a response action, EPA has expressed a preference for cleanups achieving the lower end of the cancer risk range (i.e., 10^{-6}) (EPA 1991a). Response actions achieving reductions in human health risk anywhere within the cancer risk range may be deemed acceptable by the EPA risk manager, however.

To protect human health from potential noncancer effects, EPA generally recommends using a target value of one for the non-cancer HQ (if there is a single vapor-forming chemical of health concern for vapor intrusion) or for the non-cancer HI (if there are multiple vapor-forming chemicals of health concern for vapor intrusion acting by a common effect).

---

[211] See, for example: *RCRA Corrective Action Plan (Final),* OSWER Directive 9902.3-2A (EPA 1994); and *A Guide to Preparing Superfund Proposed Plans, Records of Decision, and Other Remedy Selection Decision Documents,* OSWER Directive 9200.1-23P (EPA 1999b).

[212] An exception arises when 'background' sources pose elevated exposures, because generally EPA does not clean up to concentrations below natural or anthropogenic background levels (EPA 2002e).

Cleanup levels for indoor air can be readily calculated, as described above, without additional assumptions or modeling about vapor intrusion processes. On the other hand, cleanup levels for groundwater and/or soil gas in the vadose zone will entail developing a medium-specific vapor attenuation factor, which EPA recommends be conservatively estimated based upon site-specific information. The cleanup level for soil gas can be calculated by dividing the chemical-specific indoor air cleanup level by the site-specific soil gas vapor attenuation factor. The cleanup level for groundwater can be calculated by dividing the chemical-specific indoor air cleanup level by the site-specific vapor attenuation factor for groundwater vapors and assuming equilibrium between the aqueous and vapor phases at the groundwater table. EPA recommends that site-specific attenuation factors intended to be protective of chronic exposure conditions: be conservatively estimated when based upon mathematical models; and be based upon multiple measurements of indoor air concentration in different seasons, which have negligible influences from 'background' sources, when based upon site-specific measurements.

EPA recommends that cleanup levels be documented with at most two significant figures, even though some of the input values may carry additional significant figures (EPA 1991b, see page 19).

7.7 Options for Response Action

When response action is determined to be warranted to reduce or eliminate indoor air exposures from vapor intrusion (see Sections 7.4 and 7.5), EPA recommends that OSWER programs select, recommend, and document response action(s) consistent with statutes and regulations and considering their existing program guidance.[213]

The selection of a health-protective interim response action(s) for existing buildings will generally depend on site-specific considerations, which can include: nature of subsurface vapor source (e.g., groundwater, vadose zone soils, sewer lines), magnitude of the exposure above cleanup levels; the severity of the potential adverse health effects or health hazard; building features and conditions (e.g., construction; heating, ventilation, and air conditioning equipment); climate and season (which influence the feasibility of ventilation, for example); the quality of ambient air in the vicinity; and the feasibility of implementing a given option quickly.[214] In general, EPA recommends that response actions limit the amount of time individuals are exposed to concentrations that correspond to unacceptable human health risk, as described in Sections 7.4 and 7.5.

[213] See, for example: *RCRA Corrective Action Plan (Final),* OSWER Directive 9902.3-2A (EPA 1994); and *A Guide to Preparing Superfund Proposed Plans, Records of Decision, and Other Remedy Selection Decision Documents,* OSWER Directive 9200.1-23P (EPA 1999b).

[214] Most response actions cannot be implemented immediately upon determining that a response is warranted. For example, engineered exposure controls ordinarily entail from two to four weeks of lead time (at a minimum) for planning, design, any permit acquisition, material acquisition and construction. In many circumstances, ventilation measures to reduce exposure can be implemented more quickly, but local climate or air quality may render this option less attractive during some seasons.

TABLE 7-1
MATRIX OF OPTIONS TO RESPOND TO HUMAN HEALTH RISK POSED BY THE VAPOR INTRUSION PATHWAY

Option for Response Action	Applicability of Response Action for Common Sources of Sub-surface Vapors		
	Groundwater	Vadose Zone Soil	Sewer & Drain Lines
Remediation of Source*	•	•	•
Removal of contaminated soil via excavation	#	•	
Treatment of contaminated soil *in situ*	#	•	
Treatment of contaminated groundwater *in situ*	•		
Removal of contaminated groundwater (e.g., pump-and-treat)	•		
Decontaminating and/or rehabilitating sewer and drain lines			•
Interim Measures to Reduce or Eliminate Vapor Intrusion*	•	•	•
Subslab de-pressurization and ventilation systems	•	•	
Sealing major openings for soil gas entry, where known and identified+	•	•	
Building over-pressurization	•	•	
Installing, repairing, or maintaining vapor traps			•
Interim Measures to Reduce or Avoid Exposure to Vapors	•	•	•
Notification to local fire department about potential explosion hazards+	•	•	•
Notification and risk communication to building occupants and owners, including institutional controls (e.g., deed notices)	•	•	•
Increasing building ventilation*	•	•	•
Treating indoor air*	•	•	•
Temporary relocation+	•	•	•
Monitoring Indoor Air to Characterize Human Exposure	•	•	•

KEY: • designates potentially appropriate response action for indicated vapor source

FOOTNOTES:

* includes: associated institutional controls to maintain operations and provide public notification of residual contamination; and associated monitoring to assess effectiveness and protectiveness of the response action

\# remediation of soil may also be warranted for purposes of protecting groundwater from further contamination, even if contaminated soil in the vadose zone is not a source for vapor intrusion directly (e.g., due to the absence of an existing building near the contaminated soil)

\+ response option primarily applies to existing buildings

Table 7-1 presents an overview of key candidate response options for the vapor intrusion pathway, which are discussed further in Section 8. Response actions that may be recommended for and implemented in existing buildings include:

- Interim measures that can be implemented relatively quickly (see Section 8.2.1), if prompt action is warranted to reduce or eliminate exposures to vapor-forming chemicals (see Sections 5.2 and 7.5.2) or to mitigate explosion hazards (see Section 7.5.1);
- Engineered exposure controls (see Section 8.2.2) with associated monitoring and institutional controls (see Section 8.6), as an interim (but potentially long-term) measure to reduce or eliminate vapor intrusion into buildings; and
- Remediation of the subsurface vapor source (see Section 8.1) with associated monitoring and institutional controls (see Section 8.6).

Response actions that may be warranted in buildings that may be constructed in the future include:

- Remediation of the subsurface vapor source (see Section 8.1) with associated monitoring and institutional controls (see Section 8.6); and
- Institutional controls (see Section 8.6) to inform the need for building mitigation (see Section 8.2.2) and/or a confirmatory vapor intrusion investigation before the building is occupied, in case the building is to be or may be constructed before subsurface vapor sources are remediated to cleanup levels.

Indoor air monitoring has frequently been selected as a response action in circumstances where subsurface vapor sources are present and the vapor intrusion pathway has not been shown to be incomplete. Indoor air monitoring may be deemed warranted, for example:

- To better characterize spatial or temporal variability;
- To address uncertainty in the characterization of the vapor intrusion pathway when subsurface vapor sources have the potential to pose a health concern in overlying or nearby buildings (e.g., incomplete pathway characterization, concern about the potential for changes in building conditions, discordant lines of evidence); or
- For other site-specific or situation-specific reasons.

EPA generally prefers to obtain building access and undertake response actions through consent and cooperation from building owners, tenants, and other stakeholders (see Section 1.2).

7.8 Pre-emptive Mitigation/Early Action

It may be appropriate to implement mitigation of the vapor intrusion pathway as an early action, even though all pertinent lines of evidence have not yet been completely developed to characterize the vapor intrusion pathway for the subject building(s), when sufficient site-specific data indicate that vapor intrusion: (1) is occurring or may occur due to subsurface contamination that is being addressed by federal statutes, regulations, or guidance for environmental protection; and (2) is posing or may pose a health concern to occupants of an existing

building(s). Likewise, it may be appropriate and cost-effective to design, install, operate, and monitor mitigation systems (including passive barrier systems) in newly constructed buildings (or buildings planned for future construction) that are located in areas of vapor-forming subsurface contamination, rather than allow vapor intrusion (if any) to occur and address vapor intrusion after the fact. As described in Section 3.3, preemptive mitigation/early action is the term used to describe both situations.

Preemptive mitigation (PEM) is recognized as an early action that is intended to ensure protectiveness of human health. In this context and as described further in Section 8.2, mitigation refers to methods that seek to:

- Prevent or reduce vapor entry into a building.
- Reduce or eliminate vapors that have entered a building.

Note that the selection and implementation of PEM, when it occurs, is not necessarily intended to pre-judge final decisions about remediation of subsurface vapor sources; however, EPA generally recommends that decision-making about PEM include a consideration of the O&M and monitoring obligations. In addition, EPA recommends that the selection of PEM be based upon data and information in the administrative record and be documented in the administrative record, consistent with statutes and regulations and considering EPA guidance for the respective land restoration program (e.g., CERCLA, RCRA corrective action, brownfields, etc.), in order to provide an adequate basis for actions undertaken.

7.8.1 Rationale

In ensuring protectiveness of human health, PEM generally may be an appropriate approach to consider for buildings with potential vapor intrusion for a number of reasons, including:

- Building mitigation typically is an effective means of protecting human health and is cost effective for many buildings.
- The potential exposure scenario (e.g., inhalation of potentially toxic vapors) cannot generally be readily avoided by building occupants.
- Involuntary and unavoidable exposures and hazards are generally sources of anxiety and concern for affected building occupants and the general public, particularly when they occur in homes and in the workplace.
- Comprehensive subsurface characterization and investigations of vapor intrusion (to conclusively characterize unacceptable, but variable, levels of vapor-forming chemicals in soil, groundwater, and indoor air, as described in Section 6) can entail prolonged study periods, during which building occupants may be exposed and owners and environmental stewardship groups may remain anxious and concerned about potential indoor air exposures to subsurface vapors in the absence of mitigation.
- Conventional vapor intrusion investigations in and of themselves can be disruptive, particularly when indoor access is sought to acquire interior samples and assess interior building conditions.

- Mitigation can typically be implemented relatively quickly, while subsurface contamination is being more fully delineated or remediated.

- EPA's experience with residential communities suggests that many affected residents seek and prefer that mitigation systems be installed when vapor intrusion is suspected.

- Mitigation can be a cost-effective approach to help ensure protectiveness of human health during ongoing vapor intrusion investigations to acquire multiple lines of evidence and characterize spatial and temporal variability in subsurface and indoor air concentrations, as well as while subsurface remediation is being planned and conducted to reduce or eliminate subsurface vapor sources.

In summary, PEM, based on limited but credible subsurface and building data, can be an appropriate approach to begin to implement response actions quickly and ensure protectiveness of current building occupants. In such circumstances, resources can be used appropriately to focus first on mitigation of buildings and subsurface remediation, rather than site and building characterization efforts, which may be prolonged. Although PEM may be an effective tool to reduce the human exposure and human health risk, building mitigation is not generally intended to address the subsurface vapor source; as such, EPA recommends that it typically be used in conjunction with remediation of the subsurface source of vapor-forming chemicals (e.g., source removal or treatment), as discussed in Section 8.1.

7.8.2 General Decision Framework

To consider PEM, EPA recommends that reliable data supporting a preliminary analysis, as described in Section 5.0, and risk-based screening, as described in Section 6.5, be obtained and documented in the administrative record. In appropriate circumstances (e.g., where time is of the essence to ensure protection of human health; see, for example, Section 7.5.2), a formal human health risk assessment need not be conducted and documented before selecting PEM, but a preliminary evaluation of human health risk using individual building data or aggregated community data is generally recommended. If there are insufficient data to perform a preliminary risk analysis, but subsurface vapor sources are known to be present near buildings (see Section 5.3), EPA recommends that an appropriate vapor intrusion investigation (see Section 6) be conducted to obtain sufficient data.

EPA generally recommends that the decision to undertake building mitigation be supported by appropriate lines of site- or building-specific evidence (e.g., characterization of subsurface vapor source(s) strength and proximity to building(s); building conditions) that demonstrate that vapor intrusion has the potential to pose an unacceptable human health risk. Sections 5, 6, and 7 herein provide information about the types of evidence obtained and relied upon in assessing vapor intrusion potential and the types of analyses that can support determinations of whether the vapor intrusion pathway is complete for a specific building or collection of buildings and poses or has the potential to pose a health concern to building occupants. This information is equally pertinent for supporting final remediation and mitigation decisions and for supporting PEM consistent with applicable statutes and regulations. The premise of PEM, however, is to protect human health first without necessarily waiting to collect all lines of pertinent evidence or multiple rounds of sampling data.

Certain types of subsurface conditions may have greater potential to facilitate vapor intrusion when subsurface sources of vapors are present. These conditions include, but are not limited to:

- Shallow aquifers (for example, five feet or less from the building foundation to the seasonal high water table).

- High-permeability (e.g., gravelly) vadose zone soils that are fairly dry, which are favorable to upward migration of gases.

- Preferential migration routes, such as fractured sediments or bedrock, buried streambeds, subsurface drains, and utility conduits, as they can facilitate vertical or lateral migration of vapor with limited attenuation of chemical concentrations.

Under these conditions, it may be easier to determine that PEM may be warranted if a structure is located near a subsurface vapor source that has the potential to pose an unacceptable human health risk. Other factors to consider include the following:

- Susceptibility to soil gas entry. Some buildings have greater potential for vapor intrusion (i.e., are more susceptible to soil gas entry; see Section 2.3) than others. For example, buildings with deteriorating basements or dirt floors generally provide poor barriers to vapor (soil gas) entry. Buildings with sumps or other openings to the subsurface that can facilitate soil gas entry are also more susceptible to vapor intrusion.

- Actions undertaken or planned to address the subsurface source of vapors. For example, if the source of vapors (e.g., contaminated soil in the vadose zone) is being removed (e.g., excavation of contaminated soil or soil vapor extraction underneath the building) or is to be removed within a time frame that is protective for any potential current or near-term exposures in the overlying or nearby building, then PEM may not be warranted.

7.8.3 Some General Scenarios Where Pre-emptive Mitigation May be Warranted

Three general scenarios where PEM may be warranted are summarized below. The first two scenarios address situations where building(s) currently exist, while the third scenario addresses a situation where building(s) may be constructed in the future.

Site with High Potential to Facilitate Vapor Intrusion. In this scenario, indoor air concentration data have not been collected, but other lines of evidence support a conclusion that the vapor intrusion pathway is likely complete and may pose an unacceptable human health risk. Figure 7-1 shows a hypothetical residential area located near a shopping center that contains an active dry-cleaning facility. In this hypothetical example, a sufficient number of appropriately screened monitoring wells have been installed throughout the neighborhood to characterize a historical groundwater plume emanating from the dry cleaner that has migrated under eight homes and continues to migrate. Groundwater is encountered at approximately five feet below ground surface, and site geology consists of dry gravel and sands. “Near-source” soil gas samples have also been collected from several locations throughout the neighborhood and found to corroborate a high-strength vapor source near the buildings. All homes have crawl spaces with dirt floors. In this hypothetical example, PEM may be warranted for the eight buildings located above, near, or downgradient of the groundwater plume, based on the groundwater concentration and soil gas data available (i.e., PCE concentrations significantly exceeding

screening levels in this example),[215] and the likelihood that the proximity of the groundwater table, characteristics of the vadose zone, and building conditions will collectively facilitate vapor migration and intrusion.

Note that if a groundwater restoration system is constructed and operated and plume migration is thereby controlled, additional buildings downgradient of the plume may not warrant PEM in the future. In the meantime, an IC may be appropriate for the undeveloped parcel hydraulically down-gradient of the current leading edge of the plume.

Site with Indoor Air Data for Some Buildings but Not for All Buildings. Depending on individual owners and occupants in the affected community, it may be difficult to obtain adequate data for all buildings within a specified area. Challenges include gaining timely access into each building and other practical considerations. In such circumstances, it may be appropriate to characterize a limited number of buildings under a reasonable maximum vapor intrusion condition,[216] by collecting and weighing multiple lines of evidence, and then extrapolating those findings to similar buildings nearby. The following hypothetical scenario describes one such situation, which is represented in Figure 7-2. In this hypothetical example, a sufficient number of appropriately screened monitoring wells have been installed throughout the neighborhood to characterize a historical groundwater plume. "Near-source" soil gas samples have also been collected from several locations throughout the neighborhood and found to corroborate the measured groundwater concentrations. Indoor air has been sampled and analyzed for a few homes and found to exhibit concentrations that pose an unacceptable human health risk. In this scenario, the assumption can be made that buildings with similar construction and built about the same time may have similar susceptibility to soil gas entry. As a result, it may be determined to use a PEM approach to offer mitigation systems to all buildings within a specified area of subsurface contamination.

[215] Several site-specific factors render inappropriate the use of the recommended attenuation factors and groundwater and soil gas VISLs for purposes of identifying sites or buildings unlikely to pose a health concern through the vapor intrusion pathway, as discussed in Section 6.5.2. Nevertheless, response actions for vapor intrusion can be supported when the groundwater and soil gas VISLs are exceeded for samples from a building or site where these specific factors are present.

[216] EPA recommends basing decisions about whether to undertake response action for vapor intrusion (i.e., a component of risk management) on a consideration of a reasonable maximum exposure (e.g., EPA 1989, 1991a), which is intended to be a semi-quantitative phrase, referring to the lower portion of the high end of the exposure distribution (see Glossary).

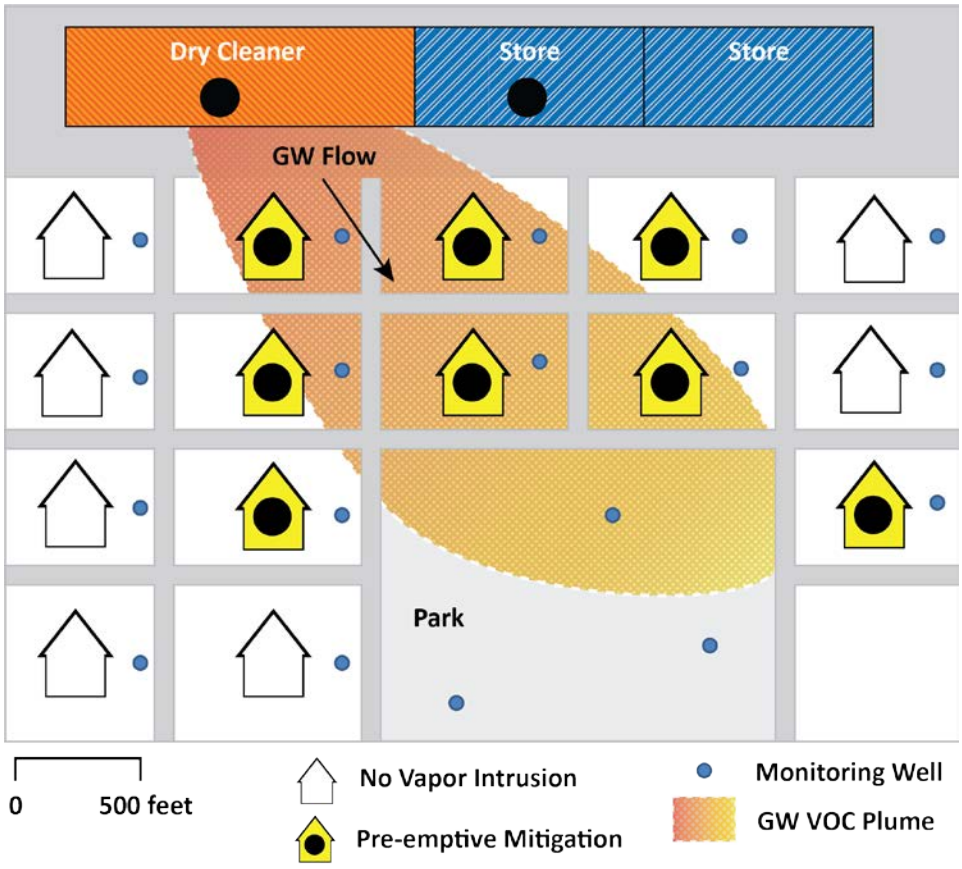

Figure 7-1 Sample Depiction of Subsurface Vapor Source and Data to Support Pre-emptive Mitigation/Early Action for Multiple Buildings, Each with Limited Data

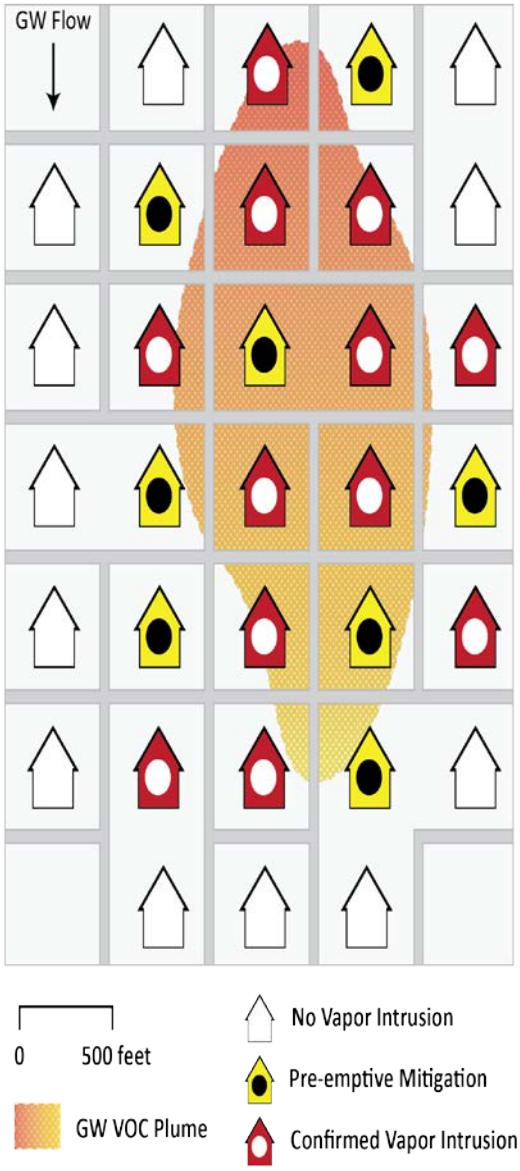

Figure 7-2 Sample Depiction of Subsurface Vapor Source and Data to Support Pre-emptive Mitigation/Early Action for Multiple Buildings, Some with Only Limited or No Data

Future Construction and Development. If current data (e.g., "near-source" soil gas) indicate that there is potential for unacceptable human health risk arising from vapor intrusion in an area where a building(s) is expected to be constructed in the future, EPA recommends that the remediation decision document record the known facts and data analyses and clearly state that vapor intrusion mitigation or site re-evaluation may be needed when the property is developed or occupied. EPA generally recommends appropriate ICs to ensure enforcement of such remediation decisions.[217]

Prior site use (see Section 5) can be particularly relevant where residential development is planned or occurring on property formerly used for commercial or industrial purposes. In these situations, it is not uncommon for residual NAPLs or shallow plumes to remain. Under this circumstance, PEM may be warranted for new construction as a precautionary measure without direct evidence of a vapor intrusion pathway. Incorporating mitigation systems into newly constructed buildings is generally easier to implement and incurs lower cost when compared with retrofitting existing structures.

On the other hand, if response actions to treat or remove the subsurface vapor source(s) are being conducted or will be conducted before a building is constructed and occupied, then building mitigation for the vapor intrusion pathway may not be warranted in the future.

7.8.4 Additional Considerations

EPA recommends that the following factors also be considered in evaluating PEM and determining whether to implement it.

Weighing Relative Costs of Characterization versus Engineered Exposure Controls. EPA recommends that cost not be the primary criterion for deciding whether or how to mitigate vapor intrusion because protection of human health could be compromised. On the other hand, cost effectiveness is addressed by CERCLA and the NCP and can be an important consideration when evaluating response alternatives. Cost can be a factor in deciding when and whether to pursue PEM, in relation to continuing to investigate and assess actual or potential vapor intrusion, and in ensuring effective human health protection through installing and operating a vapor intrusion mitigation system. At PRP-lead sites, for example, PEM may be viewed favorably where the costs associated with a complete site characterization or continued monitoring are estimated to easily exceed the cost of installing a mitigation system (and associated system monitoring). The number of buildings that would need to be characterized, or the order of priority, may be a factor in considering whether to implement PEM.

Institutional Controls. For existing vapor intrusion mitigation systems, ICs may be warranted to ensure that the system is operated, maintained, and monitored. Maintenance and monitoring of the mitigation system, which are discussed in Sections 8.3 and 8.4 of this document, are generally appropriate to ensure that the system is performing as intended. In addition, ICs may facilitate access to property to conduct routine maintenance and monitoring activities, although

[217] At undeveloped sites, or at sites where land use may change in the future, ICs may be important to ensure that the vapor intrusion pathway is effectively addressed in the future. ICs at undeveloped sites could include mechanisms to inform the need for PEM in new buildings. Selecting and implementing PEM for new buildings avoids some of the difficulties associated with attempting to predict the potential for vapor intrusion prior to building construction.

separate access agreements also warrant consideration. Additional information regarding ICs is provided in Section 8.6 of this document.

Community Input and Preferences. Community acceptance of early action may vary widely, depending on the human health risk to building occupants and past experiences at the site, including interaction with site stakeholders and regulators and perceptions of the site. Some owners and occupants may view PEM as a precautionary measure and be willing to have mitigation systems installed; some may even request them before characterization is completed. On the other hand, some home owners may not agree to have a mitigation system installed unless the pathway is demonstrated to be complete.

Others may be reluctant to install mitigation systems because of the operation costs or the inconvenience associated with the installation and subsequent monitoring. Although some owners may view mitigation systems as an advantage when they sell a property, others may be concerned with the possible negative effect on property values.

Issues and concerns about equity and fairness can also arise when some homes within a neighborhood receive mitigation systems and others do not. In some situations, it may be easier to persuade property owners to install vapor intrusion mitigation systems if the entire street, block, or neighborhood is found to warrant early action.

Public meetings and one-on-one meetings provide opportunities to discuss PEM with affected property owners and building occupants and obtain information and input. Section 9.0 of this document provides additional information about community involvement and engagement.

Refined Conceptual Site Model

Decisions to undertake pre-emptive mitigation may warrant re-evaluation as additional monitoring and/or site and/or building characterization data become available and are evaluated in the context of the conceptual site model. If and when such data shift the weight of evidence towards a conclusion that the vapor intrusion pathway is incomplete or otherwise does not pose unacceptable health risk, then EPA recommends re-considering whether continued operation, maintenance, and monitoring of the interim response action (Section 8.2) is warranted.

8.0 BUILDING MITIGATION AND SUBSURFACE REMEDIATION

This section summarizes information and recommendations on potential response options to mitigate and manage vapor intrusion. It is organized as follows:

- Section 8.1 summarizes the role of subsurface remediation in mitigating vapor intrusion.
- Section 8.2 provides an overview of engineered exposure controls (i.e., building mitigation technologies) for existing and new buildings.
- Sections 8.3 and 8.4 summarize information about operating and monitoring building mitigation systems, respectively.
- Section 8.5 summarizes information about documenting building mitigation systems.
- Section 8.6 describes and provides information about institutional controls (ICs).
- Section 8.7 provides information about exit strategies (e.g., termination of: subsurface remediation for vapor source control; building mitigation system operation; and associated ICs).

Sections 5.2, 7, and 9 discuss potential bases for deciding to implement response options for vapor intrusion. Sections 3.3 and 7.7 introduced some of the response options and policies discussed in the remainder of this Section regarding components and development of cleanup plans.

8.1 Subsurface Remediation for Vapor Source Control

The preferred long-term response to the intrusion of vapors into buildings is to eliminate or substantially reduce the level of contamination in the subsurface vapor source (e.g., groundwater, subsurface soil, sewer lines) by vapor-forming chemicals to acceptable-risk levels, thereby achieving a permanent remedy. Remediation of the groundwater plume or a source of vapor-forming chemicals in the vadose zone will eventually eliminate potential exposure pathways and can include the following actions, among others:

- Removal of contaminated soil via excavation;
- Removal of contaminated groundwater with pump-and-treat approaches;
- Decontaminating and/or rehabilitating sewer lines that harbor vapor-forming chemicals; and
- Treatment of contaminated soil and groundwater *in situ*, using technologies such as soil vapor extraction, multiphase extraction, and bioremediation, or natural attenuation.

Because there is a substantial body of EPA and other guidance on selection, design, construction, and operation of technologies for remediation of subsurface vapor sources (e.g., EPA 1993b, 2006c; NRC 2004), these topics are not discussed further here.

When monitoring to assess the performance and effectiveness of remediation technologies for subsurface vapors, EPA recommends employing the methods, approaches, and recommendations described in Sections 5.4, 6.2, 6.4 and 7.0 of this Technical Guide.

ICs may be necessary to help ensure the continued integrity of the cleanup. In some cases, therefore, ICs such as zoning or deed restrictions, may accompany implementation of vapor source remediation methods. Section 8.6 provides information about ICs and their application to the vapor intrusion pathway.

8.2 Building Mitigation for Vapor Intrusion

In cases where subsurface vapor sources cannot be remediated quickly, it may be appropriate to also undertake (interim) measures in individual occupied buildings (i.e., building mitigation for vapor intrusion) to reduce threats to human health more quickly. EPA recommends that building mitigation for vapor intrusion be regarded as an interim action that can provide effective human health protection, which may become part of a final cleanup plan. Mitigation of vapor intrusion in specific buildings generally is not a substitute for remediation of subsurface vapor sources. Thus, EPA recommends that building mitigation generally be conducted in conjunction with vapor source remediation where at all possible.

The purpose of this section is to provide an overview of vapor intrusion mitigation for new and existing buildings where response action is determined to be warranted. Section 8.2.1 summarizes response options that generally can be implemented relatively quickly to reduce indoor air concentrations. Section 8.2.2 identifies and summarizes the most commonly implemented engineered control methods for reducing vapor intrusion into existing buildings. Section 8.2.3 identifies and describes some approaches and considerations for addressing vapor intrusion for new buildings. Additional detailed information about technologies for reducing vapor intrusion into buildings and their selection, design, operation, and monitoring is provided in other EPA documents (EPA 1993a, 2008c). Building owners and occupants may find EPA's *Consumer's Guide to Radon Reduction* (EPA 2013b) a useful source of additional information, in light of similarities in technologies for reducing vapor intrusion and radon intrusion.

ICs may be necessary to help ensure the continued integrity of building mitigation systems. In many cases, therefore, ICs may accompany implementation of engineered exposure controls, for example to ensure that an active system remains operational and passive membranes are not disturbed (EPA 2008c). Additional information about ICs is provided in Section 8.6.

8.2.1 Prompt Response Options for Existing Buildings

For buildings with potential explosion and fire hazards, EPA recommends evacuation, along with notification of the local fire department about the threat. If, on the other hand, prompt action is warranted to reduce or eliminate vapor intrusion exposures in an existing building (e.g., measured indoor air concentrations pose an unacceptable human health risk for an acute or short-term exposure scenario (see Section 7.5.2)), it may be appropriate to implement response options such as the following:

- Sealing major openings for soil gas entry, where known and identified;
- Over-pressurizing nonresidential buildings by adjusting the HVAC system;

- Installing, repairing, or maintaining vapor traps for sewer or drain lines that are sources of vapor intrusion;

- Increasing building ventilation, for example using fans or natural ventilation;

- Treating indoor air (e.g., adsorption using activated carbon); and

- Temporary relocation

The fore-going response actions may take several days to a few weeks to plan (e.g., arrange, design) and implement, which generally is quicker than other interim response actions (e.g., active depressurization technologies). The first three options seek to reduce or eliminate vapor entry into the building. The last three options seek to reduce, eliminate, or avoid vapors that have entered the building by vapor intrusion. Specifically:
