EXECUTIVE SUMMARY

Illinois Power Generation Company (IPGC) conducted groundwater monitoring for Newton Power Plant's Primary Ash Pond (PAP) in the 2nd quarter of 2023. That monitoring found some exceedances of the groundwater protection standards contained in 35 Ill. Adm. Code 845. IPGC concluded that the PAP may have contributed to most of those exceedances. However, IPGC prepared an Alternative Source Demonstration (ASD) under 35 Ill. Adm. Code 845.650(e) for one of the exceedances of the groundwater protection standards (chloride at APW15). The Illinois Environmental Protection Agency (IEPA) issued a denial of the ASD based on three perceived "data gaps."

The ASD contains scientifically supported conclusions based on facts and evidence demonstrating that the chloride exceedance at APW15 was being caused by source other than the PAP and that the PAP did not contribute to the exceedance. The ASD was prepared by a qualified Professional Engineer, who used professional judgment to develop multiple lines of evidence that support the ASD's conclusions, a commonly used, scientifically sound method used for this type of forensic analysis. The multiple lines of evidence included evaluating local hydrogeology (the presence of a low-permeability till that separates the surface impoundment [SI] from the aquifer), contaminant fingerprinting (APW15 did not exhibit expected ratios of chloride and other key coal combustion residuals (CCR) indicator parameters as observed in the SI porewater and in wells carried forward for corrective measure assessment), and contaminant transport/conservation of mass (chloride concentrations were significantly higher in APW15 than potential source concentrations in porewater). IPGC also presented evidence from the Illinois State Geological Survey and published peer-reviewed literature demonstrating that the alternative source was bedrock underlying the screened interval at APW15 with an upward gradient causing a flux of elevated chloride. No additional information is necessary to conclude that the chloride exceedance is caused by another source and is not being contributed to by the PAP.

The IEPA did not concur with the ASD, citing perceived data gaps including total solids sampling in the CCR, and characterization of the alternative source in terms of hydraulic conductivity and chemistry. IEPA's denial letter is sparse on details. None of the perceived data gaps listed in IEPA's denial letter are needed to support the ASD for the PAP. However, in deposition testimony, an IEPA witness who drafted the data gaps in the denial letter suggested that the principle of conservation of mass necessitated the requirement for total solids analysis (a mass balance analysis, in effect) and indicated that a significant field sampling plan consisting of ten borings with three solid samples each were necessary as a first step to characterize the CCR source for any ASD. Part 845 does not include specific sampling and analysis requirements for either the permitting process or the ASD. The requested solid sampling data (either analyzed as total or leachable concentrations) are not necessary and would not add useful information to the ASD because total constituent data (in units of mass of contaminant over mass of solid such as milligrams per kilogram [mg/kg]) are not an input to equations of contaminant transport in groundwater (source concentration is in units of mass contaminant over volume of groundwater such as milligrams per liter [mg/L]). SI porewater data are the best representation of potential water entering groundwater (compared to total or leach test data from CCR solid samples). By itself, total solids sampling of the CCR at the PAP will not provide helpful evidence regarding what has or may have reached the groundwater. While not explicit in IEPA's noted data gaps, those solids could be analyzed for leachability; however, that would require analysis of small amounts of CCR under idealized laboratory conditions that are not reflective of real world conditions to estimate potential leaching. Porewater data are superior in demonstrating what is actually leaching from the PAP, and is the superior method to use in transport modeling and forensic analysis of the potential impact to groundwater from a CCR SI. IPGC completed its demonstration

consistent with the EPA's preferred approach for evaluating a CCR SI's impact to groundwater. Further, from a technical basis, explicit identification of an alternative source is unnecessary to determine that a source other than the PAP is causing the chloride exceedance and that the PAP did not cause or contribute to the exceedance. This demonstration can be accomplished by ruling out the SI as a source. IPGC's submitted ASD ruled out the PAP as a source to APW15 with its three lines of evidence, therefore, it demonstrated that the CCR SI did not contribute to the exceedance and that another source was the cause. Regardless, the ASD presents the best available facts and evidence demonstrating that the source of the chloride exceedance is naturally occurring chloride from underlying bedrock.

Finally, I note that several documents in IEPA's Record are irrelevant to or further support the ASD. Additionally, the IEPA's data gaps would be impossible to collect during the short time period that was available to complete the ASD.

1. INTRODUCTION

Ramboll Americas Engineering Solutions, Inc. (Ramboll) was retained by ArentFox Schiff on behalf of Illinois Power Generation Company (IPGC) to review relevant documents and data and to prepare expert opinions regarding the Alternate Source Demonstration (ASD) for the Newton Power Plant Primary Ash Pond (PAP) located near Newton, Illinois (the "Site") and the Illinois Environmental Protection Agency's (IEPA) denial of this demonstration.

The qualifications of Melinda Hahn, Ph.D. are provided as Attachment A. Dr. Hahn has formed opinions as stated herein to a reasonable degree of scientific and technical certainty. This report includes a discussion of opinions and a discussion of the underlying bases for these opinions. Ramboll reserves the right to supplement or modify this report and its opinions to respond to any new or additional information that may become available after the date of this report, to add additional opinions and to rebut, as necessary, any opinions offered by witnesses in this case. In addition, all opinions provided in my December 15, 2023 Declaration are incorporated herein.

A list of documents relied upon in this report is included in Section 3. Documents relied upon for this report and my December 15, 2023 Declaration not included in the IEPA's Record are provided in Attachment 2.

2. BACKGROUND

This section provides background on basic concepts relevant to IPGC's ASD and IEPA's denial.

2.1 Environmental Sampling and Analysis

Environmental sampling and analysis are fundamental activities that support environmental site investigation, risk assessment, remediation, and environmental regulation. Reliable and reproducible data are necessary for each endeavor. Samples of soil, rock, sediment, or solid waste are considered "solid samples," and samples of groundwater, surface water, leachate, porewater, or wastewater are considered liquid or "aqueous samples."

- A "total" constituent analysis of a solid sample (or what IEPA appears to call a "total solids sample" in its ASD denial letter) yields results in units of mass of constituent over mass of solid (e.g., mg-constituent/kg-solid), usually on a dry weight basis.
- An analysis of contaminant concentration in an aqueous sample yields results expressed as mass of contaminant over volume of water (e.g., mg-contaminant/L-water).
- "Leaching tests" are performed on a solid sample in an effort to predict the chemical quality of water that has been in contact with the solid and received constituent mass transfer from the solid (the "leachate"). A leach test cannot represent all aspects of real world conditions, but is a laboratory simulation where conditions or parameters are selected to attempt to predict the chemical quality of interstitial porewater in a solid under land disposal conditions. Parameters of the leach tests that can impact final results include the liquid-to-solid ratio (L/S ratio), the starting chemistry of the water contacting the solid, or the eluent, the geometry of the system (including either "batch" or "column"), and the contact style and time. After completion of the leach test, the resulting water is called the eluate.
- A "porewater sample" (discussed further below) is a liquid sample of the interstitial water (porewater) within the void space of a solid.

The U.S. Environmental Protection Agency (EPA) has developed a compendium of laboratory analytical tests for solid and liquid samples and procedures for field and laboratory quality control, sampling, for the determination of hazardous constituents in waste, determination of hazardous characteristics of waste, and for the determination of physical properties of wastes. The compendium also contains guidance on how to select appropriate analytical methods. EPA often recommends these methods, collectively known as Test Methods for Evaluating Solid Waste, Physical/Chemical Methods (SW-846), for compliance with the Resource Conservation and Recovery Act (RCRA).[1] However, as stated in the SW-846 abstract and disclaimer, any reliable analytical method may be used to meet RCRA requirements unless Subtitle C of RCRA explicitly requires specific methods for certain applications. Importantly, SW-846 is neither a comprehensive set of procedures nor the only valid procedures used for environmental sample collection and analysis. For example, Clean Water Act methods are not included in SW-846,[2] and EPA has a number of validated methods that have been through extensive review, but are not included in the in the SW-846 Compendium. EPA encourages the use of validated

[2] U.S. EPA Q&A for SW-846, https://www.epa.gov/hw-sw846/frequent-questions-about-sw-846-compendium-and-related-documents

methods as they represent the most current method versions.[3] The American Society for Testing and Materials (ASTM) and the United States Geological Survey (USGS) both publish test methods for analysis of solid and liquid samples. The USGS has used many of its own methods in its studies of properties of both coal and coal ash.

2.2 The Composition of Coal and Coal Combustion Residuals

Coal is formed from peat which consists of loosely consolidated layers of plant and mineral matter. Peat accumulates in wetlands, or peat swamps. Peat swamps are wetlands with appropriate conditions for peat to accumulate over time, including consistent moisture, a stable to slowly sinking land surface, deposition of waterborne or windborne inorganic sediments, and protection from erosional forces. Over millions of years, this peat decomposition and burial under inorganic sediments (compression) with the addition of heat from volcanic sources causes the formation of coal, a complex mixture of organic and inorganic matter with the appearance of well-bedded sedimentary rock.[4] As peat decomposes, it releases elements such as iron, calcium and magnesium that combine with other elements to form minerals such as pyrite (FeS_2) or calcite ($CaCO_3$) in the resulting coal.

Components of coal are primarily carbon and oxygen, but elements of potential environmental concern such as arsenic, cadmium, molybdenum and selenium are often present at trace levels (i.e., part per million).[5] Coal also contains elements known as halogens, including chlorine and bromine. The mean concentration of chlorine (Cl) in U.S. coals is 614 mg/kg.[6]

The behavior of trace elements of coal in pulverized-coal-fired boilers is dependent on relative element volatilities. Highly volatile elements such as mercury are released to air, others remain in the ash, but most have more intermediate behavior and are both emitted and retained within ash to some degree.[7] The materials that remain are called coal combustion residuals or CCR. Types of CCR include fly ash, bottom ash, boiler slag, and flue-gas desulfurization (FGD) materials. Fly ash is a product of burning finely ground coal that is removed from the exhaust gases. It is a fine, powdery material. Bottom ash is CCR that is too large to be entrained with flue gas and is collected from the bottom of the furnace. Bottom ash typically has grain sizes similar to sand or gravel. Boiler slag is molten bottom ash that has been quenched with water. It has hard, black angular particles that have a smooth, glassy appearance. FGD material is a byproduct of emission control equipment designed to reduce sulfur dioxide emissions from the boiler. The state of this material (wet sludge or dry powdered material) depends on the process. CCRs that are not reused are managed in wet or dry disposal systems. In wet systems, CCRs are sluiced to a surface impoundment (SI). In dry systems, CCRs are transported to landfills for disposal.[8]

2.3 CCR Surface Impoundments and Migration of CCR Constituents into Groundwater

A CCR SI is a facility or part of a facility that is a natural topographic depression, man-made excavation, or diked area, which is designed to hold an accumulation of CCR and liquids, and the SI treats, stores, or disposes of CCR.[9] CCR SIs are used to receive CCRs that have been sluiced (flushed or mixed with water to facilitate movement) or wastes from wet air pollution control devices often in addition to other related solid and liquid wastes such as coal pile runoff, coal mill rejects, boiler blowdown, cooling tower wastes, storm water, etc.[10] Solids tend to sink to the bottom over time and become consolidated due to the pressure of the overlying materials.[11] A conceptual cross section of a CCR SI is shown in Figure 1.

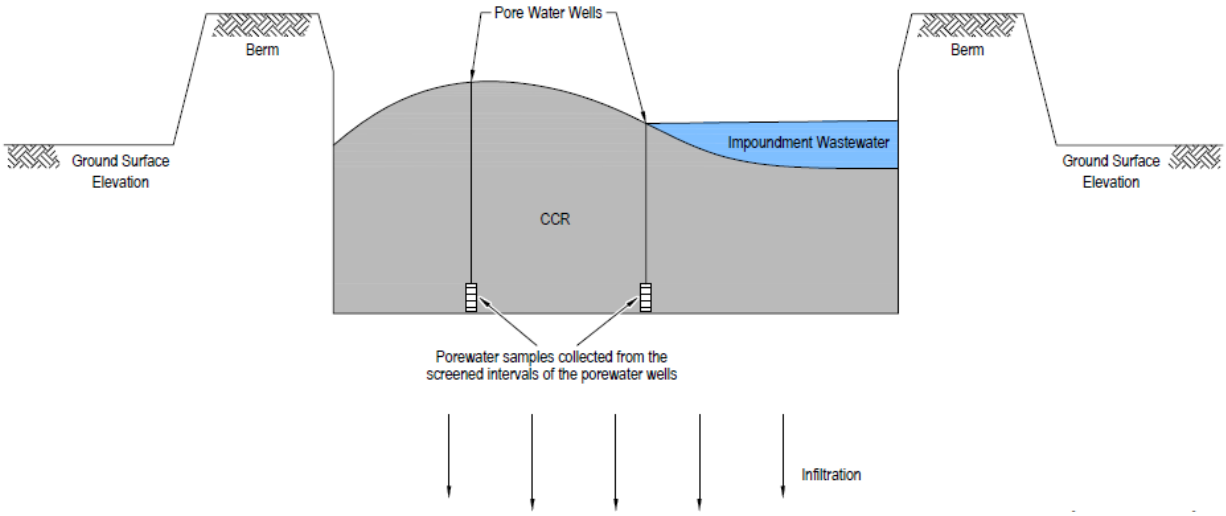

Figure 1: Conceptual Model Cross Section View of CCR Surface Impoundment

Chemical constituents are primarily released from unlined SIs through the leaching of constituents from CCR particles into the interstitial water (i.e., water in the CCR pore space, also known as porewater) and subsequent migration of the porewater to native material. Leaching is dependent on the porewater pH and the local L/S ratio within the impoundment. The L/S ratio represents the cumulative amount of water passing through the total mass of CCR subject to leaching (L-water/kg-CCR) and depends on many factors including the initial concentration of the disposed slurry, the addition of new materials, evaporation, precipitation, and runoff, decanting or dewatering, and settling of solids and consolidation or compaction of solids at the base. Porewater pH depends on the chemical nature of the CCR and comanaged materials and the L/S ratio. Both pH and L/S ratio can vary with time and space in a CCR SI. The L/S ratio begins relatively high in the disposed slurry and decreases as solids settle and consolidate. LS is lower at the base of the SI where compressed CCR has less pore space for water to occupy. A leach test requires selecting an eluent pH and an L/S ratio for the test system. Given the variation of pH and L/S ratio at a CCR SI over time and space, laboratory leach tests have limited value in estimating actual leaching from a CCR SI.

[11] U.S. EPA, Human and Ecological Risk Assessment of Coal Combustion Wastes, August 2007, p. 3-15.

Porewater at a CCR SI is sampled with monitoring wells set in the CCR (Figure 1 shows monitoring wells set at the base of the SI). Typically, low-flow sampling techniques are used to collect porewater samples to reduce the turbidity of the samples. It is important to reduce turbidity to collect a sample that is representative of the water that may migrate rather than the CCR solids that may have been disturbed in the process of collecting a water sample. Porewater has the potential to percolate (migrate) downward into the subsurface soil and mix with groundwater. The CCR constituents can then be transported underground through the groundwater in the direction of groundwater flow, thus potentially causing a CCR SI to contribute to groundwater contamination. Exposures to CCR constituents could potentially occur if contaminated groundwater migrates to a downgradient well used as a source of drinking water, or to a downgradient surface water body where human receptors may be exposed through the ingestion of fish and ecological receptors may be exposed to contaminated water or sediment.[12]

A witness for IEPA has suggested that the principle of conservation of mass logically triggers sampling requirements for total constituents in CCR for an ASD.[13] However, the governing equations for models of contaminant transport in groundwater that are derived from the principle of conservation of mass do not depend on the total constituents in a solid such as CCR. Instead, the principle of conservation of mass in a groundwater system evaluates the rate of change of mass as an aqueous unit volume (i.e., mass of contaminant per groundwater volume or concentration) and reflects the balance between aqueous inputs and outputs from physical and chemical processes such as advection, dispersion, diffusion, decay and chemical reaction. Groundwater contaminant transport models can be complex and solve the governing equation describing the physical and chemical processes for contaminant concentration within a groundwater plume in three dimensions and time, or simplifying assumptions can be made to allow an analytic solution with a simple equation. Illinois uses one such simplification of the solution to this equation (the "Domenico" equation, or R26 in 35 IAC 742) as adopted in the ASTM Risk-Based Corrective Action Standard[14] to describe one-dimensional groundwater contaminant transport downgradient from a source (additional simplifying assumptions include steady state and no chemical reactions or processes other than decay) for sites seeking regulatory closure in its Site Remediation Program.[15] This equation is shown below:

$$C_{(x)} = C_{source} \bullet \exp\left[\left(\frac{X}{2\alpha_x}\right) \bullet \left(1 - \sqrt{1 + \frac{4\lambda \bullet \alpha_x}{U}}\right)\right] \bullet erf\left[\frac{S_w}{4 \bullet \sqrt{\alpha_y \bullet X}}\right] \bullet erf\left[\frac{S_d}{2 \bullet \sqrt{\alpha_z \bullet X}}\right]$$

where C(x) is the contaminant concentration in groundwater at location x (in mg/L), C_{source} is the source concentration in groundwater (mg/L), x is the distance downgradient along the center line of the plume, Sw and Sd are source widths and depths in cm, U is the specific discharge (contaminant velocity) in cm/d, the α's are dispersivity values in units of cm, and λ is the decay constant in units of d^{-1}. The mass of the contaminant in an associated soil or solid source is *not* an input to this equation.

[15] Illinois Title 35 Part 742 Tiered Approach to Corrective Action Objectives, Appendix C, Table C, Equation R26.

The source concentration and the downgradient concentrations at "x" distances are all concentrations in groundwater.

Evaluation of this equation and the resulting contaminant concentrations reveals that downgradient concentrations of contaminants in groundwater are greatest along the primary axis of the groundwater plume (in the downgradient direction) and lower in off-axis locations (cross-gradient). Also, downgradient concentrations are always lower than the source concentration in groundwater (C_{source}) due to attenuating processes such as dispersion, diffusion, decay and adsorption. This observed attenuation is a direct consequence of the principle of conservation of mass.

Constituents in groundwater that are not subject to decay, adsorption, or other chemical processes will travel in groundwater at approximately the same speed as the groundwater itself. These are known as conservative solutes. Sodium and chloride are examples of conservative solutes. Conservative solutes, like all solutes, exhibit decreasing concentrations moving downgradient from a source due to dispersion and diffusion. Conservative solutes can be useful in tracing groundwater flow direction and speed.

2.4 Characterizing Potential Leaching of CCR Contaminants

EPA has done extensive work to characterize both total and leachable concentrations for contaminants of potential concern (COPCs) in CCR in preparation for rulemakings over many decades. Through this work, EPA has created a model for pathway of migration of COPCs from CCR SIs that is consistent with the approach contained within IPGC's ASD. EPA's work has led the Agency to conclude that porewater sampling is the most appropriate method to characterize the potential impact of a CCR SI upon groundwater.

In the 1980s and 1990s, EPA collected leach test data to evaluate whether CCR should be regulated as a hazardous waste. EPA's 1988 Report to Congress contained data from multiple leach testing procedures including Extraction Procedure Toxicity test (EP Tox), Toxicity Characteristic Leaching Procedure (TCLP), ASTM leach tests, and column tests (early precursors of Leaching Environmental Assessment Framework, or LEAF tests) for multiple types of CCR, primarily fly ash and FGD material. The results supported EPA's determination that CCR is not subject to RCRA Subtitle C regulation. In 1999, EPA updated its report to Congress, this time addressing CCR and other low volume waste streams that are often co-disposed in SIs and landfills, such as coal pile runoff, coal mill rejects, boiler blowdown, cooling tower wastes, etc. These low-volume comanaged wastes and high-volume CCR wastes will generally have the characteristics of the high-volume fraction, but differences can be apparent in localized areas of a waste management unit.[16] Based on data from pore waters and TCLP data, EPA determined that comanaged wastes do not exhibit the characteristics of hazardous waste. EPA again concluded that CCR reuse or disposal of comanaged CCR wastes should not be regulated under RCRA Subtitle C.

EPA did not conclude from the leach test results and porewater data, however, that comanaged waste are incapable of mobilizing constituents at levels of concern. To assess potential risks to human health and the environment, EPA used porewater data from some comanaged wastes to model migration from CCR SIs to groundwater. Porewater data were used instead of TCLP data for fate and transport modeling and in turn risk assessment purposes because "(1) they represent actual leachate conditions

[16] EPA, Report to Congress: Wastes. from the Combustion of Fossil Fuels, Vol. 1 – Executive Summary, March 1999, EPA 530-S-99-010m p. 3-15

at the sampled sites, and (2) a larger and more representative database exists for pore water analyses than for TCLP analyses."[17] Early EPA risk assessment results indicated that of CCR constituents, only arsenic had the potential to migrate from CCR SIs to drinking water wells above health-based levels.

In support of a more comprehensive multi-pathway human health and ecological risk assessment of land disposal of CCR in 2007, EPA assembled a source characterization database of total and leachate sample results for 41 CCR constituents taken from more than 140 CCR disposal sites, including SIs and landfills around the country.[18] The constituents evaluated are shown in the table below. Waste streams included both conventional fly ash, bottom ash, mixed ash, and comanaged materials. Leachate data included actual porewater sample results for SIs and TCLP data for landfills (available data for landfills were mainly TCLP).[19] This data set was an improvement over that used in the 1990s as it included data on the major ions in CCR leachate such as calcium, chloride, sulfate and pH.[20]

[20] EPA, Human and Ecological Risk Assessment of Coal Combustion Wastes, Draft, 2007, p. 2-2.

Increasing use of air pollution control systems at U.S. coal-fired power plants and the need for evaluation of comanaged residues in land applications and beneficial reuse prompted EPA to further characterize the nature and leaching potential of comanaged CCR in a range of field conditions in 2009.[21] EPA tested both total and leachate constituent concentrations for CCR samples from multiple facilities with different types/ranks of coal and air pollution control processes and came to the following conclusions:[22]

> The major conclusions from this research include:
>
> - There is great variability in both the range of total constituent concentration values and in leaching values (orders of magnitude). In comparing there results to health indicator values such as the maximum concentration limit or toxicity characteristic, there are multiple COPCs of potential concern.
> - Distinctive patterns in leaching behavior have been identified over a range of pH values that would plausibly be encountered for CCR management.
> - Total constituent content is not a good indicator of leaching which has been found to be a function of the characteristics of the material (pH) and field conditions in which the material is managed.
> - The maximum eluate concentration from leaching test results varies over a wide range in pH and is different for different CCR types and elements. This indicates that there is not a single pH for which testing is likely to provide confidence in release estimates over a wide range of disposal and beneficial use options, emphasizing the benefit of multi-pH testing. Furthermore, for CCRs, the rate of constituent release to the environment is affected by leaching conditions (in some cases dramatically so), and that leaching evaluation under a single set of conditions will, in many cases, lead to inaccurate conclusions about expected leaching in the field.

EPA analyzed total metal content of CCR samples using ICP-MS or ICP-AES SW-846 methods or by X-Ray Fluorescence (XRF) Spectroscopy. CCR total chloride content was measured by XRF and found to range between approximately 80 to 10,000 mg/kg in concentration.[23] Leach test results were found to vary by orders of magnitude with eluent pH and L/S ratio. Leachate concentrations are greatest at the lowest L/S ratios and decrease with increasing L/S ratio.[24] One question that EPA sought to answer in this study was whether or not total content of an element in a CCR sample (e.g., mg-COPC/kg-CCR) is a useful indicator of potential environmental impact by leaching. The results showed: (1) there is poor correlation between leachate concentration and total content of any of the elements considered, (2) a wide range of total content values (over more than an order of magnitude) can result in the same or very similar eluate concentrations, and (3) a wide range of eluate concentrations (over more than an order of magnitude) are observed for CCRs with similar total content values. If leaching were correlated closely with total concentration, the data would have

[21] EPA, Characterization of Coal Combustion Residues from Electric Utilities- Leaching and Characteristic Data, 2009, p. 1

[22] EPA, Characterization of Coal Combustion Residues from Electric Utilities- Leaching and Characteristic Data, 2009, p. ii.

[23] EPA, Characterization of Coal Combustion Residues from Electric Utilities- Leaching and Characteristic Data, 2009, p. 74.

[24] EPA, Characterization of Coal Combustion Residues from Electric Utilities- Leaching and Characteristic Data, 2009, p. 52.

shown strong linearity, rather than significant scatter. This indicates that constituent leaching is better characterized by collecting porewater samples than by estimating based on total constituent concentration alone or with use of linear Kd partitioning values.

In 2014, EPA updated and finalized its probabilistic risk assessment of land disposal of CCR to human and ecological receptors from CCR disposal practices. The final assessment built on its prior assessments of CCR disposal in SIs and landfills in that it incorporated new data and addressed comments received by independent external peer reviewers and public commenters on the methodology, data sources, and assumptions used by the Agency. By this time, EPA had expanded its database to include data from 384 facilities with on-site CCR WMUs for a total of 953 SIs and 431 landfills.[25] For the groundwater pathway screening analysis, EPA used the 90th percentile of SI porewater concentrations to represent the source concentration of each constituent, and applied a dilution attenuation coefficient to account for reduction in concentration associated with migration to a downgradient receptor.[26] For the full probabilistic analysis, EPA used the porewater data distributions from its database for each waste type to represent the source concentration release from a SI as porewater samples best reflect leachate as it is released into underlying soils.[27] "Pore water data were collected from core samples both in and beneath SIs. Since the cores take leachate directly from the field, these data are known to represent field conditions and no further comparison is necessary."[28]

In its response to comments on the federal CCR disposal final rule in 2015, EPA stated that, even with the advent of the LEAF methods for leach testing, the use of porewater data is still considered the most appropriate approach to estimate constituent fluxes to groundwater for CCR SIs. This is because sufficient site-specific pH data was not available to probabilistically assign LEAF data to modeled units, and because there was no way to account for partitioning of the leachate into wastewater versus porewater.[29]

2.5 The Newton PAP ASD and Denial

The Newton PAP is an unlined CCR SI that was constructed in 1977 and has a design capacity of approximately 9,715 acre-feet. It currently receives bottom ash, fly ash, storm water runoff and low-volume wastewater from the plant's two coal-fired boilers. IPGC submitted to IEPA a Hydrogeological Characterization Report for the PAP in October 2021 that contains aquifer characterization information, leachate quality data, and upgradient and downgradient monitoring well data. IPGC also submitted an operating permit application for the PAP in October 2021 that includes additional information including waste types disposed and waste characterization data (as total concentration). Currently, IPGS is conducting quarterly monitoring of groundwater wells about the PAP.

In the second quarter of 2023, IPGC reported several groundwater protection standard exceedances at the PAP, including chloride at well APW15, and lithium, sulfate, and total dissolved solids (TDS) at

[25] EPA, Human and Ecological Risk Assessment of Coal Combustion Residuals, Final Report, December 2014, p. 2-7.

[26] EPA, Human and Ecological Risk Assessment of Coal Combustion Residuals, Final Report, December 2014, p. 3-18.

[27] EPA, Human and Ecological Risk Assessment of Coal Combustion Residuals, Final Report, December 2014, p. 4-5.

[28] EPA, Human and Ecological Risk Assessment of Coal Combustion Residuals, Final Report, December 2014, p. 5-47

[29] EPA, 80 FR 21302 40 CFR Parts 257 and 261 Hazardous and Solid Waste Management System: Disposal of Coal Combustion Residuals from Electric Utilities, Final Rule April 17, 2015, p. 21442.

several other wells.[30] The lithium, sulfate and TDS exceedances were carried forward for evaluation of corrective measures under Part 845, but an ASD was prepared for the chloride exceedance at well APW15. Evidence demonstrated that the Newton PAP was likely contributing to the lithium, sulfate, and TDS exceedances. Groundwater chemistry at the wells with those exceedances was similar to porewater chemistry, but concentrations did not exceed porewater concentrations, and the wells with those exceedances were also located closer to the PAP both horizontally and vertically than APW15. These observations suggested that the exceedance wells carried forward for a corrective measures evaluation under Part 845 would benefit from corrective measures at the SI, but APW15 would not.

The three lines of evidence (LOEs) supporting the ASD for chloride in APW15 presented in the October 3, 2023 ASD report are as follows:

i) LOE 1: The thick layer of low permeability till that separates the PAP from the screened aquifer in APW15 prevents vertical migration of CCR constituents;

ii) LOE 2: Primary CCR indicators, boron and sulfate, do not exceed background limits and are not increasing at APW15; and

iii) LOE 3: Concentrations of chloride at APW15 are greater than PAP porewater concentrations.

The ASD report also noted that concentrations of chloride at APW15 are consistent with published data for regional bedrock aquifer quality and the observation of a saline spring (that establishes the presence of an upward hydraulic gradient) within approximately 10 miles of the Newton Power Plant, suggesting that the underlying bedrock aquifer is the alternative source of chloride in well APW15.

In its November 7, 2023 letter, the IEPA denied the ASD due to the following perceived data gaps:

i) Source characterization of the CCR at the PAP must include total solids sampling in accordance with SW-846.

ii) Hydraulic conductivities from laboratory or in-situ testing must be collected, analyzed, and presented with hydrogeologic characterization of the bedrock unit.

iii) Characterization to include sample and analysis in accordance with 35 IAC 845.640 of alternative source must be provided with the ASD.[31]

[30] Ramboll, Groundwater Monitoring, Data and Detected Exceedances, Quarter 2, 2023, August 7, 2023.

[31] In deposition testimony, Ms. Lauren Hunt of the IEPA stated that the third data gap refers only to 35 IAC845.640(a). This section states that the CCR SI owner or operator must develop a sampling and analysis plan for its groundwater monitoring program that includes procedures for sample collection, preservation and shipment, analytical procedures, chain of custody and quality assurance/quality control. Ms. Hunt suggested that this documentation, including laboratory reports, are required for any sampling of the alternative source and the CCR SI. (May 28, 2024 deposition transcript at pp. 88-93). This data gap only references the alternative source. Regardless, and without agreeing it is required, I note that this documentation was provided to IEPA for the porewater samples of the Newton PAP. Ramboll, Groundwater Monitoring, Data and Detected Exceedances, Quarter 2, 2023, August 7, 2023.

3. OPINIONS

3.1 Alternative Source Demonstration Requirements

Opinion 1: The ASD requirement (Part 845.650(e)) can be met by ruling out a SI as a source of contamination to the exceeding well.

Illinois promulgated regulations regarding disposal of CCR in SIs in 2021. Among those provisions is, in the event of an exceedance of a groundwater protection standard at a monitored compliance well, that the owner or operator must either begin the assessment of corrective measures process, or within 60 days, submit a demonstration to the Agency that a source other than the CCR SI caused the contamination and the CCR SI did not contribute to the contamination, or that the exceedance of the groundwater protection standard resulted from error in sampling, analysis, statistical evaluation, natural variation of groundwater quality, or a change in the potentiometric surface and groundwater flow direction (i.e., an ASD).[32] I am not providing a legal opinion here regarding the interpretation of Part 845.650(e); however, from a scientific basis, the requirement to determine that "a source other than the CCR SI caused the contamination" can be met by ruling out the CCR SI as a source of the contamination. Notably, Part 845 is not a site-wide remediation program and does not contain provisions requiring corrective action or remediation concerning any source other than CCR SIs. It is designed to address risks associated with CCR SIs and if the CCR SI is not a source of the contamination, then the groundwater corrective measures requirements of Part 845 are inapplicable. If Part 845 is a site-wide remediation program, it would be appropriate to read into 845.650(e) a requirement to identify with specificity an alternative source because a site-wide remediation program is intended to address all sources, not one specific source. As it stands, Part 845 does not build in a timeline or process for such identification.

Opinion 2: Determining whether or not a potential source is a contributing source of observed environmental contamination requires engaging in the process of environmental forensic analysis. A multiple lines of evidence analysis is a commonly used, scientifically supported method by which to conduct an environmental forensic analysis.

Environmental forensic analysis seeks to make causal determinations regarding the source of observed contamination, and often relies on a multiple lines of evidence (MLE) approach as a standard practice.[33,34,35,36,37] The MLE approach involves analysis of multiple independent sets of data or information and analysis to test whether an identified source can explain observed data. Information

[37] EPRI, Guidelines for Development of Alternative Source Demonstrations at Coal Combustion Residual Sites, 2017 Technical Report, p. viii.

to consider can be site-specific, regional, or from the literature.[38,39] These independent lines of evidence are developed until sufficient confidence is achieved to either confirm or rule out a source.[40] Rarely is an environmental remediation professional required to collect all of the quantitative data necessary to perform a complex conservation of mass analysis.

Instead, environmental remediation professionals use their judgment and rely on commonly accepted lines of evidence to identify or rule out sources. Typical lines of evidence can include but are not limited to diagnostic ratios of key contaminant concentrations, multivariate contaminant fingerprinting (use of multiple relative abundances, or concentration ratios, of key source constituents), hydrogeologic information such as aquifer hydraulic conductivities and gradients, the spatial distribution of contamination and consistency with models and concepts of contaminant migration, historical evidence from documents, maps or photos, and isotopic analysis for age dating or identification. Diagnostic constituent ratios and fingerprinting analysis are most often used because they rely on commonly collected data. EPA has developed its own contaminant fingerprinting tool: Fingerprint Analysis of Leachate Contaminants (FALCON) in response to the need for identifying the source of groundwater contaminant plumes.[41] FALCON relies on differences in relative abundances of key chemical parameters to develop a distinctive graphical fingerprint or multi-parameter chemical signature. These fingerprint patterns can be used to identify the source of a contaminant plume, differentiate the contaminant plume from background conditions at the source, and monitor the migration of leachate into the environment.[42] None of these accepted forensic methods of data analysis require the calculation of a mass balance with constituent concentration data from solid samples of the potential sources and impacted groundwater.

Opinion 3: There is no "cookie cutter" data set for conducting an ASD. It requires independent professional judgment.

Conducting a forensic analysis for an ASD requires gathering and evaluating available facts and evidence, based on site characteristics within the time-period provided for conducting the ASD. Deposition testimony from an IEPA employee involved in reviewing the ASD and drafting the "data gaps" included statements suggesting the type of data included in the purported "data gaps," characterizing the CCR source and the alternate source (i.e., solids sampling of the CCR source and direct sampling of the alternate source) are necessary as a baseline to begin an ASD.[43] This is not true. Based on my technical experience and review, I am aware of no requirements for such baseline data to be presented with an 845.650(e) ASD, including through Illinois regulations or guidance. Rather, in my experience, an ASD (and similar forensic analyses) will typically include multiple lines of

[43] Lauren Hunt deposition, May 28, 2024, pp. 66-68.

evidence that rely on available data.[44] There is a wide variety of chemical and hydrogeologic data (including background groundwater quality, porewater data, the geometry of the system, hydrogeologic data such as hydraulic conductivities and gradients) and analytical techniques (including fingerprinting, contaminant fate and transport modeling, isotopic comparisons, etc.) that could be used in the assessment and the process is dependent on the professional judgment of the professional engineer (PE) tasked with completing the ASD. As discussed further below, the Newton PAP ASD's conclusions are sound and the ASD analysis was conducted using the best available data and analytical techniques available for the site and circumstances.

Significantly, 845.650(e) does require that the ASD include a report that contains the factual, evidentiary, and logical basis for any conclusions and a certification of accuracy prepared by a qualified PE. A PE has satisfied educational requirements in collegiate engineering, gained sufficient experience, and has passed a licensing exam. Section 845.650(e) does not specify any particular data or analytical requirements necessary to complete an ASD, so some amount of professional judgment is required. Consistent with standard scientific practice for forensic analysis, the PE must draw conclusions based on reliable data using standard analytical techniques to a reasonable degree of scientific certainty such that a reasonable engineer or scientist would agree.

3.2 IPGC's ASD is Sufficient to Exclude the PAP as a Source of Chloride to APW15

Opinion 4: The lines of evidence presented in the PAP ASD are sufficient to conclude that coal ash in the PAP is not a source of the chloride concentrations observed in monitoring well APW15, and that those concentrations are consistent with adjacent natural groundwater quality.

Opinion 5: LOE 1 is based on appropriate supporting facts and evidence and is sufficient to establish that there is not a viable migration pathway between the PAP and APW15.

LOE 1 stated that the thick layer of low permeability till between the base of the PAP and the screen of APW15 would prevent vertical migration of CCR leachate to APW15. In order for the PAP to contribute to chloride concentrations in APW15, a pathway needs to exist for chloride from the PAP to reach APW15. For this LOE, IPGC relied upon the boring and well log for APW15 from the PAP construction permit application that shows approximately 60 feet of till separating the PAP from the screened interval of APW15, and hydraulic conductivity data that shows a vertical conductivity of 10^{-8} cm/s from the PAP's Hydrogeologic Site Characterization Report. This low hydraulic conductivity (consistent with an aquitard rather than an aquifer) means that any vertical seepage would occur at such a slow rate that the potential porewater travel time through the 60-foot layer would be much greater than the age of the SI, thereby ruling out the PAP as the source of the exceedance.

None of IEPA's perceived data gaps relate to the collection of facts or evidence that would further support or disprove LOE 1. If the information requested in IEPA's perceived data gaps was collected it could not disprove the evidence or conclusions contained within this LOE. None of IEPA's requested data could change the conclusion that there is no viable migration pathway between the PAP and APW15.

Opinion 6: LOE 2 is based on appropriate supporting facts and evidence and is sufficient to establish that the groundwater chemistry at APW15 is inconsistent with an impact from the PAP.

[44] U.S. EPA, Office of the Science Advisor, Risk Assessment Forum, Weight of Evidence in Ecological Assessment, EPA/100/R-16/001, December 2016, p. 1.

LOE 2 states that primary CCR indicator constituents boron and sulfate are not present above background limits and are not increasing in APW15. IPGC relied on multiple rounds of groundwater data from upgradient and compliance wells around the PAP, and multiple porewater samples from four monitoring wells installed at the base of the CCR within the PAP (porewater wells) using low-flow sampling techniques in support of this conclusion.[45] The porewater wells are installed at four locations along a cross-section of the PAP in order to capture variability across the SI. The porewater data are representative of the range of leachate quality potentially leaving the PAP because they were collected at the base of the SI (where L/S ratios should be lowest and leachate concentrations highest) in multiple locations over multiple sampling events. The groundwater and porewater data and the background analysis are included in the Hydrogeological Characterization Report, Groundwater Monitoring Plan, and the 2nd Quarter Groundwater Monitoring Report for the PAP referenced in IPGC's ASD.

As discussed above, the relative abundances (or concentration ratios) of key waste constituents can be used as a fingerprint in forensic analysis. The CCR fingerprint for groundwater impact can be defined by the relative abundances of boron, sulfate, and chloride in the porewater as these analytes all behave conservatively in groundwater (i.e., they are likely to travel together at a similar rate in groundwater without being influenced by chemical processes or decay thereby maintaining similar concentration ratios). In its final rulemaking for CCR land disposal, EPA identified the following CCR constituents as indicator parameters for CCR detection monitoring: boron, chloride, fluoride, pH, sulfate and TDS. These parameters are commonly observed in CCR leachate. Out of all constituents in CCR and CCR leachate, EPA determined that these parameters would behave most conservatively (flow with groundwater) in an aquifer, and when observed together in monitoring wells, might signal a CCR release is impacting that well.[46] Also, EPA determined that, out of all the coal ash constituents modeled, boron has the fastest travel time, meaning that boron is likely to reach potential receptors (or a well that is being impacted) before any other constituents, [47] although this difference is likely to be small for other constituents that behave like conservative solutes in groundwater such as sulfate and chloride.

The evidence presented in LOE 2 shows that the boron, sulfate, and chloride fingerprint at APW15 is marked by only background levels of boron and sulfate, but significantly elevated chloride. On the other hand, the CCR porewater data have elevated concentrations of boron and sulfate, but concentrations of chloride consistent with background. In other words, the ratio of chloride to boron and chloride to sulfate is much lower in APW15 than the ratios that exist in PAP porewater. The CCR SI is not a source of chloride at APW15 because it is not accompanied by either boron or sulfate. On the other hand, the CCR indicator concentrations in wells with exceedances attributed to the PAP have ratios similar to the porewater.[48] The ASD further reported that the boron and sulfate concentrations at APW15 are not increasing with time, as one would expect if CCR leachate was migrating to APW15. The lack of an increasing trend of boron and sulfate further supports that the PAP is not contributing

[46] EPA, 80 FR 21302 40 CFR Parts 257 and 261 Hazardous and Solid Waste Management System: Disposal of Coal Combustion Residuals from Electric Utilities, Final Rule April 17, 2015, p. 21342.

[47] EPA 83 FR 11584, Hazardous and Solid Waste Management system: Disposal of Coal Combustion Residuals from Electric Utilities; Amendments to the National Minimum Criteria (Phase one); Proposed Rule, March 15, 2018, p. 11588.

[48] Ramboll, Hydrogeologic Site Characterization Report, Primary Ash Pond, Newton Power Plant, October 25, 2021, Table 4-1.

to the chloride exceedance in APG15. This line of evidence is consistent with EPA's own FALCON fingerprinting method, discussed above, because both methods rely on a comparison of the relative concentrations of key constituents in sources and impacted groundwater.[49]

None of IEPA's perceived data gaps relate to the collection of facts or evidence that would further support or disprove LOE 2. If the information requested in IEPA's perceived data gaps was collected it could not disprove the evidence or conclusions contained within this LOE i.e. none of IEPA's requested data could change the conclusion that the concentrations and concentration trends of chloride, boron and sulfate in APW15 indicate that the Newton PAP is not contributing to the chloride exceedance in that well and that it is, thus, being caused by an alternate source.

Opinion 7: LOE 3 is based on appropriate facts and evidence sufficient to establish that the chloride concentrations observed could not have come from the PAP SI.

LOE 3 provides evidence that the concentration of chloride in APW15 is significantly (four to ten times) greater than chloride in the porewater data. This LOE is based on the same underlying data as LOE 2 above. As discussed in Section 3.3, contaminants being transported in groundwater experience decreasing concentrations moving away from the source due to the principle of conservation of mass (contaminant transport equations are derived from this principle). Porewater represents the maximum source concentration to underlying groundwater. Meaning, if chloride is leaching from the Newton PAP, its maximum concentration would be expected to be found in the porewater samples gathered from the base of the PAP (as that is the last possible input of mass from the CCR to the porewater that could leach from the PAP). Chloride concentrations would then decrease moving vertically from the base of the SI downward to the uppermost aquifer (assuming such a pathway existed, though evidence suggests it does not given the 60 feet of low permeability till), and would continue to decrease moving horizontally downgradient within the uppermost aquifer to APW15 due to dilutive processes such as dispersion and diffusion.

Therefore, it follows from the principle of conservation of mass (and the resulting equations for contaminant transport in groundwater such as R26 from TACO) that, in the event of a release from a CCR SI, the CCR constituent concentration in groundwater at a downgradient monitoring well would necessarily be less than the porewater (source) concentration. For the PAP, the maximum chloride concentration at well APW15 is four times the maximum porewater concentration, and the median APW15 chloride concentration is more than an order of magnitude higher than the median porewater concentration in the PAP. This indicates that the PAP is not the source of elevated chloride at APW15.

None of IEPA's perceived data gaps relate to the collection of facts or evidence that would further support or disprove LOE 3. If the information contained in IEPA's perceived data gaps was collected it could not disprove the evidence or conclusions contained within this LOE i.e. none of IEPA's requested data could change the conclusion that chloride concentrations at APW15 are much higher than chloride concentrations in Newton PAP porewater and that the chloride in APW15 is therefore not from the Newton PAP but, rather, is from an alternative source.

Opinion 8: Given the three strong LOEs (consistent with EPA's practice of modeling potential groundwater impacts from CCR SIs using porewater concentrations) presented in the ASD – including the lack of a viable vertical pathway, the lack of corroborating CCR indicator parameters at APW15 as

[49] U.S. EPA, Technical Support Center Issue, Fingerprint Analysis of Contaminant Data: A Forensic Tool for Evaluating Environmental Contamination, EPA/600/5-04/054, May 2004.

observed in porewater, and chloride concentrations at APW15 greater than is physically possible from a release of the observed porewater – a reasonable scientist or engineer would conclude that the Newton PAP is not causing or contributing to the observed chloride exceedance at APW15. Since the Newton PAP can be ruled out as a source, then the chloride must be coming from an alternate source.

Opinion 9: The ASD identified an alternative source using best available information.

IPGC's ASD also provided evidence that the underlying bedrock aquifer is the source of the chloride exceedance in APW15. This included providing facts and evidence demonstrating the close proximity (within approximately 10 to 15 feet vertically) of the screened interval at APW15 to underlying bedrock based on PAP boring logs, the naturally occurring elevated concentrations of chloride in the underlying bedrock aquifer, and the local upward gradients based on the presence of a saline spring within approximately ten miles of the PAP. IPGC's ASD relied on two key documents for this information.[50] The first is an article published by the National Groundwater Association called "Groundwater" (the "Panno article").[51] This article provides information regarding the chloride content of bedrock aquifers in southern Illinois. Chloride content of the uppermost bedrock aquifer as presented in the Panno article does not show significant variability across southern Illinois, so site-specific data are not necessary to identify the bedrock as an alternative source. The figure below[52] shows chloride concentrations in bedrock aquifers along a west-to-east cross section in southern Illinois, including Jasper County, where the Newton Power Plant is located. The plotted chloride isoconcentration line (a line through which concentrations are the same value) shows that chloride concentrations at 1,000 mg/L are present at the top of the Pennsylvanian shale (uppermost bedrock) across seven counties from Washington County in Illinois to Vigo County in Indiana. This includes Jasper County. The consistency in the data (i.e., lack of variability in the data) suggests that future sampling would yield very similar results.

[50] Additional supported documents cited in the ASD that I also reviewed include: Cartwright, K., Groundwater Discharge in the Illinois Basin as Suggested by Temperature Anomalies, Water Resources Research, Vol. 6, No. 3, 1970. pp. 912-918, Panno and Hackley, Geologic Influences on Water Quality, In Geology of Illinois, ed. Kolata and Nimz, Illinois State Geological Survey, 2010, pp. 337-350, Siegel, Geochemistry of the Cambrian-Ordovician Aquifer System in the Northern Midwest, U.S. Geological Survey Professional Paper 1405-D, 1989, and Willman et al, Geologic Map of Illinois: Illinois State Geological Survey Map, scale 1:500,000, 1967.

[51] Panno, S.V et al, Recharge and Groundwater Flow Within and Intracratonic Basin, Midwestern Unites States, Groundwater, Vol. 56, Jan/Feb 2018, pp. 32-45. (originally published online in July 2017).

[52] Panno, V.P. et al, Recharge and Groundwater Flow Within an Intracratonic Basis, Midwestern United States, Groundwater, 2017, Vol. 56, No. 1, p. 41.

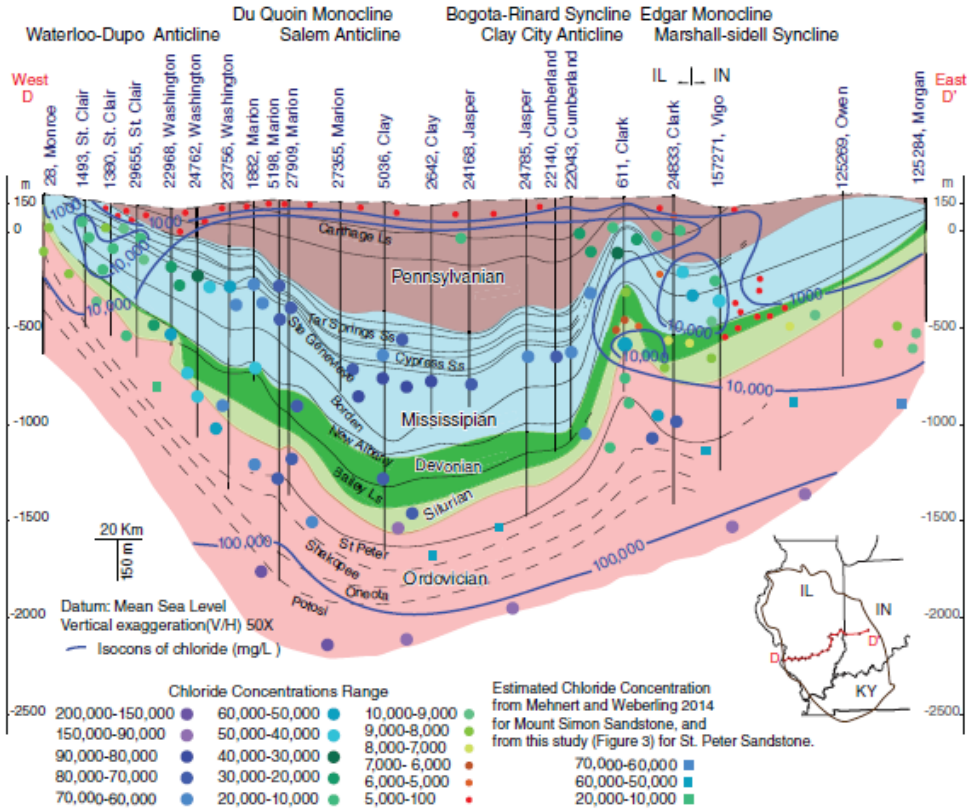

Figure 7. Cross section D–D′ extending east-west across southern Illinois and southern Indiana. Freshwater recharge affects the western and eastern margins of the basin, but not to the extent seen in cross sections farther north. Brines are also diluted along the LaSalle Anticlinorium (groundwater movement toward the reader). Again, the most concentrated brines are present in the Cambrian strata.

The second key document is a report jointly prepared by the Illinois State Water Survey (ISWS), the Illinois State Geological Survey (ISGS), and the Prairie Research Institute at the University of Illinois at Urbana-Champaign that shows a saline spring in close proximity to the PAP.[53] The primary author of the Panno article is an employee of the Illinois State Geological Survey. As a governmental agency document and a document published in a peer-reviewed journal, both documents were subject to peer review, and are reliable for the purposes of the ASD. It therefore should not be necessary to request documentation of field procedures and laboratory data packages from the ISWS and ISGS for their official publications to present as attachments to the Newton PAP ASD.

The facts and evidence provided in the ASD show that there is a pathway for chloride to migrate from the bedrock to APW15 (in contrast to the lack of pathway from the PAP to APW15). This includes evidence from PAP boring logs demonstrating the short distance between the well screen and underlying bedrock,[54] the elevated chloride concentrations from published ISGS data, and the presence of a saline spring based in ISGS observation. This supporting information establishes a viable

[53] Kelley, et al (ISWS, ISGS, and University of Illinois at Urbana-Champaign), The Sources, Distribution and Trends of Chloride in the Waters of Illinois, March 2012.

[54] Ramboll, Hydrogeologic Site Characterization Report, Primary Ash Pond, Newton Power Plant, October 25, 2021, Figure 2-7.

pathway for chloride migration from the underlying bedrock to APW15, whereas the 60-foot thick low permeability till between the PAP and APW15 precludes a pathway from the PAP.

In my opinion, the ASD concludes that elevations of chloride in APW15 are naturally occurring due to the underlying bedrock based on the best available information available to IPGC at the time it was putting together the ASD.

3.3 The "Data Gaps" in IEPA's Denial Letter Are Unnecessary for the Newton ASD

Opinion 10: The information in IEPA's data gap #1 is not necessary to support the conclusions of the ASD. This data would not change the conclusions in the ASD.

Data gap #1, "source characterization of the CCR at the Primary Ash Pond must include total solids sampling in accordance with SW-846," is not entirely clear in its meaning. Most directly, it appears to mean collect additional CCR solid samples[55] and analyze those samples for total chlorine or chloride content in units of mg/kg by an SW-846 method.[56] IEPA's Record does not cite to any specific SW-846 analysis method for a solid sample that it believes should have been used. Notably, there is no EPA SW-846 method that includes chloride or chlorine as an analyte in a solid sample so the request for "total solids sampling" using an SW-846 method for chloride or chlorine is not possible as written.

Regardless, any total solid analysis, irrespective of methodology, is unnecessary to support the Newton ASD and will not provide useful information regarding whether the PAP is impacting groundwater in APW15 without further assumptions or estimations of leaching concentrations because total constituent data are not a direct input to the equations of contaminant transport in groundwater as discussed in Section 3.3. As explained above, total solids analysis provides information regarding constituents that are currently within the solids in a CCR SI. It does not provide information regarding the concentrations of constituents in porewater that are potentially leaving a CCR SI and entering into groundwater. Meaning, if solids sampling and total constituent analysis was conducted at the Newton PAP (regardless of the methodology or number of borings and samples) it would not, by itself, provide useful information for an ASD to determine whether contaminants leaching from a CCR SI are contributing to contamination in groundwater.

As discussed in Section 2.4, after extensive testing, EPA found that the total concentrations of CCR constituents are not correlated with the leachable concentrations and elected to use CCR SI porewater concentrations as the basis to model contaminant migration in groundwater from a hypothetical SI in support of its risk assessment.[57] The input to a contaminant transport equation in groundwater such as R26 in TACO is a source concentration in groundwater (e.g., mg/L), not a mass or a total solids concentration in CCR (mg/kg). IEPA's total solids sampling is not relevant to understanding the potential for migration in groundwater and would not add any helpful information to the ASD. The leachate concentration from the source is the only relevant factor for understanding potential migration to groundwater. Total solids sampling and associated total mass calculation would be

[55] Total concentration of SW-846 analytes in Newton CCR samples expressed as mg/kg were provided in the Site Hydrogoelogic Characterization Report at Table 2-2.

[56] In deposition, IEPA witness Ms. Hunt suggested the data gap is intended to mean that ten borings throughout the CCR surface impoundment are necessary and three solid samples from each boring must be collected and analyzed to characterize the CCR source. Notably, Part 845 would be impossible for owners and operators to comply with if the Agency has significant internal data requirements that are not spelled out in the rule.

[57] EPA, Human and Ecological Risk Assessment of Coal Combustion Residuals, Final Report, December 2014, p. 5-47

relevant to an estimation of the total leaching lifetime of a SI, but that is not needed or relevant for an ASD, which is focused on whether a SI contributed to a particular exceedance.

Opinion 11: Porewater data is the better indicator of groundwater impact from a SI, compared to leach test data.

Total solid sampling could have some value if it the sample is analyzed by a leach test method. However, porewater data is superior to leach testing data to characterize whether a CCR SI is impacting groundwater. While not explicitly clear from the language in IEPA's ASD denial letter, it is also possible IEPA intended data gap #1 to mean collect CCR solid samples and analyze them for leachable concentrations using one of the SW-846 leach test methods. If IEPA intended to request SW-846 leaching analysis of Newton CCR, that information would not be superior to the existing porewater data set for the PAP for purposes of performing an ASD. After extensive research on the topic, as described above in Section 3.4, EPA found that actual porewater data for CCR SIs are best to represent the source term for risk assessment for the pathway of migration to groundwater because they are direct measurements, rather than estimates or simulations, of actual leachate quality at the CCR SIs,[58] and are best representation of field conditions such that no further data are necessary.[59] Differences between lab and field conditions include the size, scale and geometry of the leaching vessel, the particle size of the solid sample, the pH of the beginning eluent (rainwater is slightly acidic), the variability CCR placed over time, the variability of L/S ratios within the SI, and codisposal with additional wastes and wastewaters that are important in leachate generation and cannot be replicated in a laboratory. In contrast, SW-846 leach test methodologies such as LEAF tests are conducted under laboratory conditions and require selection of test L/S ratios and eluent pH that may not align with real world field conditions. The LEAF tests will generate multiple potential leachate concentrations (i.e., groundwater source terms) based upon laboratory selection of eluent pH, L/S ratio, and scenario (flow through or flow around). EPA does not provide guidance that addresses how to select a representative result. EPA documents not included in the IEPA Record indicate that field-measured, site-specific data are preferable to laboratory simulations or probabilistic estimates from multiple laboratory simulations.[60] Other research has corroborated that porewater is a better indicator of potential groundwater impact than leach test data.[61]

Why choose to simulate or predict data that can be directly measured? The Newton PAP ASD's method of characterizing what is leaching from the Newton PAP is more appropriate because it reflects real

world data and collects porewater samples in areas of highest concentration using a method that is less likely to collect excessive and unrepresentative solids.

Opinion 12: Neither PAP porewater data nor PAP CCR solids sampling and total constituent analysis or leach testing will represent leachate quality from the distant past. However, porewater data are still the best representation for potential groundwater impact. Past porewater concentrations at the base of an unlined SI were not likely higher in concentration than those observed after decades of operation.

Basis: All sampling methodologies will necessarily reflect leachate quality at the current time. However, as CCR leaches constituents, the total constituent concentrations necessarily decrease over time as mass is lost to the fluid phase. Current porewater data represents mass lost from CCR in the past, while data from solid CCR samples would reflect future leachate that is likely lower in concentration than current porewater. Further, porewater CCR constituent concentrations at the base of a CCR SI are likely to increase over the lifetime of a CCR SI due to the high L/S ratio of original sluiced materials, the over time of total volume of materials managed, the increased migration path (and CCR contact time) that the porewater must follow vertically through the SI, and decreasing L/S ratio as materials at the bottom of the SI are compressed by an overlying materials. Over time, the mass available for leaching increases and the L/S ratio decreases, thereby increasing the leachate and porewater concentrations until these the SI is mature and the volume and L/S ratio are no longer changing significantly.

Opinion 13: Conducting a mass balance of all the chloride in the CCR SI and nearby groundwater is not necessary for the ASD.

While not clear or explicit from IEPA's denial letter, in deposition, Ms. Hunt seemed to suggest that a mass balance between the CCR SI and the groundwater must be calculated in order to apply the contaminant transport equation in groundwater.[62] This is simply not true. As explained in Section 3.3 above, porewater with dissolved solids or solutes, rather than gross solids, can potentially migrate to groundwater and create a groundwater plume.[63] The porewater data can be used as an input for source concentration to the contaminant transport equation in groundwater. Mass or total solids concentration cannot be used as an input to the equation without further manipulation or assumption. The leachable concentration must be modeled with a partition coefficient or simulated in a laboratory from a solid sample. Further, a mass balance cannot be completed when there is an exchange of materials from outside the system (e.g., chloride coming into the system from deeper groundwater). As discussed above in Section 3.4 and as practiced by EPA in its risk assessment of CCR SIs, the porewater concentrations represent the best estimate of source strength potentially migrating to groundwater. The contaminant transport equation predicts groundwater concentrations downgradient from a groundwater source concentration. These units are mg/L, not mass or mg/kg as in totals samples.

Opinion 14: Data gaps #2 and #3, bedrock hydraulic conductivity and alternate source characterization data (and underlying documentation), are not needed for the ASD, and would not have been possible to collect in the time allowed to submit an ASD.

[62] Lauren Hunt deposition, May 28, 2024, p. 44, 77, 78, 91, 92,118-121

[63] Fetter et al, Contaminant Hydrogeology, Third Edition, Waveland Press, 2018, p. 61.

Basis: Data gap #2, collecting, analyzing and presenting hydraulic conductivities from laboratory or in-situ testing with hydrogeologic characterization of the bedrock unit, is also not necessary. Fulfilling this request would require substantial drilling and well installation in the bedrock that would be very time consuming and expensive, based on my professional experience and the testimony of Cynthia Vodopivec. [64] It could not be done in the 60-day timeframe for submitting an ASD required by the regulation. It is also unnecessary because there are regional and local data available in the literature, which, as discussed in Opinion 8, was included with the ASD.

Data Gap #3, characterization to include sample and analysis in accordance with 35 IAC 845.640 of alternative source, is confusing based on subsequent IEPA witness testimony. It is unclear whether IEPA is requesting well installation and sampling in the bedrock aquifer with field procedures and laboratory data packages for the well installation and sampling of the bedrock aquifer, or provision of field procedures, and laboratory data packages for data published in the government and peer-reviewed professional journal articles that were relied upon. Again, in my professional experience bedrock drilling and sampling would be prohibitively time-consuming and could not be conducted within the ASD filing time limit required by 35 IAC 845. It is also unnecessary because there are regional and local data available in the literature, which, as discussed in Opinion 8, was included with the ASD.

While direct drilling and well installation and sampling was an impossibility, IPGC's ASD did use the best available facts and evidence available to determine that the chloride exceedance was naturally occurring, caused by bedrock underlying APW15. As discussed in Opinion 8, this included a wide array of reliable, peer-reviewed documents demonstrating the presence of elevated chloride levels in the bedrock underlying APW15 and demonstrating a potential pathway/connection between the bedrock and APW15. Given the evidence in the ASD, if the information in data gap #2 and #3 were collected, I would expect it to support the conclusion that the bedrock is the source of the chloride exceedance in APW15. Additionally, even if the information in data gap #2 and #3 were collected, it would never support a conclusion that the Newton PAP is contributing to the chloride exceedance or that it is not being caused by an alternative source.

Opinion 15: The documents included in IEPA's Record do not support the denial of the ASD.

I conducted a review of the scientific and technical documents contained within IEPA's Record. This included a review of the following documents:

- Drever, James I. The Geochemistry of Natural Waters: Surface and Groundwater Environments. Prentice Hall. Third Edition. 1997, Select pages (Record Document 1)

Many of the documents in IEPA's Record are general textbooks, excerpts from textbooks or USEPA guidance that are not directly relevant. Other documents included by the IEPA support concepts in the ASD such as the fact that chloride has both natural and anthropogenic sources, and behaves as a conservative solute in groundwater.[65] Others describe the laboratory methods and limitations of LEAF test methods.

IEPA included three documents from SW-846, each related to LEAF testing methods. None are useful to the ASD. LEAF Testing Method 1314 documentation notes,[66] "This method provides eluate solutions considered indicative of leachate under field conditions only where the field leaching pH is controlled by the alkalinity or acidity of the solid material and the field leachate is not subject to dilution or other attenuation mechanisms." The test would not be representative of field conditions at the PAP due to codisposal of wastewaters. Further, in contrast to field conditions, LEAF tests use small volumes of solid samples and reagent grade water rather than rainwater that is naturally acidic. These shortcomings of rather idealized laboratory conditions highlight the fact that these tests merely provide estimates of potential leachate quality, and that direct measurement of porewater quality is much more accurate in terms of understanding the actual source concentration of contaminant available for transport from the SI because it is the integral result of lifetime variability of the L/S and spatial variability of the CCR itself. Further, multiple porewater samples can give a picture of the field-scale variability in leaching potential due to differences in CCR chemistry of all placed materials.

Documentation for other LEAF methods, Methods 1315[67] and 1316,[68] in IEPA's Record have similar statements regarding their lack of representation of field leaching conditions. This is consistent with EPA's decision to select field porewater data over laboratory leachate tests to model the potential migration of CCR constituents to groundwater. Method 1315 further relates to monolithic and

compacted granular material. In my opinion CCR in a SI behaves more like a porous medium than a monolithic or compacted granular material.

The IEPA Record includes select pages from a textbook by Drever.[69] This document discusses certain constituents, but does not include a discussion of chlorine or chloride. It also, includes a description of geochemical modeling and redox reactions using software. This description and modeling applies to non-conservative solutes and does not apply to a conservative solute like chloride.

The IEPA Record includes select pages from a book by Nelson.[70] This text identifies chloride as a conservative solute that has both natural and anthropogenic sources. This text supports the conclusions in the ASD which relies upon chloride's role as a conservative solute to support the fact that the chloride in APW15 is not from the Newton PAP. It further supports the idea that chloride can come from natural sources, such as bedrock.

The IEPA Record includes much of a classic textbook in Contaminant Hydrogeology by Fetter et al.[71] Chapter 2 of this text discusses mass or solute transport in groundwater. As discussed above, the governing equations describe concentration in groundwater (e.g., mg/L), not on mass (kg) or total solid concentration (mg/kg) of a source. Fetter also states that the derivation of the advection-dispersion equation for solute (mg/L in groundwater) transport (similar to the TACO R26 Domenico equation) is based on the conservation of mass of solute flux into a unit volume of groundwater.[72] This does not mean that one must complete an actual mass balance of a solute in the system of interest in order to use the equation, so this document does not support IEPA's data gap #1, to characterize total solids in the CCR source. Instead of attempting to reinvent the wheel on the characterization of leachable constituents, IEPA should have relied upon the decades of work that EPA has completed in order to characterize CCR, CCR leachate, and the potential for migration of CCR constituents from porewater to groundwater in support of its rulemaking process. These include documents referenced in the ASD and comment letter, my declaration, and this expert report.

The record also contains a USEPA porewater sampling guidance document for sediment. While none of IEPA's data gaps appear to refer to the porewater sampling IPGC conducted to characterize what might be leaching from the Newton ASD, the document in IEPA's record is not relevant to the analysis of CCR SI porewater because it describes sampling of porewater in a shallow water body with a hand-held direct push device and a mechanism to collect a grab sample of porewater from relatively shallow depths, typical of shallow rivers or streams. This is not relevant to a CCR SI because SI porewater samples representative of liquid that may migrate to groundwater is typically collected using monitoring wells. The presence of this document in the record may suggest that IEPA misunderstands how porewater data were collected at the Newton PAP and are typically collected for a CCR SI. The Newton PAP porewater samples were collected from wells with screens set at the base of the CCR (in the zone where CCR would be most consolidated with a lower L/S ratio and higher leachate concentration) using low-flow sampling techniques. This is an appropriate methodology for collecting

porewater samples from a CCR SI because saturated CCR is effectively a porous medium, similar to natural sands, gravels and silts, with interstitial water that may be sampled with a monitoring well.

I did not see any facts or evidence, including a scientific or technical document, in IEPA's record supporting the idea that total solids sampling of the Newton PAP is necessary to support an ASD for chloride at APW15. I did not see any facts or evidence, including a scientific or technical document, in IEPA's record suggesting that direct sampling of an alternative source is needed or required to support an ASD for chloride at APW15.

Opinion 16: The Newton ASD uses all available and appropriate data to determine the strongest forensic lines of evidence in the limited time period provided to submit the ASD report, and these lines of evidence clearly rule out the Newton PAP as a source of or contributor to chloride at APW15, and provide evidence that chloride is coming from an alternative source. The 60-day deadline does not provide adequate time to collect the information requested by IEPA in its denial or in explanations provided by IEPA employees in depositions. As a practical matter, the ASD can only be completed with data already collected or that can be collected analyzed and included in a report within the 60-day window to complete the ASD.

As discussed above, neither the ten boring CCR solid characterization nor the bedrock aquifer characterization could have been completed before the 60-day ASD deadline. In fact, simply completing the ASD can fill the time requirement. The tasks that need to be completed to provide an ASD within the 60-day timeframe include contracting with a PE, having him/her gather and review the relevant data, conduct an analysis, draft a report, complete necessary reviews, and finalize the report. Each of these tasks can take a week or more to complete, so the baseline timeframe is approximately 6 weeks. There is simply insufficient time to add the tasks of develop a field sampling plan, safety plan, data objectives plan, engage with contractors, collect the data, and wait for analysis for any significant field investigation. These additional tasks can each take a week or more to complete as well. Typical laboratory turn-around-times are two weeks, so that single task pushes the project beyond 60 days. IEPA's source and alternate source data requirements are simply not possible to comply with in the allowed 60-day window.

Groundwater Discharge in the Illinois Basin as Suggested by Temperature Anomalies

KEROS CARTWRIGHT

Illinois State Geological Survey, Urbana, Illinois 61801

Abstract. Areas where ground water in the Illinois basin is moving vertically should be reflected by temperature anomalies. To test this hypothesis, an isothermal map for a depth of 500 feet was constructed, based on bottom hole temperatures of deep wells. This map was compared with a theoretical isothermal map for a depth of 500 feet that was made by projecting temperature gradients (calculated from the thermal conductivities of the rock) downward from the surface where mean annual air temperatures were known. The residual temperature map that was made on the basis of this comparison (calculated minus observed temperature) shows several warm and cool anomalies that are postulated to be discharge and recharge areas, respectively. Analysis of the curvature of the earth's thermal profile calculated for the basin suggests that approximately 59,000 acre-feet of ground water per year are discharged upward from the deep rocks in the Illinois basin. This figure is of the same magnitude as an estimated excessive groundwater discharge into the region's streams of 43,000 acre-feet, based on comparison of unit-area discharge of streams in the basin with streams in similar areas outside the basin. From a simplified model of the basin, a groundwater inflow of about 36,500 acre-feet from the surrounding highlands is estimated. A significant portion of this discharge must be through fracture zones associated with faults and anticlines in the basin, inasmuch as this amount of flow would require that the shales have a vertical permeability from one to three orders of magnitude higher than is generally observed. One such discharge area in southwestern Illinois is suggested by field data.

INTRODUCTION

Movement of ground water within the lithosphere has long been known to affect the flux of heat within the earth. *Van Orstrand* [1934] suggested that the movement of ground water caused variations in the geothermal gradient in the Salt Creek oil field, Wyoming. The effect of groundwater movement is significant because the natural heat flux density from the earth is small.

Stallman [1960] presented the basic equation for the simultaneous transfer of heat and water within the earth and suggested they might be used to measure the rates of groundwater movement. *Bredehoeft and Papadopulos* [1965] and *Stallman* [1965] presented solutions of the basic equations applied to the vertical movement of water for certain boundary conditions. The Bredehoeft and Papadopulos solution is used in this paper to estimate the quantity of ground water discharge from the Illinois basin.

The general differential equation for simultaneous nonsteady flow of heat and fluid through fully saturated, isotropic, homogeneous, porous medium was developed [*Stallman*, 1960] from consideration of a unit volume of the medium. The equation is

$$\frac{\delta^2 T}{\delta x^2} + \frac{\delta^2 T}{\delta y^2} + \frac{\delta^2 T}{\delta z^2} - \frac{c_w \rho_w}{k} \left[\frac{\delta(v_x T)}{\delta x} + \frac{\delta(v_y T)}{\delta y} + \frac{\delta(v_z T)}{\delta z} \right] = \frac{c\rho}{k} \frac{\delta T}{\delta t} \quad (1)$$

where

- v, velocity of fluid flow; direction of flow specified by subscripts x, y, z;
- T, temperature at any point at time t;
- t, time since flow started;
- c, specific heat of rock fluid complex;
- c_w, specific heat of fluid;
- ρ, density of rock fluid complex;
- ρ_w, density of fluid;
- k, thermal conductivity of rock fluid complex;
- x,y,z, Cartesian coordinates.

For steady one-dimensional (vertical) flow of

Electronic Filing: Received, Clerk's Office 08/1/2024

heat and fluid, equation 1 according to *Bredehoeft and Papadopulos* [1965] becomes

$$k\frac{\delta^2 T}{\delta z^2} - v_z c_w \rho_w \frac{\delta T}{\delta z} = 0 \qquad (2)$$

which when solved subject to the boundary conditions

$$T_z = T_0 \text{ at } z = 0 \qquad (3)$$

$$T_z = T_L \text{ at } z = L \qquad (4)$$

where T_z is the temperature measurement at any depth z, T_0 is the uppermost temperature measurement, T_L is the lowermost temperature measurement, and L is the length of vertical section over which temperature is measured, yields

$$\frac{(T_z - T_0)}{(TL - T_0)} = f(\beta, z/L) \qquad (5)$$

where

$$f(\beta, z/_L) = \frac{[\exp(\beta z/L) - 1]}{[\exp(\beta) - 1]} \qquad (6)$$

and

$$\beta = \frac{c_w \rho_w v_z L}{k} \qquad (7)$$

β is a dimensionless parameter that is positive or negative depending on whether v_z is downward or upward. *Bredehoeft and Papadopulos* [1965] presented a table and type curves for the solution of equation 6.

ILLINOIS BASIN

The Illinois basin is an oval-shaped structural and topographic depression with over 9000 feet of maximum relief in the granite basement [*Bell et al.*, 1964] and 1000 feet maximum topographic relief. Definition of the exact limits of the basin vary. However, at its broadest defined limits the basin extends from the Ozark uplift on the southwest to the Cincinnati and Kankakee arches on the east and northeast.

Very little is known of the distribution of hydrostatic head within the rocks of the basin. The difference in head between the rocks on the periphery of the basin and the water table at the center is 100 to at least 500 feet [*Bredehoeft et al.*, 1963]. Theoretical analyses by *Toth* [1963] and *Freeze and Witherspoon* [1966; 1967; 1968], and work by *Hitchon* [1969] in the Western Canadian sedimentary basin suggest that basins of this general shape should be discharging water upward from the deep, basin-wide flow system.

A mechanism for the concentration of the highly saline brine found in the basin was suggested by *Bredehoeft et al.* [1963]. The character and origin of these brines were further discussed in a series of papers by *Clayton et al.* [1966] and *Graf et al.* [1965; 1966]. The consensus of these studies is that the water in the deep formations of the basin is in motion and that some upward discharge of ground water is taking place through the clay shales that act as an osmotic membrane.

This study estimates the quantity of water being discharged, and where and how the major portion of discharge may be taking place. Most, if not all, of the fluid being discharged is in areas of high vertical permeability associated with the structural features of the basin.

TEMPERATURE ANOMALY

To test the hypothesis of upward flow of water and its effect on the geothermal gradients, an isothermal map for a depth of 500 feet was constructed from recorded bottom hole temperatures of deep wells. The wells are not evenly distributed throughout the mapped area (Figure 1). The first six wells (maximum of two per section where many datum points are available) for each Congressional township were selected from the mineral resource records of the Illinois State Geological Survey. Only wells over 1000-feet deep were chosen and records of obviously poor quality were eliminated from the sample. About 2000 well records were used. The temperature at 500 feet was calculated for each well by assuming that a linear gradient existed between the bottom hole temperature and the mean annual air temperature [*Jones*, 1966]. The mean of the temperature at 500 feet for all the selected wells was calculated for each township and plotted as a single point in the township. The inaccuracies of this type of temperature data are well known, but the fairly high degree of internal consistency in the data suggests the approach is valid.

Electronic Filing: Received, Clerk's Office 08/1/2024

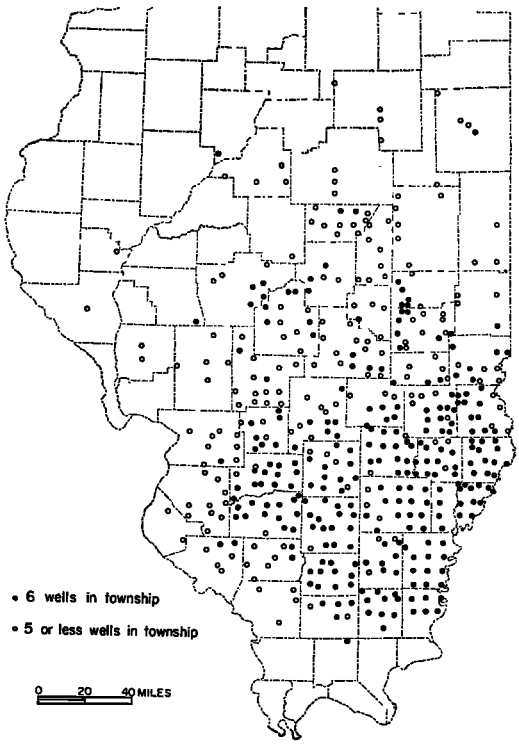

Fig. 1. Distribution of deep wells used in compiling isothermal map for 500-foot depth.

The resulting isothermal map (Figure 2) is a reasonable representation of the distribution of temperatures at the 500-foot depth. Two striking features appear on the map: (1) a general decrease in temperature from south to north reflects the trend of the mean annual air temperatures, and (2) the warm areas generally coincide with anticlinal areas and fault zones in the Illinois basin, which are also the principal oil producing areas in the state.

A theoretical isothermal map for the 500-foot depth was prepared (Figure 3) for comparison with the map based on well temperatures. For the theoretical map, temperatures at the 500-foot depth were calculated by estimating temperature gradients (based on assumed thermal conductivities of the rocks and geothermal gradient given below), and projecting the gradients downward from the surface where mean annual air temperatures were known. The air temperature data were from weather stations in the state [*Jones,* 1966]. The following thermal conductivities and geothermal gradients were used [*Cartwright,* 1968]:

Glacial sediments	0.0025 cgs units (cal/cm sec °C)
Pennsylvanian rocks	0.005 cgs units
Deep carbonate rocks	0.007 cgs units (and 1°F per 100 ft temperature gradient)

The thickness of the glacial drift in wide areas around the various weather stations was averaged.

A residual map (Figure 4) was then made to show the difference between the two isothermal maps by subtracting the observed temperature data from the calculated temperature data. The warm (negative) areas were assumed to be zones of upward movement (discharge) of water from deep aquifers in the basin, and the cool (positive) areas are zones of downward movement (recharge). Temperature anomalies in the northern third of the map probably are of little significance inasmuch as the data are sparse, and the thickness

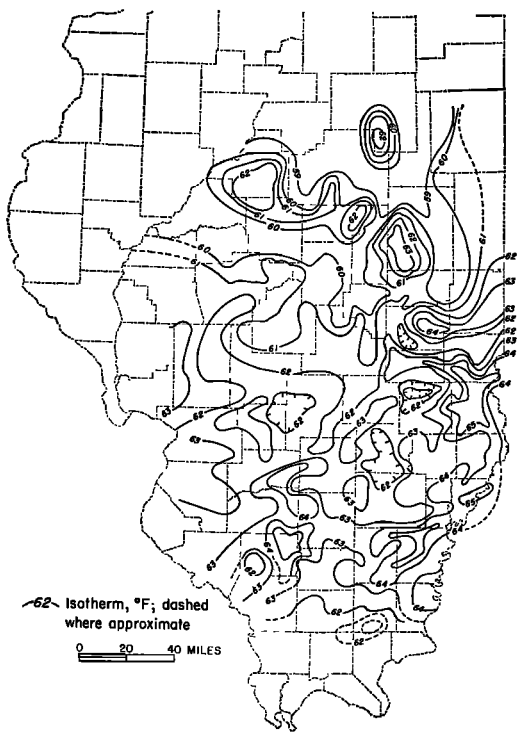

Fig. 2. Isothermal map for the 500-foot depth, based on temperature data from deep wells.

Electronic Filing: Received, Clerk's Office 08/1/2024

of glacial drift, which has the greatest effect on the calculated temperature values, varies greatly. The Mahomet buried bedrock valley [*Horberg*, 1950], for instance, which contains 300 to 400 feet of fill, is reflected on the map as a cool area. This could be the result of the permeable drift's acting as a recharge zone, but it is probably due to not taking the effect of the thick drift when the temperature was calculated completely into account.

The residual map (Figure 4) also reflects some of the structural features of the area. The Wabash valley fault zone and the DuQuoin-Louden anticlinal belt are anomalously warm and probably are the principal discharge areas. In the latter area, saline waters too brackish for human consumption immediately underlie the water table. The area along the Shawnee hills to the south and the Mississippi river area to the west are both cool areas, and data suggest that recharge is probably occurring.

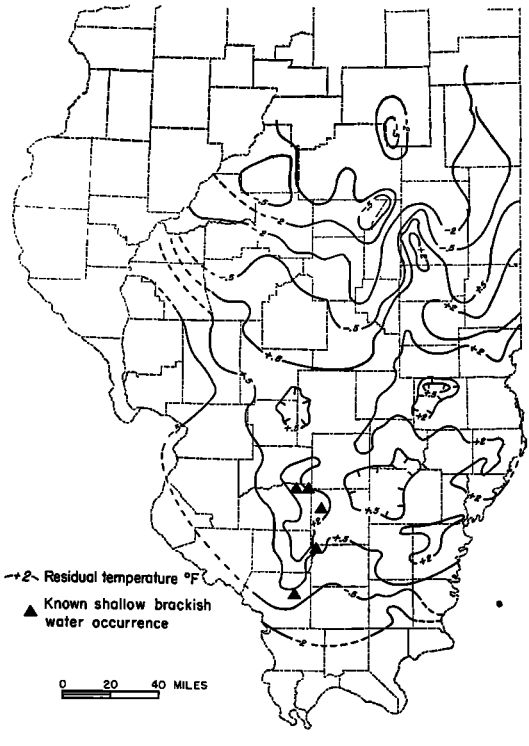

Fig. 4. Residual temperature map (calculated temperature minus observed temperature), showing anomalously warm (positive) and cool (negative) areas.

VOLUME OF DISCHARGE

The mean velocity of upward movement of water in the Illinois basin was calculated from the temperature data with equation 5. The average temperature in the warm discharge areas was determined at intervals of 300 feet for depths between 500 and 3500 feet, the range of depth that includes most oil wells in Illinois. At each 300-foot interval all points that fell within 50 feet of that depth were averaged to obtain a single value. The temperatures for 500 and 800 feet were determined by an upward extrapolation of the temperature data. The plotted temperature curve (Figure 5) compared with the type curves of *Bredehoeft and Papadopulos* [1965] yielded a velocity of 0.16×10^{-8} feet per second. The very small velocity can be detected because of the relatively large vertical distance over which the temperature is observed.

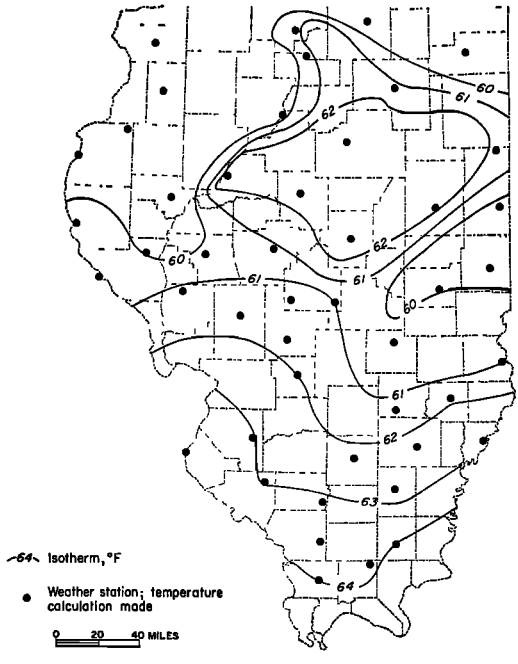

Fig. 3. Isothermal map calculated for 500-foot depth on basis of mean annual surface temperatures and thermal conductivity of the rocks.

Most of the discharge probably takes place in the anomalously warm areas within a radius of 100 miles from the center of the basin. This is approximately 1800 square miles. The quantity of water discharged was calculated by using

Electronic Filing: Received, Clerk's Office 08/1/2024

$$Q = V_s A \quad (8)$$

where Q is the quantity of fluid discharge per unit of time, V_s is the velocity of fluid flow (upward), and A is the area over which discharge takes place. The discharge amounts to 59,000 acre-feet per year.

The quantity of water flowing into the Illinois basin was estimated by using the simplest model of *Bredehoeft et al.* [1963], which assumes the change of head over distance is linear (2.8×10^{-4} feet per feet). According to the model, all the water would pass through the sandstone aquifers (principally the Mt. Simon, St. Peter, Chesterian, and basal Pennsylvanian), which were assumed to average 3000 feet thick and have the permeability of the Mt. Simon sandstone of northern Illinois (1.34 feet per day according to *Walton and Csallany* [1962]). The discharge would be equal to the water that passes into the basin through the circumference of a circle with a radius of 100 miles, the center of which is the center of the basin. From this model it was calculated that 36,500 acre-feet of water per year moves into the basin.

Streams and rivers presently draining the central part of the Illinois basin have a normal annual groundwater runoff of about 2,670,000 acre-feet per year [*Walton,* 1965] exclusive of flow in the Wabash River which crosses the eastern part of the basin. The 59,000 acre-feet of discharge from the deeper rocks of the basin is only 2.2% of the total groundwater runoff, and only 0.7% of the total average stream discharge of 8.26 million acre-feet per year [*Mitchell,* 1957].

To determine whether streams of the Illinois basin have different discharge characteristics,

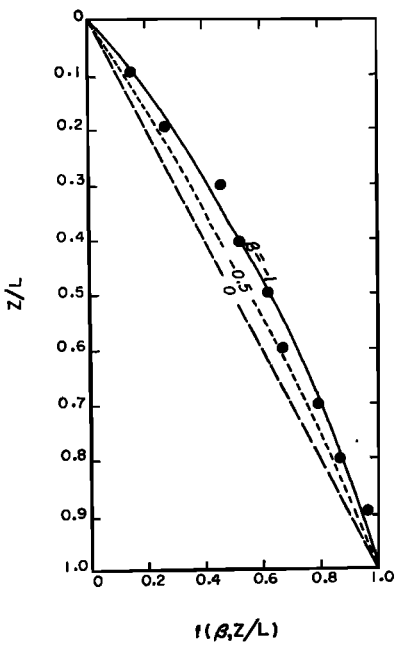

Fig. 5. Temperature profile (dots) in the Illinois basin compared with type curves of *Bredehoeft and Papadopulos* [1965]. The depth and temperatures of the profile are plotted as the ratios

$$\frac{z - Z_0}{L} \quad \text{and} \quad \frac{T_z - T_0}{T_L - T_0} \quad \text{(equation 5)}$$

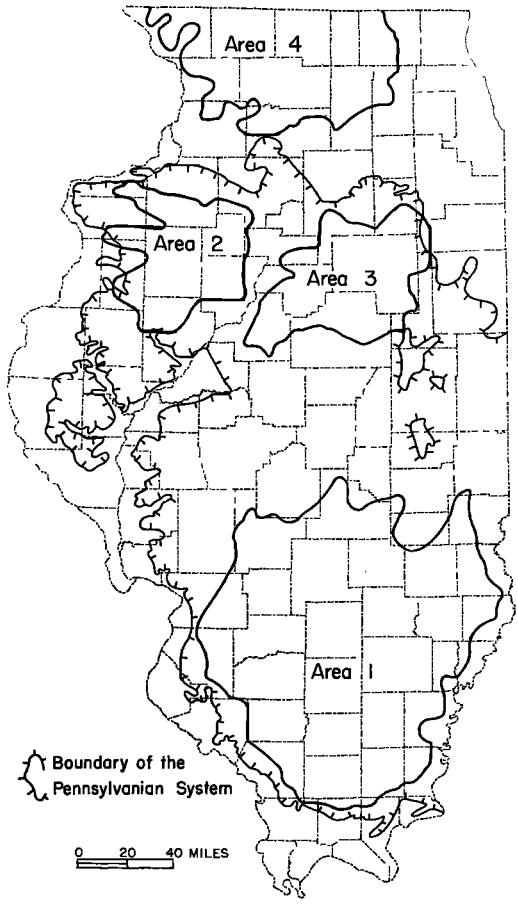

Fig. 6. Drainage areas studied for comparison of the groundwater discharge characteristics between years of normal and below normal precipitation.

Electronic Filing: Received, Clerk's Office 08/1/2024

TABLE 1. Average Annual Groundwater Runoff

Region	Precipitation, inches	Runoff in Year of Normal Precipitation, cfs/mi²	Runoff in Year of Below Normal Precipitation, cfs/mi²	Percent of Below Normal Year's to Normal Year's Runoff	Area of Drainage Basin, mi²
1	35 to 45	0.19	0.11	57.9	10,161
		0.23*	0.14	60.9	6,609
2	34 to 37	0.19	0.09	44.3	4,731
3	33 to 37	0.16	0.06	37.5	2,984
4	33 to 34	0.31	0.21	67.7	9,663

* Stream with high drought period flow only.

a comparison was made of the annual groundwater runoff or base flow of streams, for four regions of the state [*Walton,* 1965]. The regions are shown in Figure 6. Region 1 is the area where discharge from the Illinois basin occurs. Regions 1, 2, and 3 are geologically similar and contain generally thin glacial tills [*Piskin and Bergstrom,* 1967] overlying rocks of the Pennsylvanian system, principally shale. Region 4 is different and has generally thin glacial tills overlying permeable Ordovician and Silurian carbonates. The evapotranspiration in the four regions varies in a pattern similar to the variation in precipitation [*Jones,* 1966] (Table 1). The variability in precipitation is slightly greater in region 1 than in the other three areas [*Huff and Changnon,* 1963].

The figures in the table suggest that the groundwater runoff characteristics of region 1 resemble those of region 4 rather than those of regions 2 and 3, even though region 1 is more similar geologically to the latter two.

Region 1 had a higher groundwater runoff in drought years in comparison to the other three regions and at least part of it must be discharge of deep basin waters. All areas except region 1 have 0.10 cfs/mi² differences between below-normal and normal years; area 1 has only a 0.08 cfs difference or a 0.09 cfs difference if we consider only streams with more than 55% of below-normal to normal discharge. This may be merely fortuitous; nevertheless, I assumed that the 0.01 cfs extra groundwater runoff of the streams with high flow during drought years is the result of discharge of water from the deep basin groundwater flow system. This amounts to 43,000 acre-feet of water per year.

If the shale of the Illinois basin has the same permeability of 0.13×10^{-4} feet per day found in the Ordovician shales of northern Illinois [*Walton,* 1960] and 100 feet of hydraulic head, the possible leakage upward would be only 2000 acre-feet per year. Thus, possibly as much as 95% of the discharge must be moving upward through vertical fractures. Concentration of fractures are present within the main structural features of the basin and therefore saline water discharges in the area of these features.

Regions where naturally brackish water is encountered immediately below the water table are shown on Figure 4. Brackish water also is found elsewhere, but from data presently available, it cannot be determined with certainty whether those occurrences are natural or related to the activities of man. The brackish water occurs within the areas of anomalously warm temperatures (Figure 4) near the main structural features of the basin. Furthermore, the anomalously cool area along the southern edge of the map coincides with the region of recharge to the thick basal Pennsylvanian sandstones that dip steeply toward the center of the basin.

DISCUSSION

Hydrogeologists working in the Illinois basin area have long believed that ground water is circulating in the basin. Lack of data on the fluid potentials in the water transmitting zone has necessitated reliance on chemical data and the theoretical explanation of these data. Theoretical calculations supported by chemical data suggest hydrodynamic rather than hydrostatic conditions. This paper further corroborates this hypothesis, and suggests that the quantity of

Electronic Filing: Received, Clerk's Office 08/1/2024

groundwater discharge is about 40,000 to 60,000 acre-feet per year.

Parameter Estimation Guidelines for Risk-Based Corrective Action (RBCA) Modeling

Abstract

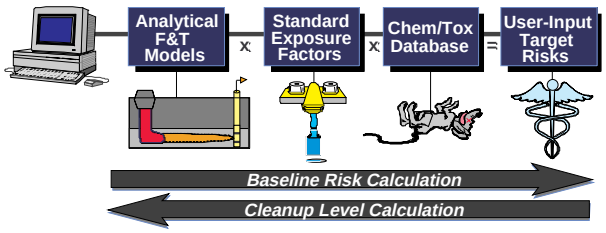
For use in risk-based corrective action (RBCA) analyses, simple analytical fate-and-transport models can provide a cost-effective means of estimating exposure concentrations and developing risk-based soil and groundwater remediation standards. Under ASTM E-1739 "Standard Guide for Risk-Based Corrective Action Applied at Petroleum Release Sites," such models are recommended as a conservative first step under Tiers 1 and 2 of the site evaluation process, prior to use of more complex numerical modeling methods under Tier 3. However, the reliability of an analytical model as a conservative predictor of chronic exposure levels depends upon proper characterization of key physical and chemical parameters.

This paper reviews a system of analytical fate-and-transport models compiled expressly for use with the ASTM RBCA Standard and provides practical guidelines for measurement and/or estimation of key input parameters for each model. Contaminant transport pathways addressed in this paper include soil-to-air volatilization, soil-to-groundwater leaching, lateral air transport, and lateral groundwater transport. Parameter selection guidelines discussed in this paper relate specifically to the analytical expressions listed in Appendix X.2 of ASTM E-1739. However, these guidelines are generally applicable to a broad range of soil, air, and groundwater transport models.

RBCA Spreadsheet System

The RBCA Spreadsheet System, developed by Groundwater Services, Inc. (GSI), is designed to complete all calculations required for Tiers 1 and 2 of the ASTM RBCA planning process (Connor et al, 1995). Based upon site-specific data supplied by the user, the RBCA software combines fate-and-transport modeling and risk characterization functions to complete the following tasks:

- Exposure Concentrations
- Average Daily Intake
- Baseline Risk Levels
- Risk-Based Media Cleanup Levels



Using a system of ten analytical models linked to internal libraries of standard exposure factors and chemical/ toxicological data for 90 compounds, the RBCA Spreadsheet can calculate either baseline risk levels or cleanup standards for each complete exposure pathway identified by the user. Key calculation steps are as follows:

- **Exposure Concentrations:** Based on representative concentrations of constituents of concern (COCs) present in the affected source media, maximum steady-state concentrations likely to

Electronic Filing: Received, Clerk's Office 08/1/2024

occur at the point of exposure (POE) are calculated using the steady-state analytical fate-and-transport models identified in Appendix X.2 of ASTM E-1739. To perform these calculations, the system evaluates cross-media partitioning (e.g., volatilization from soil to air) and lateral transport from the source to the POE (e.g., contaminant transport via air or groundwater flow). The source media and optional exposure pathways included in the software as as follows:

SOURCE MEDIA	EXPOSURE PATHWAYS
Surface Soils	• Inhalation of Volatiles and Particulates • Dermal Contact with Soil • Ingestion of Soil and Dust • Leaching to Groundwater/Ingestion
Subsurface Soils	• Inhalation of Volatiles • Leaching to Groundwater/Ingestion
Groundwater	• Ingestion of Potable Water • Inhalation of Volatiles

- **Average Daily Intake:** Based upon the exposure factors selected by the user, the average daily chemical intake for each receptor along each selected pathway is calculated in accordance with EPA guidelines (see Connor et al, 1995). These values are used in baseline risk calculations for each complete pathway.

- **Baseline Risk Characterization:** Human health risks associated with exposure to COCs are calculated by the spreadsheet on the basis of average daily intake rates and the corresponding toxicological parameters for carcinogenic and non-carcinogenic effects. For each complete pathway, the system output provides both individual and additive constituent results for carcinogens and non-carcinogens.

- **Media Cleanup Values:** The RBCA Spreadsheet System has the ability to i) compare site data to Tier 1 Risk-Based Screening Levels (RBSLs), computed using default parameter values as listed in ASTM E-1739, or ii) calculate Tier 2 Site-Specific Target Levels (SSTLs) based on user-supplied site characterization information. For each source medium (i.e., affected soil and groundwater), the software reports target concentrations for all complete pathways and identifies the applicable (i.e., minimum) value for source remediation.

Fate and Transport Modeling Methods

The RBCA Spreadsheet System contains a series of fate and transport models for predicting COC concentrations at the point of exposure (POE) for each of the optional exposure pathways listed above. Under Tier 2 of the RBCA process, relatively simple analytical models are to be employed for this calculation, representing a minor incremental effort relative to Tier 1. The spreadsheet modeling system is consistent with Appendix X.2 of ASTM E-1739, although selected algorithms and default parameters have been updated to reflect advances in evaluation methods.

The idealized schematic shown on Figure 1 illustrates the steps for predicting transport of contaminants from the source zone to the POE for air and groundwater exposure pathways. Each element in Figure 1 represents a step-specific attenuation factor, corresponding to either a cross-media transfer factor (CM) or a lateral transport factor (LT). The effective natural attenuation factor (NAF) for each COC on each pathway is then calculated as the arithmetic product of the various attenuation factors occurring along the flow path from source to receptor. These steady-state NAF values are then used for calculation of baseline risks and back-calculation of Site-Specific Target Levels (SSTLs), as discussed above. Please note that fate and transport modeling is *not* required for exposure via direct contact with the source medium, such as soil ingestion or dermal contact,

where the source and exposure concentrations are equal (i.e., NAF = 1). Analytical models used for conservative estimation of each transport factor per ASTM E-1739 are described below.

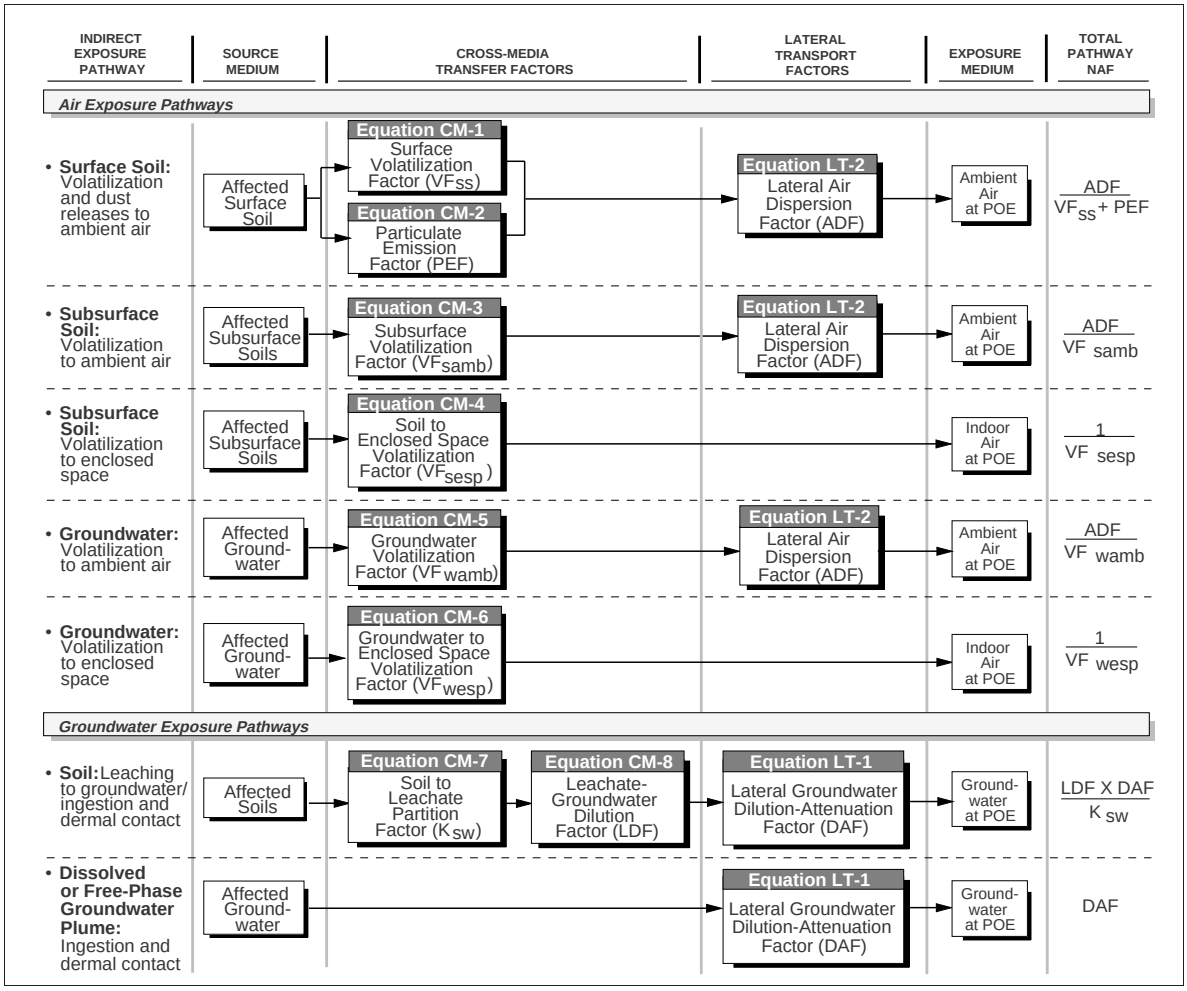


FIGURE 1. NAF CALCULATION SCHEMATIC FOR EXPOSURE PATHWAYS IN RBCA SPREADSHEET SYSTEM

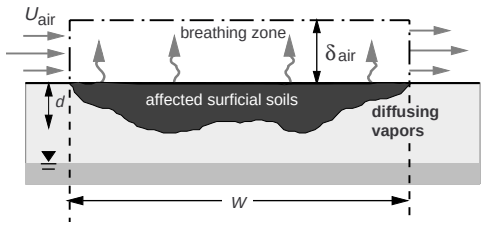
CROSS-MEDIA TRANSFER FACTORS

Exposure pathways involving transport of COCs from one medium to another (e.g., soil-to-air, soil-to-groundwater) require estimation of the corresponding cross-media transfer factor. Various analytical expressions are available for estimating soil-to-air *volatilization factors* as a function of site soil characteristics and the physical/chemical properties of volatile organic COCs. *Leaching factors* for organic and inorganic constituent releases from soil to groundwater can similarly be estimated as a function of COC characteristics, soil conditions, and annual rainfall infiltration. Cross-media transfer equations incorporated in the RBCA Spreadsheet System are presented in Figure 2. Detailed discussion of each of these cross-media factors is provided in the Tier 2 RBCA Guidance Document (Connor et al, 1995).

Equation CM-1: Surface Soil Volatilization Factor (VFss)



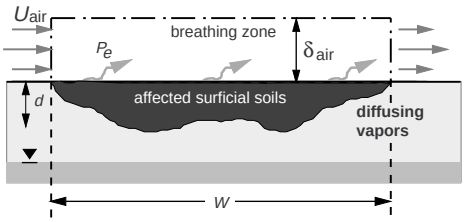
CM-1a:

$$VF_{ss}\left[\frac{(mg/m^3-air)}{(mg/kg-soil)}\right]=\frac{2W\rho_s}{U_{air}\delta_{air}}\sqrt{\frac{D_s^{eff}H}{\pi\tau(\theta_{ws}+k_s\rho_s+H\theta_{as})}}\times10^3$$

or CM-1b: $$VF_{ss}\left[\frac{(mg/m^3-air)}{(mg/kg-soil)}\right]=\frac{W\rho_s d}{U_{air}\delta_{air}\tau}\times10^3$$

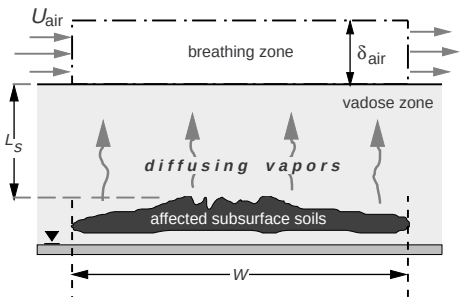
whichever is less

Equation CM-2: Soil Particulate Emission Factor (PEF)



$$PEF\left[\frac{(mg/m^3-air)}{(mg/kg-soil)}\right]=\frac{P_eW}{U_{air}\delta_{air}}\times10^3$$

Equation CM-3: Subsurface Soil Volatilization Factor (VFsamb)



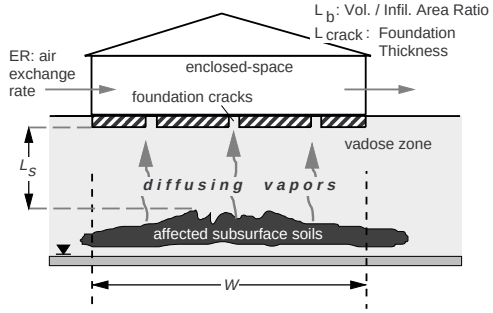
CM-3a:

$$VF_{samb}\left[\frac{(mg/m^3-air)}{(mg/kg-soil)}\right]=\frac{H\rho_s}{[\theta_{ws}+k_s\rho_s+H\theta_{as}]\left[1+\frac{U_{air}\delta_{air}L_s}{D_s^{eff}W}\right]}\text{x}10^3$$

or CM-3b: $$VF_{samb}\left[\frac{(mg/m^3-air)}{(mg/kg-soil)}\right]=\frac{W\rho_s d_s}{U_{air}\delta_{air}\tau}\text{x}10^3$$

whichever is less

Equation CM-4: Subsurface Soil to Enclosed Space Volatilization Factor (VFsesp)



CM-4a:

$$VF_{sesp}\left[\frac{(mg/m^3-air)}{(mg/kg-soil)}\right]=\frac{\frac{H\rho_s}{[\theta_{ws}+k_s\rho_s+H\theta_{as}]}\left[\frac{D_s^{eff}/L_s}{ER\ L_B}\right]}{1+\left[\frac{D_s^{eff}/L_s}{ER\ L_B}\right]+\left[\frac{D_s^{eff}/L_s}{(D_{crack}^{eff}/L_{crack})\eta}\right]}\text{x}10^3$$

or CM-4b: $$VF_{sesp}\left[\frac{(mg/m^3-air)}{(mg/kg-soil)}\right]=\frac{\rho_s d_s}{L_B ER\tau}\text{x}10^3$$

whichever is less

Definitions for Cross-Media Transfer Equations

D_s^{eff} Effective diffusivity in vadose zone soils:

$$D_s^{eff}\left[\frac{cm^2}{s}\right] = D^{air}\,\frac{\theta_{as}^{3.33}}{\theta_T^2} + \left[\frac{D^{wat}}{H}\right]\left[\frac{\theta_{ws}^{3.33}}{\theta_T^2}\right]$$

D_{ws}^{eff} Effective diffusivity above the water table:

$$D_{ws}^{eff}\left[\frac{cm^2}{s}\right] = \left(h_{cap} + h_v\right)\left[\frac{h_{cap}}{D_{cap}^{eff}} + \frac{h_v}{D_s^{eff}}\right]^{-1}$$

d	Lower depth of surficial soil zone (cm)
d_s	Thickness of affected subsurface soils
D^{air}	Diffusion coefficient in air (cm^2/s)
D^{wat}	Diffusion coefficient in water (cm^2/s)
ER	Enclosed-space air exchange rate (l/s)
f_{oc}	Fraction of organic carbon in soil (g-C/g-soil)
H	Henry's law constant (cm^3-H_2O)/(cm^3-air)
h_{cap}	Thickness of capillary fringe (cm)
h_v	Thickness of vadose zone (cm)
I	Infiltration rate of water through soil (cm/year)
k_{oc}	Carbon-water sorption coefficient (g-H_2O/g-C)
k_s	Soil-water sorption coefficient (g-H_2O/g-soil)
L_B	Enclosed space volume/infiltration area ratio (cm)
L_{crack}	Enclosed space foundation or wall thickness (cm)
L_{GW}	Depth to groundwater = $h_{cap} + h_v$ (cm)
L_s	Depth to subsurface soil sources (cm)
P_e	Particulate emission rate (g/cm^2-s)
U_{air}	Wind speed above ground surface in ambient mixing zone (cm/s)
V_{gw}	Groundwater Darcy velocity (cm/s)

D_{crack}^{eff} Effective diffusivity through foundation cracks:

$$D_{crack}^{eff}\left[\frac{cm^2}{s}\right] = D^{air}\,\frac{\theta_{acrack}^{3.33}}{\theta_T^2} + \left[\frac{D^{wat}}{H}\right]\left[\frac{\theta_{wcrack}^{3.33}}{\theta_T^2}\right]$$

D_{cap}^{eff} Effective diffusivity in the capillary zone:

$$D_{cap}^{eff}\left[\frac{cm^2}{s}\right] = D^{air}\,\frac{\theta_{acap}^{3.33}}{\theta_T^2} + \left[\frac{D^{wat}}{H}\right]\left[\frac{\theta_{wcap}^{3.33}}{\theta_T^2}\right]$$

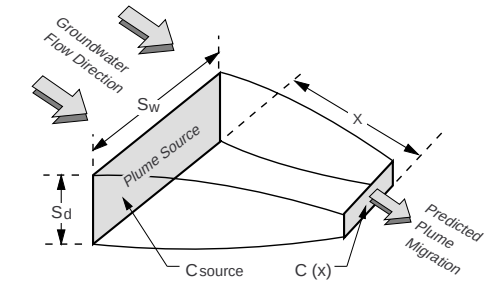
W	Width of source area parallel to wind, or groundwater flow direction (cm)
δ_{air}	Ambient air mixing zone height (cm)
δ_{gw}	Groundwater mixing zone thickness (cm)
η	Areal fraction of cracks in foundations/walls (cm^2-cracks/cm^2-total area)
θ_{acap}	Volumetric air content in capillary fringe soils (cm^3-air/cm^3-soil)
θ_{acrack}	Volumetric air content in foundation/wall cracks (cm^3-air/cm^3 total volume)
θ_{as}	Volumetric air content in vadose zone soils (cm^3-air/cm^3-soil)
θ_T	Total soil porosity (cm^3-pore-space/ cm^3-soil)
θ_{wcap}	Volumetric water content in capillary fringe soils (cm^3-H_2O/cm^3-soil)
θ_{wcrack}	Volumetric water content in foundation/wall cracks (cm^3-H_2O)/cm^3 total volume)
θ_{ws}	Volumetric water content in vadose zone soils (cm^3-H_2O/cm^3-soil)
ρ_s	Soil bulk density (g-soil/cm^3-soil)
τ	Averaging time for vapor flux (s)

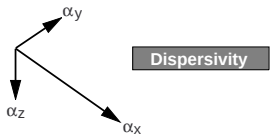
FIGURE 2. CROSS-MEDIA PARTITIONING EQUATIONS IN THE RBCA SPREADSHEET SYSTEM

LATERAL TRANSPORT FACTORS

During lateral transport within air or groundwater, COC concentrations in the flow stream will be diminished due to mixing and attenuation effects (see Figure 1). Site-specific attenuation factors characterizing COC mass dilution or loss during lateral transport can be estimated using the air dispersion and groundwater transport models provided in the RBCA Spreadsheet System. Equations for the steady-state analytical transport models incorporated in the RBCA spreadsheet are shown on Figure 3. Equations LT-1 and LT-2 correspond to the Domenico 3-D groundwater solute transport model and the standard gaussian air dispersion model, respectively. The user must provide information regarding COC properties and transport parameters (flow velocities, dispersion coefficients, retardation factors, decay factors, etc.), as required for the selected contaminant transport model. Procedures for definition of the contaminant source term for the groundwater solute model (Equation LT-1) are illustrated on Figure 4. Key assumptions of these lateral transport models are detailed in the Tier 2 RBCA Guidance Manual (Connor et al, 1995).

Equation LT- 1: Lateral Groundwater Dilution Attenuation Factor





LT-1a: Solute Transport with First-Order Decay:

$$\frac{C(x)_i}{Csi} = \exp\left(\frac{x}{2\alpha_x}\left[1-\sqrt{1+\frac{4\lambda_i\alpha_x R_i}{\nu}}\right]\right) erf\left(\frac{S_w}{4\sqrt{\alpha_y x}}\right) erf\left(\frac{S_d}{4\sqrt{\alpha_z x}}\right)$$

where: $\nu = \dfrac{K \cdot i}{\theta_e}$

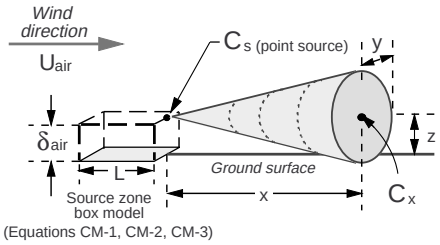
LT-1b: Solute Transport with Biodegradation by Electron-Acceptor Superposition Method:

$$C(x)_i = \left[\left(C_{si} + BC_i\right) erf\left(\frac{S_w}{4\sqrt{\alpha_y x}}\right) erf\left(\frac{S_d}{4\sqrt{\alpha_z x}}\right)\right] - BC_i$$

where: $BC_i = BC_T \text{ x} \dfrac{C_{si}}{\sum C_{si}}$ *and* $BC_T = \Sigma\ \dfrac{C(ea)_n}{UF_n}$

[Note: For Equations LT-1a and LT-1b, NAF = $Cs_i / C(x)_i$]

Equation LT-2: Lateral Air Dispersion Factor



(Equations CM-1, CM-2, CM-3)

$$\frac{C(x)_i}{C_{si}} = \frac{Q}{2\pi U_{air}\sigma_y\sigma_z} \text{ x } \exp\left(-\frac{y^2}{2\sigma_y^2}\right)\left(\exp\left(-\frac{(z-\delta_{air})^2}{2\sigma_z^2}\right) + \exp\left(-\frac{(z+\delta_{air})^2}{2\sigma_z^2}\right)\right)$$

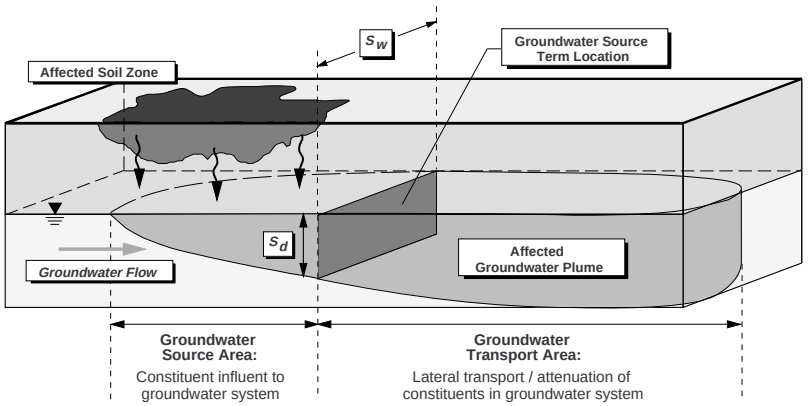
where: $Q = \dfrac{U_{air}(\delta_{air})(A)}{L}$

[Note: For Equation LT-2, NAF = $Cs_i / C(x)_i$]

Definitions for Lateral Transport Equations

$C(x)_i$	Concentration of constituent *i* at distance x downstream of source (mg/L) or (mg/m^3)
C_{si}	Concentration of constituent *i* in Source Zone (mg/L) or (mg/m^3)
BC_i	Biodegradation capacity available for constituent *i*
BC_T	Total biodegradation capacity of all electron acceptors in groundwater
$C(ea)_n$	Concentration of electron acceptor *n* in groundwater
UF_n	Utilization factor for electron acceptor *n* (i.e., mass ratio of electron acceptor to hydrocarbon consumed in biodegradation reaction)
x	Distance downgradient of source (cm)
α_x	Longitudinal groundwater dispersivity (cm)
α_y	Transverse groundwater dispersivity (cm)
α_z	Vertical groundwater dispersivity (cm)
θ_e	Effective Soil Porosity
λ_i	First-Order Degradation Rate (day^{-1}) for constituent *i*
υ	Groundwater Seepage Velocity (cm/day)
K	Hydraulic Conductivity (cm/day)
R_i	Constituent retardation factor
i	Hydraulic Gradient (cm/cm)
S_w	Source Width (cm)
S_d	Source Depth (cm)
δ_{air}	Ambient air mixing zone height (cm)
Q	Air volumetric flow rate through mixing zone (cm^3/s)
U_{air}	Wind Speed (cm/sec)
σ_y	Transverse air dispersion coefficient (cm)
σ_z	Vertical air dispersion coefficient (cm)
y	Lateral Distance From source zone (cm)
z	Height of Breathing Zone (assumed equal to δ_{air}) (cm)
A	Cross Sectional Area of Air Emissions Source (cm^2)
L	Length of Air Emissions source (cm) parallel to wind direction

FIGURE 3. LATERAL TRANSPORT EQUATIONS IN THE RBCA SPREADSHEET SYSTEM



SELECTION OF GROUNDWATER MODEL INPUT PARAMETERS

For use of Domenico groundwater solute transport model (see Equations LT-1a and LT-1b, Figure 3), select source term location, dimensions, and concentration as follows:

1) Groundwater Source Term Location

The source term corresponds to a vertical source plane, normal to the direction of groundwater flow, located at the downgradient limit of the area serving as the principal source of constituent release to groundwater (e.g., affected unsaturated zone soils, NAPL plume, land disposal unit, spill area, etc.). In the absence of such data, the source term should be located at the point of the maximum measured plume concentration(s). Distances to downgradient points of exposure (POEs) should then be measure from this location along the principal direction of groundwater flow.

2) Groundwater Source Term Width, S_W

The width of the source term should be matched to the **greater** of the following dimensions:

i) the measured groundwater plume width, (as defined by Tier 1 limits) normal to the principal direction of groundwater flow at the designated source term location.

ii) the maximum width of the affected soil zone, normal to the principal groundwater flow direction.

3) Groundwater Source Term Thickness, S_d

The thickness of the source term should be matched to **either**:

i) the measured vertical extent of the affected groundwater plume, at the designated source term location.

ii) in the absence of actual site measurements establishing the vertical extent of the affected groundwater plume, the full saturated thickness of the water-bearing unit at this location.

4) Groundwater Source Term Concentration, C_S

To calculate baseline risk levels, the user must also provide a groundwater source concentration for each constituent of concern (COC). The vertical plane source functions as a constant source term, applying these input concentrations to all groundwater flowing through the source location. Under a Tier 2 evaluation, the source concentration of each COC may be defined as follows:

i) use the maximum concentration of each COC detected at the source location or

ii) if multiple sampling locations are available to characterize plume concentrations across the source term width Sw, calculate a weighted average source concentration for each constituent across this plume transect based on time-consistent measurements.

FIGURE 4. DEFINITION OF SOURCE TERM FOR USE IN DOMENICO SOLUTE TRANSPORT MODEL

Parameters Selection Guidelines

For purpose of parameter value selection, the input parameters required for each of the fate-and-transport models identified above can be grouped in the following categories:

- **Site-Specific Parameter Measurements**: Required for parameters which i) exhibit a wide range of site-specific variability (e.g., orders of magnitude) that may significantly impact model predictions and ii) are amenable to characterization based upon limited site-specific measurements. Examples include hydraulic conductivity, flow gradient, source dimensions, etc.

- **Reasonable Parameter Estimates**: Suitable for parameters which i) exhibit a moderate degree of site-specific variability (e.g., less than 1X) and ii) may be characterized on the basis of generic estimates without significantly impacting model predictions. Examples include soil porosity, soil unit weight, and volumetric air and water content, etc.

- **Chemical-Specific Parameter Values**: Physical properties of chemical constituents which must be characterized on the basis of published laboratory values. Examples include Henry's Law constant, air and water diffusion coefficients, and carbon-water sorption coefficients, etc.

For each of the analytical fate-and-transport models identified in Appendix X.2 of ASTM E-1739 and incorporated in the RBCA Spreadsheet System, practical guidelines for appropriate selection of input parameters per these general categories are outlined below. Please note that, although these recommendations relate to the modeling equations listed on Figures 1-3, these guidelines are generally applicable to various analytical models used for characterization of chronic exposure conditions.

VOLATILIZATION MODELS: Equations CM-1 through CM-6

The volatilization models provided in Equations CM-1 thorugh CM-6 (see Figure 2) define the steady-state ratio of the concentration in air at the POE to the source concentration in the underlying soil (Equations CM-1 through CM-4) or groundwater (Equations CM-5 and CM-6). Guidelines for selection of input parameters, grouped according to the three categories noted above, are summarized on Table 1.

SOIL-TO-GROUNDWATER LEACHING MODELS: Equations CM-7 and CM-8

Per the approach outlined in Appendix X.2 of ASTM E-1739, a soil-to-groundwater DAF value can be calculated as the product of: i) a leachate-groundwater dilution factor (Equation CM-8), divided by ii) a soil-leachate partition factor (Equation CM-7), providing a steady-state ratio between the concentration of a constituent on the affected soil mass to the resultant concentration in the underlying groundwater mixing zone. The model is applicable to both organic and inorganic constituents; however, as noted on Table 2, care must be taken to employ the appropriate equation for estimation of the soil-water sorption coefficient (k_s). Guidelines for selection of each input parameter required for Equations CM-7 and CM-8 are summarized on Table 2.

LATERAL GROUNDWATER TRANSPORT MODEL: Equation LT-1

To account for attenuation of affected groundwater concentrations between the source and POE, the Domenico analytical solute transport model has been incorporated into the RBCA software. This model uses a partially or completely penetrating vertical plane source, perpendicular to groundwater flow, to simulate the release of organics from the mixing zone to the moving groundwater (see Figure 4). Within the groundwater flow regime, the model accounts for the effects of advection, dispersion, sorption, and biodegradation. Given a representative source zone concentration for each COC, the model can predict steady-state plume concentrations at any point (x, y, z) in the downgradient flow system. In Equation LT-1 (see Figure 3), the model is set to

Electronic Filing: Received, Clerk's Office 08/1/2024

predict centerline plume concentrations at any downgradient distance x, based on 1-D advective flow and 3-D dispersion. The receptor well is assumed to be located on the plume centerline, directly downgradient of the source zone at a location specified by the user. Note that the model incorporates biodegradation of organic constituents, based on use of a first-order decay function (LT-1a) or an electron-acceptor superposition algorithm (LT-1b). Inorganic constituents are assumed to be conservative ($\lambda = 0$), with no resultant sorption or bioattenuation under steady-state conditions. Guidelines for selection of key input parameters are outlined on Table 3.

LATERAL AIR TRANSPORT MODEL: EQUATION LT-2

The RBCA software includes a 3-dimensional gaussian dispersion model to account for transport of air-borne contaminants from the source area to a downwind POE (see Equation LT-2 on Figure 3). The model incorporates two conservative assumptions: i) a source zone height equivalent to the breathing zone and ii) a receptor located directly downwind of the source at all times. As indicated on Figure 3, an effective pathway NAF value is calculated as the steady-state ratio between the source concentration in the on-site affected soil zone and the ambient organic vapor or particulate concentration at the downwind POE. The model requires input data for the affected soil zone dimensions and concentrations, wind speed, and horizontal and vertical air dispersion coefficients to compute the resulting COC concentrations in ambient air at the POE. Guidelines for defining key input parameters are provided on Table 4.

Summary

As demonstrated by the RBCA Spreadsheet System, a system of simple analytical fate-and-transport models can be used for comprehensive evaluation of chronic exposure levels associated with potential soil, air, and groundwater exposure pathways. However, as with all predictive modeling efforts, reliable results require proper characterization of the input parameters, particularly those requiring site-specific measurement as noted on Tables 1-4. In all cases, model predictions must be shown to be consistent with the actual constituent distributions observed at the site. Use of the Tier 1 and Tier 2 calculation methods discussed in ASTM E-1739 and incorporated in the RBCA Spreadsheet System can significantly reduce the time and effort required for estimation of baseline risk levels or calculation of site-specific, risk-based soil and groundwater remediation goals. However, proper scientific and/or engineering expertise is required for both characterization of input parameters and assessment of model results.

TABLE 1. PARAMETER SELECTION GUIDELINES: VOLATILIZATION MODELS

Input Parameter		Typical Range	Parameter Measurement or Estimation Guidelines	Reference
Symbol	**Description**			
SITE-SPECIFIC PARAMETER MEASUREMENTS				
W	Soil source zone dimension parallel to wind direction (cm)	Site-specific	Measure lateral extent of soil zone serving as source of vapor release (e.g., zone exceeding Tier 1 limits). For on-site POE, use maximum lateral source dimension. For off-site POE, use dimension measured along line passing from source zone to nearest downwind off-site POE location.	Connor et al, 1995
L_{GW}	Depth to groundwater	Site-specific	For unconfined unit, measure depth to static water level. For confined unit, measure depth to top of water-bearing stratum.	Connor et al, 1995
L_S	Depth to subsurface soil source (cm)	Site-specific	Measure depth from ground surface to top of affected source zone.	Connor et al, 1995
d or d_S	Thickness of affected soil zone	Site-specific	Measure average vertical dimension from top to base of affected soil zone over lateral area corresponding to W.	Connor et al, 1995
h_V	Thickness of vadose zone (cm)	Site-specific	Measure from ground surface to depth of static water level in unconfined unit. In confined unit, measure from ground surface to depth of soil saturation (often corresponding to potentiometric surface elevation).	Connor et al, 1995
f_{OC}	Fraction of organic carbon in soil (g-C/g-soil)	0.001 - 0.03	Conduct lab analyses on representative unaffected soil samples over depth interval of vertical vapor migration or use generic value of 0.01 for vadose zone.	LaGrega, 1994
REASONABLE PARAMETER ESTIMATES				
U_{air}	Windspeed above ground surface in ambient mixing zone (cm/s)	45 - 450 cm/sec	Match to average annual windspeed for site area, based on published climatic data.	Connor et al, 1995
δ_{air}	Ambient air mixing zone height (cm/s)	200 cm	Match to typical height of human breathing zone (6 ft or 2m).	Connor et al, 1995
k_S	Soil-water sorption coefficient (g-H_2O/g-soil)	-----	For organics, estimate as: $k_S = k_{OC} \times f_{OC}$. For ionizing organics (e.g., chlorophenols), estimate k_S based on published pH-dependent partitioning coefficients for ionized and neutral forms. For inorganics, estimate k_S per published pH-dependent isotherms, based on measured groundwater pH. Detailed guidelines provided in U.S. EPA SSL Background Document (1996).	U.S. EPA, 1996
ρ_S	Soil bulk density (g-soil/cm^3-soil)	1.6 - 1.75	Use median soil value of 1.7 g/cm^3.	ASTM, 1995
Θ_T	Total soil porosity (cm^3-pore space/cm^3-soil)	35 - 55%	Estimate based on predominant soil type as follows: Uniform Sand: 40% Soft Clay: 55% Mixed-Grain-Sand: 35% Stiff Clay: 37% Silt: 50%	Peck et al, 1974
Θ_{ws}	Volumetric water content in vadose zone soils (cm3-H_2O/cm^3-soil)	13 - 52%	Estimate based on predominant soil type as follows: Uniform Sand: 13% Soft Clay: 52% Mixed-Grain-Sand: 16% Stiff Clay: 34% Silt: 42% NOTE: Typical Θ_{ws} values approximated as saturated water content minus specific yield of soil.	Peck et al, 1974 Todd, 1980
Θ_{as}	Volumetric air content in vadose zone soils (cm^3-air/cm^3-soil)	3-27%	Calculate as $\Theta_{as} = \Theta_T - \Theta_{ws}$, where Θ_{ws} and Θ_T estimated per predominant soil type as above.	Peck et al, 1974 Todd, 1980
NOTE: See Equation CM 1 through CM 6 on Figure 2 regarding use of the above parameters for estimation of steady-state volatilization factors for affected soils. Detailed discussion of these volatilization models is provided in the Tier 2 RBCA Guidance Manual (see Connor et al, 1995).

TABLE 1. PARAMETER SELECTION GUIDELINES: VOLATILIZATION MODELS *continued*

Input Parameter				
Symbol	**Description**	**Typical Range**	**Parameter Measurement or Estimation Guidelines**	**Reference**
REASONABLE PARAMETER ESTIMATES (CONT'D)				
h_{cap}	Thickness of capillary fringe (cm)	2 - 200 cm	Estimate based on predominant soil type, as follows: Medium Samd: 25 cm Clayey Silt: 200 cm Fine Sand: 43 cm Silt: 105 cm	Todd, 1980
P_e	Particulate emission rate (g/cm^2-s)	-----	Use generic upperbound value (e.g., 6.9 x 10^{-14} g/cm^2-sec)) or estimate reasonable site-specific value using method outlined in U.S. EPA SSL guide.	ASTM, 1995 EPA, 1996
z	Averaging time for vapor flux (s)	-----	Match to assumed exposure duration (in seconds).	ASTM, 1995
ER	Enclosed space air-exchange rate (L/s)	-----	Use generic lowerbound value (e.g., 0.00014 L/s for residential, 0.00023 L/s commercial) or match to minimum allowable indoor air ventilation rate per local building code.	ASTM, 1995
L_B	Ratio of enclosed space volume to infiltration area (cm)	-----	Use generic lowerbound value (e.g., 200 cm) or develop reasonable estimates based on size (no. of floors) and area (foundation outline) of typical residential or commercial structures in site area.	ASTM, 1995
L_{crack}	Enclosed space foundation or wall thickness (cm)	-----	Use generic upperbound value (e.g., 15 cm) or match to local building code specifications for residential or commercial structures.	ASTM, 1995
Z	Areal fraction of cracks in foundations /walls (cm^2-cracks/cm^2-total area)	-----	Use generic upperbound value (e.g., 1%) or estimate based on observed site conditions.	ASTM, 1995
CHEMICAL-SPECIFIC PARAMETER VALUES				
H	Henry's Law Constant (cm3-H_2O/cm^3-air)	-----	Use median value reported for each constituent of concern in published chemical reference.	Connor et al, 1995 a
k_{oc}	Carbon-water sorption coefficient (g-H_2O/g-C)	-----	Use median value reported for each constituent of concern in published chemical reference.	Connor et al, 1995 a
D^{air}	Diffusion coefficient in air (cm^2/s)	-----	Use median value reported for each constituent of concern in published chemical reference.	Connor et al, 1995 a
D^{wat}	Diffusion coefficient in water (cm^2/s)	-----	Use median value reported for each constituent of concern in published chemical reference.	Connor et al, 1995 a
D_s^{eff}	Effective diffusivity in vadose zone soils (cm^2/s)	-----	Estimate as shown on Figure 2.	-----
D_{ws}^{eff}	Effective diffusivity above the water table (cm^2/s)	-----	Estimate as shown on Figure 2.	-----

NOTE: See Equation CM 1 through CM 6 on Figure 2 regarding use of the above parameters for estimation of steady-state volatilization factors for affected soils. Detailed discussion of these volatilization models is provided in the Tier 2 RBCA Guidance Manual (see Connor et al, 1995).

Electronic Filing: Received, Clerk's Office 08/1/2024

TABLE 2. PARAMETER SELECTION GUIDELINES: SOIL-TO-GROUNDWATER LEACHATE MODELS (EQUATIONS CM-7 AND CM-8)

Input Parameter		Typical Range	Parameter Measurement or Estimation Guidelines	Reference
Symbol	**Description**			
SITE-SPECIFIC PARAMETER MEASUREMENTS				
W	Soil source zone dimension parallel to groundwater flow direction (cm)	Site-specific	Measure lateral extent of soil zone serving as source of leachate release to underlying groundwater (e.g., exceeding Tier 1 limits) along line parallel to natural groundwater flow.	Connor et al, 1995
f_{oc}	Fraction of organic carbon in soil (g-C/g-soil)	0.001 - 0.03	Measure on representative unaffected soil samples over vertical depth interval of vapor migration or use generic lowerbound value of 0.01 for vadose zone.	La Grega, 1994
V_{gw}	Groundwater Darcy velocity (cm/w)	Site-specific	Estimate as follows: $V_{gw} = K \bullet i$ where K and i are defined as noted below.	Bedient et al, 1994
K	Hydraulic conductivity of water-bearing unit (cm/sec)	Site-specific	Measure K values vased upon either i) rising-head slug tests or ii) constant-rate aquifer pumping tests conducted on wells properly installed and developed in water-bearing unit. Re-evaluate test results if measured values fall outside typical range for predominant soil type, as follows: Clays: $<1x10^{-6}$ cm/s Silts: $1x10^{-6}$ - $1x10^{-3}$ cm/s Silty Sands: $1x10^{-4}$ - $1x10^{-2}$ cm/s Clean Sands: $1x10^{-1}$ - 1 cm/s Gravels: >1 cm.s	Bedient et al, 1994
i	Lateral hydraulic flow gradient of water-bearing unit (cm/cm)	0.001 - 0.1	Measure lateral flow gradient in area beneath soil source zone based on triangulation among 3 or more monitoring wells or piezometers screened within water-bearing unit.	Newell et al, 1996
δ_{gw}	Groundwater mixing zone thickness (cm)	Site-specific	Measure vertical extent of affected groundwater zone within water-bearing unit in area underlying soil source zone. If vertical plume extent undetermined at this location, use lowerbound estimate (e.g., 200 cm).	ASTM, 1995
REASONABLE PARAMETER ESTIMATES				
I	Infiltration rate of water through soil (cm/year)	------	Estimate I as function of annual rainfall (P) in site area, depending on predominant surface soil type, as follows: Clayey Soils: I = (1 - 2%) x P Sandy Soils: I = (5 - 10%) x P Paved Site: I = (0.1 - 1%) x P	(NOTE: Values are preliminary. Supporting guidelines under development.)
P_s	Soil bulk density (g-soil/cm^3-soil)		Use median soil value of 1.7 g/cm^3.	ASTM, 1995
Θ_{ws}	Volumetric water content in vadose zone soils (cm3-H_2O/cm^3-soil)		Estimate based on predominant soil type as follows: Uniform Sand: 13% Soft Clay: 52% Mixed-Grain-Sand: 16% Stiff Clay: 34% Silt: 42% NOTE: Typical Θ_{ws} values approximated as saturated water content minus specific yield of soil.	Peck et al, 1974 Todd, 1980
Θ_{as}	Volumetric air content in vadose zone soils (cm^3-air/cm^3-soil)		Calculate as $\Theta_{as} = \Theta_T - \Theta_{ws}$, where Θ_{ws} and Θ_T estimated per predominant soil type as above. NOTE: Values correspond to drained conditions. Dry weather may increase Θ_{as} in near-surface silts and clays (< 6 ft depth).	Peck et al, 1974 Todd, 1980
NOTE: See Equations CM-7 and CM-8 on Figure 2 regarding use of the above parameters for estimation of soil-to-groundwater leaching factor for affected soils. Detailed discussion of this soil leachate model is provided in the Tier 2 RBCA Guidance Manual (Connor et al, 1995).

REASONABLE PARAMETER ESTIMATES (CONT'D)				
k_S	Soil-water sorption coefficient (g-H_2O/g-soil)	-----	For organics, estimate as: $k_S = k_{OC} \times f_{OC}$. For ionizing organics (e.g., chlorophenols), estimate k_S based on published pH dependent partitioning coefficients for ionized and neutral forms. For inorganics, estimate k_S as published pH-dependent isotherms, based on measured groundwater pH.	U.S. EPA, 1996
CHEMICAL-SPECIFIC PARAMETERS				
H	Henry's Law Constant (cm3-H_2O/cm^3-air)	-----	Use median value reported for each constituent of concern in published chemical reference.	Connor et al, 1995a
k_{oc}	Carbon-water sorption coefficient (g-H_2O/g-c)	-----	Use median value reported for each constituent of concern in published chemical reference.	Connor et al, 1995a
NOTE: See Equations CM-7 and CM-8 on Figure 2 regarding use of the above parameters for estimation of soil-to-groundwater leaching factor for affected soils. Detailed discussion of this soil leachate model is provided in the Tier 2 RBCA Guidance Manual (Connor et al, 1995).				

TABLE 3. PARAMETER SELECTION GUIDELINES: LATERAL GROUNDWATER TRANSPORT MODEL (EQUATION LT-1)

Input Parameter		Typical Range	Parameter Measurement or Estimation Guidelines	Reference
Symbol	**Description**			
SITE-SPECIFIC PARAMETER MEASUREMENTS				
υ	Groundwater seepage velocity (cm./sec)	Site-specific	Calculate site-specific value based on the following equation: $\upsilon = \frac{K \bullet i}{\theta_e}$ where K, i, and θ_e are determined as specified below..	Bedient et al, 1994
K	Hydraulic conductivity of water-bearing unit (cm/sec)	Site-specific	Measure K values based upon either i) rising-head slug tests or ii) constant-rate aquifer pumping tests conducted on wells properly installed and developed in water-bearing unit. Re-evaluate test results if measured values fall outside typical range for predominant soil type, as follows: Clays: <$1x10^{-6}$ cm/s Silts: $1x10^{-6}$ - $1x10^{-3}$ cm/s Silty Sands: $1x10^{-4}$ - $1x10^{-2}$ cm/s Clean Sands: $1x10^{-1}$ - 1 cm/s Gravels: >1 cm.s	Bedient et al, 1994
i	Lateral hydraulic flow gradient of water-bearing unit (cm/cm)	0.001 - 0.1	Measure lateral flow gradient in area beneath soil source zone based on triangulation among 3 or more monitoring wells or piezometers screened within water-bearing unit.	Newell et al, 1996
R_i	Constituent retardation factor	Site-specific	Calculate site-specific values based on the following equation: $R = 1 + \frac{k_s \bullet \rho_s}{\theta_e}$ where k_s, ρ_s, and θ_e are determined as specified below.	Newell et al, 1996

TABLE 3. PARAMETER SELECTION GUIDELINES: LATERAL GROUNDWATER TRANSPORT MODEL (EQUATION LT-1) *continued*

Input Parameter		Typical Range	Parameter Measurement or Estimation Guidelines	Reference
Symbol	**Description**			
SITE-SPECIFIC PARAMETER MEASUREMENTS (CONT'D)				
k_S	Soil-water sorption coefficient (g-H_2O/g-soil)		For organics, estimate as: $k_S = k_{OC} \times f_{OC}$. For ionizing organics (e.g., chlorophenols), estimate k_S based on published pH dependent partitioning coefficients for ionized and neutral forms. For inorganics, estimate k_S as published pH-dependent isotherms, based on measured groundwater pH. See EPA SSL Guidance for detailed information.	U.S. EPA, 1996
f_{oc}	Fraction of organic carbon in soil (g-C/g-soil)	0.001 - 0.03	Measure depth from ground surface to top of affected source zone. Measure average vertical dimension from top to base of affected soil zone over area corresponding to W. Generic lowerbound value of 0.001.	La Grega, 1994
BC_i	Biodegradation capacity for constituent i	Site-specific	If using electron-acceptor superposition form of Domenico model (Equation LT-1b), calculate BC_i value as indicated on Figure 3. Detailed instructions for BC_i and BC_T estimation are provided in BIOSCREEN user's manual (Newell et al, 1996). Calculation must be based on site-specific measurement of principal electron acceptor concentrations in site groundwater.	Newell et al, 1996 Connor et al, 1995
X	Distance from source to downgradient POE (cm)	Site-specific	Measure from source term location to downgradient POE location along line of groundwater flow.	Connor et al, 1995
S_w	Groundwater source term width (cm)	Site-specific	See Figure 4 for guidelines regarding site-specific determination of source width of water-bearing unit.	Connor et al, 1995
S_d	Groundwater source term thickness (cm)	Site-specific	See Figure 4 for guidelines regarding site-specific determination of source thickness in water-bearing unit.	Connor et al, 1995
REASONABLE PARAMETER ESTIMATES				
θ_e	Effective porosity of water-bearing unit (cm^3-pore/cm^3-soil)	0.001 - 0.1	Match to representative value for predominant soil type in water-bearing unit, as follows: Clay = 0.01 - 0.20 Silt = 0.01 - 0.30 Fine Sand = 0.10 - 0.30 Med. Sand = 0.15 - .30 Coarse Sand = 0.20 - 0.33 Gravel = 0.10 - 0.35	Domenico et al, 1990 Walton, 1988

Electronic Filing: Received, Clerk's Office 08/1/2024

TABLE 3. PARAMETER SELECTION GUIDELINES: LATERAL GROUNDWATER TRANSPORT MODEL (EQUATION LT-1) *continued*

Input Parameter		Typical Range	Parameter Measurement or Estimation Guidelines	Reference
Symbol	**Description**			
REASONABLE PARAMETER ESTIMATES (CONT'D)				
α_x α_y α_z	Groundwater dispersivity coefficients in longitudinal (x), transverse (y), and vertical (z) dimensions	-----	For use with biodegradation functions in Domenico model (LT-1a or LT-1b), reasonable dispersivity estimates may be derived as follows: **Longitudinal Dispersivity**: $\alpha_x = 3.28 \bullet 0.83 \bullet \left[\log_{10}\left(\frac{X}{3.28}\right)\right]^{-2.414}$ **Transverse Dispersivity**: α_y = 0.10 alpha x (*based on high reliability points from Geihar et al, 1992*) **Vertical Dispersivity**: α_z = very low (i.e., 1 x 10^{-99} ft) (*based on conservative estimate*)	Xu and Eckstein, 1995 Gelhar et al, 1992 Newell et al, 1996
			Other commonly used relationships include: $\alpha_x = 0.1 \bullet X$ $\alpha_y = 0.33 \bullet \alpha_x$ α_z = 0.025 to 0.1 $\bullet \alpha_x$ [Note: If used with electron-acceptor superposition version of Domenico model (Equation LT-1b), these later relationshipos may result in overestimation of biodegradation effects.]	Pickens and Grisak, 1981 ASTM, 1995 EPA, 1986
λ_e	First-order degradation rate for constituent i (sec^{-1})	------	Optional methods for selection of appropriate decay coefficients for each constituent of concern are as follows: **Calibrate to Existing Plume Data**: If the plume is in a steady-state or diminishing condition, the BIOSCREEN or FATE II models can be used to determine first-order decay coefficients that best match the observed site concentrations. This site-specific calibration effort will require representative measurements of each constituent along the centerline of the groundwater plume. Detailed instructions are provided in the BIOSCREEN and FATE II User's Guides. **Literature Values**: If the plume is in an expanding condition or if a preliminary estimate of biodegradation effects is desired, decay half-life values for hydrolysis and biodegradation from published references (e.g., see Howard et al, 1991). Note that many references report the half-lives; these values can be converted to the first-order decay coefficients using k = 0.693/$t_{1/2}$ (see dissolved plume half-life). In the absence of site-specific calibration data, minimum values (maximum half-life values) should be used. The selected values should correspond to the half-life for full constituent decay to non-hazardous progeney. For inorganics, λ = 0.	Newell et al, 1996 Connor et al, 1995 Connor et al, 1994

NOTE: See Equation LT-1 on Figure 3 regarding use of the above parameters for estimation of steady-state groundwater dilution attenuation factor for dissolved groundwater plume. Detailed discussion of this groundwater solute transport model is provided in the Tier 2 RBCA Guidance Manual (see Connor et al, 1995).

TABLE 4. PARAMETER SELECTION GUIDELINES: LATERAL AIR TRANSPORT MODEL (EQUATION LT-2)

Input Parameter		Typical Range	Parameter Measurement or Estimation Guidelines	Reference
Symbol	**Description**			
SITE-SPECIFIC PARAMETER MEASUREMENTS				
L	Length of affected soil zone parallel to wind direction (cm)	Site-specific	Determine lateral extent of affected soil zone serving as source of vapor release (e.g., zone exceeding Tier 1 limits) measured along line passing from source zone to downwind off-site POE.	Connor et al, 1995
A	Lateral area of affected soil zone (cm^2)	Site-specific	Measure areal extent of affected soils serving as source of vapor release (e.g., zone exceeding Tier 1 limits).	Connor et al, 1995
X	Lateral distance downwind of source zone (cm)	Site-specific	For most conservative evaluation, measure as distance from edge of affected soil zone to nearest off-site POE location (in some direction as L above). For typical case, measure this distance along line of predominant annual wind direction.	Connor et al, 1995
REASONABLE PARAMETER ESTIMATES				
$\mathbf{U_{air}}$	Windspeed above ground surface in ambient mixing zone (cm/s)	45 - 450 cm/sec	Match to average annual windspeed for site area, based on published climatic data.	Connor et al, 1995
δ_{air}	Ambient air mixing zone height (cm/s)	200 cm	Match to typical height of human breathing zone (6 ft or 2m).	ASTM, 1995
y	Transverse distance off air plume centerline (cm)	-----	To evaluate exposure concentrations along plume centerline, y is set equal to zero.	Connor et al, 1995
z	height of breathing zone (cm)	-----	Assume equal to δ_{air} above.	Connor et al, 1995
σ_y, σ_z	Air dispersion coefficients (cm) in the transverse (y) and vertical (z) directions	-----	For average annual climatic conditions, characterize σ_y, σ_z based on Stability Class C (slightly unstable) using the following relationships: $\sigma_y = 10^{(\text{Log (x)} \bullet 0.941 - 0.861)}$ $\sigma_z = 10^{(\text{Log (x)} \bullet 0.927 - 1.01)}$ If Stability Class C determined to be inapplicable, estimate air dispersion coefficient values using Pasquill-Gifford system as discussed in DeVaull et al, 1994.	Connor et al, 1995 Devaull et al, 1994 U.S. EPA, 1988
C_{si}	Concentration of constituent i in ambient air at point source	-----	Estimate based on appropriate soil-to-air volatilization model (see Equations CM-1 through CM-3 on Figure 2) or conduct site-specific measurements in breathing zone air overlying affected soil source area.	Connor et al, 1995
NOTE:	See Equation LT-2 on Figure 3 regarding use of the above parameters for estimation of lateral air dispersion factor for wind-borne contaminant transport to downwind receptor. Detailed discussion of this air dispersion model is provided in the Tier 2 RBCA Guidance Manual (see Connor et al, 1995).

DISCOVERY DEPOSITION

The deposition of LAUREN HUNT taken on behalf of the Petitioner at 133 South 4th Springfield, IL on May 28th, 2024, before Deann K. Parkinson, Certified Shorthand Reporter of the State of Illinois. Deposition taken pursuant to the discovery provisions of the Illinois Code of Civil Procedure and the Rules of the Supreme Court promulgated pursuant thereto.

(The time is 1:54 p.m.)

LAUREN HUNT,

the deponent herein, called as a witness, after having been first duly sworn, testified as follows:

EXAMINATION BY

MS. JOSHI:

Q. Good morning. I'm Bina Joshi from Arentfox Schiff representing Illinois Power Generating Company in this matter. Thank you very much for your time and for being here today. Would you mind starting by stating your name and current business address for the record.

A. Lauren Hunt. 1021 North Grand Avenue something. South Grand Avenue. I don't know.

Q. That's okay.

A. I live in Peoria. I'm really not familiar with Springfield. So --

Q. You currently work for the Illinois Environmental Protection Agency?

A. Yes.

Q. I'm going to start by going over some ground rules, just so that everyone is on the same page for this deposition. So, as you just saw,

you will be giving testimony under oath today. Is there anything that might impact your ability to answer truthfully today?

A. No.

Q. Are you aware of anything that would preclude your ability to understand any of my questions this afternoon?

A. Not that I'm aware of.

Q. I'd ask that you just give verbal answers to any of my questions because we have the court reporter here, and unfortunately the transcript can not pick up head nods.

A. Okay.

Q. Let me know if you don't understand a question that I ask, and I will try my best to clarify. Let me know if you, or let us know if you need a break at any point, and we can stop and take a break. Just if we're in the middle of a question and answer, I would ask that you finish the answer before we take the break, okay?

A. Okay.

Q. Do you understand these instructions?

A. Yes.

Q. Any questions about those?

A. No.

Q. Okay. I'm just going to go over some shorthand so we're on the same page. As you know, we live in a world of acronyms. When I refer to Illinois Power, IPGC, during this deposition, I'm going to be referring to Illinois Power Generating Company. Newton means the Newton Power Plant. The PAP or Newton PAP will refer to the Newton Primary Ash Pond that was the subject of the Alternative Source Demonstration at issue in this appeal.

When I use the term ASD, I'm referring to the Newton Alternative Source Demonstration, again, that's the subject of this proceeding. When I refer to IEPA, or the agency, I'm referring to the Illinois Environmental Protection Agency. And when I refer to part 845, I'm referring to the regulations located at Title 35 Illinois Administrative Code Part 845. Does all of that make sense to you?

A. Yes.

Q. I'm going to start by just asking a few questions about your background and experience. So, where did you get your bachelor's degree?

A. Western Illinois University.
Q. And in what subject did you get your degree in?
A. Geology.
Q. Do you have any other bachelor's degrees?
A. No.
Q. Do you have a Master's degree?
A. Yes.
Q. In what subject?
A. Hydrogeology.
Q. And where did you get that Master's degree?
A. Illinois State University.
Q. Do you have any other degrees at the collegiate or post-collegiate level?
A. No.
Q. Let's talk briefly about your employment history. What's your current position at IEPA?
A. Environmental protection geologist three.
Q. How long have you held that position?
A. The three, or can you clarify? The three or just been at the agency?

Q. The three?
A. Okay. Since February of 2022.
Q. Can you describe your, just generally, your responsibilities in that role?
A. Generally, we review documents from various responsible parties and citizens. We provide approvals where required by, or comments and approvals or reviews for documents where it's required by the regulations.
We work with the coal combustion residuals rule, part 620. And mines and permits where we're asked to help out with permit reviews.
Q. Would you consider your role a managerial position?
A. No.
Q. Do you have a direct superior?
A. I do.
Q. Who is that?
A. I am currently reporting to Joey Logan-Pugh.
Q. And were you reporting to anyone before Joey Logan-Pugh while you were in this position?
A. Yes.
Q. Who was that?

A. Mike Brown.
Q. Anyone else?
A. Mike Summers.
Q. When did you report to Mike Summers?
A. From basically since the end of 2020 until he left the agency at the end of 2023.
Q. Other than Mike Summers, were any of your other sort of direct superiors, Mike Brown or Joey Logan-Pugh, involved in reviewing the Newton PAP ASD?
A. No.
Q. So, prior to your current position at IEPA, did you hold any previous positions at IEPA?
A. Yes, environmental protection geologist one and environmental protection geologist two.
Q. And during what time period was that?
A. Starting in February of 2020, until 2021 I was an environmental protection geologist one. And then in 2021 to 2022 I was an environmental protection geologist two.
Q. And what were your responsibilities in those roles generally?
A. Generally the same as they are now.
Q. So what difference from going to a two

to a three, for example?

A. There's not much. I came to the agency with previous experience, so -- it was -- it's all kind of been the same.

Q. Okay. In terms of your responsibilities, it's been similar?

A. Yes.

Q. Did you hold employment prior to starting at IEPA?

A. Yes.

Q. Okay. And so where were you directly before you came to the agency?

A. CH2M Hill. Which it's formerly CH2M Hill. It's now owned by Jacobs Engineering.

Q. And how long were you there?

A. From 2005 to 2020.

Q. What were your responsibilities when you were at CH2M Hill?

A. A great many things. So, I was a geologist. I worked as a field team leader, construction manager, construction supervisor, construction quality manager. Subject matter expert. I guess an engineering geologist in the field. Site characterization site manager. Site

manager. A number of things; a lot, yeah.
Q. If I can ask you a little bit about a couple of those. You said you served as a Site characterization site manager. Can you elaborate on the kind of work that you did as a site characterization site manager?
A. As a site characterization site manager, I was in charge of reviewing and insuring the implementation of site characterization in the field for two projects while I was in the Middle East that are covered by an NDA.
Q. So I won't get into the details. So you were in the field hoping to implement this site characterization, is that correct?
A. Representing the client and checking that it's being implemented appropriately and accurately.
Q. Did you develop the method by which the sites would be characterized?
A. No.
Q. If you are able to talk about it, and if it's confidential, please feel free to let me know. What types of methodology -- you mentioned two sites in the Middle East, is that correct?

A. Uh-huh.
Q. Okay. Let's just start with the earliest of the two that you worked on?
A. They were concurrent.
Q. Okay. So, for the two site characterizations that you helped implement, what methodology was being used to characterize the sites?
A. What's I guess like overall subjects, is that what you're asking? That we're looking at? 'Cuz I was looking at geotechnical engineering, hydrogeology, geology, biology, meteorology, were all things that were being characterized at the time that I was there and I was reporting on. And possibly more.
Q. Okay. Are you a -- well, were you anywhere before CH2M Hill?
A. Yes.
Q. Where was that?
A. I worked at Whitney & Associates as an intern while I was in undergrad. And then after undergrad. And then I worked at Nicor while I was in grad school. And I did an internship for them in the summer.

Q. Okay. What kind of work did you do at Nicor?
A. Basically I worked on my thesis. They paid me to work on my thesis.
Q. Which was?
A. Basically setting the gas migration pathways from the gas storage field at Torrey Grove gas storage field here in Illinois to the surface.
Q. And then so was it Whitney the other place that you worked?
A. Yes.
Q. And what did you do there?
A. It would be engineering geology and construction materials testing. It was a geotechnical engineering firm that does third party inspections of construction sites.
Q. Are you licensed as a professional engineer?
A. No.
Q. Are you licensed as a professional geologist?
A. No.
Q. So, in all of that experience that

you've had, have you ever performed total solid sampling for CCR surface impoundment?

A. Not for CCR surface impoundment.

Q. Have you performed it for another type of source?

A. Yes.

Q. What type of source?

A. Various. First things that comes to mind is chromium ore process residuals. Various sites in Illinois. Like the Elgin O'Hare had a lot of solids collected for characterization for movement of the soil along the Elgin O'Hare western access when they, I guess managed the soil and put it in different places.

Q. Okay. And so was the source itself sort of the byproduct of the chromium ore processing facility?

A. Correct.

Q. And the source itself was then -- what was it? Was it a landfill or was it an impoundment? Or what, I guess --

A. It was Dundalk Marine Terminal in Baltimore, Maryland. It underlies all of the Port of Baltimore.

Q. Okay. So was it like fill underneath the port?
A. They mud waved the chromium ore process residuals into the Chesapeake Bay and created the port on top of it.
Q. So, what types of total solid sampling did you perform on the site?
A. We soil sampled, we tested it in the field. We tested to see if there was hex chrom in the solids, in the groundwater. Installed wells. Collected soil. Collected groundwater. I set up the geotechnical lab. We performed geotechnical testing at the site as well.
Q. Can you describe for me what geotechnical testing is?
A. Geotechnical testing would be like soils testing, such as we did Atterberg Limits. Moisture contents. Just various soil characterization methods, probably specific to specific gravity and dry densities. And, yeah.
Q. Did your testing involve any testing related to potential leaching from the source?
A. Yes. We collected groundwater samples and studied the groundwater to see what was

actually making it offsite. They also collected groundwater in catch basins and treated it on site to keep it from going offsite.

Q. Were there any pore water samples that were collected?

A. No.

Q. Was there any leach testing that was conducted?

A. No.

Q. Have you ever worked on a site where --

A. Not to my knowledge that I can remember.

Q. Have you ever worked on a site where pore water samples were collected?

A. Yes.

Q. Where was that?

A. Waukegan, it was the Waukegan Harbor area. One of the USEPA Superfund sites. No, it's not a Superfund site. Sorry. I take that back. It's not a Superfund site. So, when I was at Jacobs or CH2M Hill we were a USEPA contractor, so we did third-party oversight on the part of the USEPA. There are a number of sites along the Waukegan Harbor area that were being monitored. One of those included pore water sampling. But it

was in the hyporheic zone.

Q. And for this non engineer here, and I'm pointing to myself, can you explain what that zone is?

A. It is the -- between where the lake water and the groundwater come together; that zone where the sediment, and it's partial surface water and it's partial groundwater.

Q. So this was in the harbor itself?

A. Yes. On a barge.

Q. You accessed it through a barge?

A. Yes.

Q. And were you personally involved in collecting the pore water samples?

A. No.

Q. Did you oversee the process?

A. We watched.

Q. You watched as it was conducted?

A. Yeah.

Q. Okay. Did you analyze the pore water samples afterwards?

A. No, I wasn't involved in that.

Q. Any other sites with the experience with pore water sampling?

A. Not that I know of.
Q. Okay. I understand I'm asking you to reach into your memory here.
And any other sites where you might have conducted leach testing?
A. No.
Q. Have you ever performed a characterization of bedrock as part of your experience?
A. Yes.
Q. When was that?
A. When was the last time or when was --
Q. Yeah, let's start with the most recent.
A. So, I guess that would be -- I believe, I believe, and there could be others, but the last major site that I was on was in the Simi Hills. I'm trying to think if this was also covered by an NDA? As for -- but it was characterizing Simi Hills for fractures and what had gone on previously. It was a federal site.
Q. Okay. Can you explain, first of all, is that Simmi Hills? S-I-M-M --
A. No, S-I-M-I. Like Simi Valley, LA area here. The Simi Hills or the mountains around

there.

Q. And why was a characterization of bedrock occurring there?

A. Because the site was in the mountains.

Q. And what kind of site was it?

A. A NASA site.

Q. Under what program was it being -- was it being characterized under a particular regulatory program?

A. I am not 100 percent sure what regulatory program it was under. But yes, it was under one. I'm not sure if it was just a part of like DOD general work, or if it was CERCLA or specifically RECRA or Superfund. I'm not sure.

Q. Did the characterization include installing monitoring wells?

A. Correct. Yes.

Q. What else did the characterization include?

A. Packer testing.

Q. Anything else?

A. Groundwater sampling. This was ten years ago. So --

Q. Was the waste source that you were

trying to characterize located in the bedrock?
A. Yes. Well, no, wait a second; sorry.
The waste source? The plume, yes.
Q. So, the plume from the source had, or
had entered into the bedrock?
A. Yes.
Q. Or rather were you characterizing to see
sort of how far the plume had gotten into the
bedrock?
A. Yes.
Q. And how long did that process take?
A. Well, I am just a hydrogeologist, and I
was a subject matter expert for it. But I had,
like, I guess there were lead technologists on the
project as well. So, I'm not really sure. It's
probably still ongoing right now. But, I was only
involved for a few years.
Q. Okay. I got it. Thank you.
Have you ever prepared an alternative
source demonstration?
A. Do you mean an alternative source
demonstration like under regulation that says
specifically the alternative source demonstration?
Or do you mean just in general like determined an

alternative source?

Q. Let's go with the latter. And have you ever had experience determining whether a particular exceedance was coming from an alternative source?

A. Yes.

Q. And when was that?

A. 2009-2010.

Q. And what were the circumstances?

A. There was TCE in the bedrock. And not in the soil at the site.

Q. What kind of site was it?

A. A FUD site.

Q. A Superfund site?

A. FUDS.

Q. FUDS? What is a FUDS site?

A. A federal something defense systems. I'd have to look it up. It's a FUD site.

Q. Was it like an old like weapons manufacturing site?

A. Old World War II radar school.

Q. Okay. And there was TCE found in a well, is that right?

A. In the public water well.

Q. In a public water well. Okay. And you were helping to determine whether that TCE might have a source other than this FUD site? Is that right?

A. Correct. Well, we were determining where it was coming from, and whether it was coming from the soil at the actual site; if it was from the radar school or if it was from somewhere else offsite.

Q. And what type of process did you engage in to try to figure that out?

A. We installed bedrock wells. We installed -- and then we packer tested. We also sampled through the packers before we packer tested for TCE. We did flow meters in the holes to see, and a number of downhill geophysics to see how the groundwater was flowing in the bedrock when it was opened up.

And then once we had done that, we were able to take those results and match them with the results that had been previously taken of the soil and show that there was in fact no TCE at the site. It was coming in, in the bedrock from offsite. Much deeper than previously recognized.

Q. And did you have evidence showing that the TCE wasn't coming from the site?
A. Yes.
Q. What kind of evidence was that?
A. The TCE was highest at the lowest -- or deepest interval in the wells.
Q. And was it generally getting lower as you got --
A. Higher in the well and closer to the surface, yeah.
Q. Was there any other evidence that showed that it wasn't coming from the site?
A. We had known responsible parties offsite.
Q. Okay. When you were doing that, it sounds like your task was to figure out what the actual source was, is that right? Or was it just to show that it --
A. My task was to characterize what is going on. And then we can make a decision on what the data was telling us.
Q. Okay. Including whether there was another responsible party --
A. Correct.

Q. -- perhaps? When did you decide you had gathered enough data for your characterization?

A. I guess -- so, I came in and just designed the last bedrock investigation to determine where the groundwater was going to and coming from in the bedrock. And after that, like, we had collected enough samples that it showed conclusively that there was TCE coming in from offsite. And so at that point we were done. And under CERCLA rules, yeah, we were -- done.

Q. When you say it was coming from offsite, was the source the bedrock or was it something else?

A. The source was -- again, the likely a BP liquids terminal two miles away.

Q. When you say likely, why do you use the term likely?

A. Because we did not actually sample over there. But, we knew, it was a known fact that Naperville had TCE in their public water supply while between us and the BP terminal. And then we had an on-site well that was a public water supply well, that it was 80 years old that had TCE as well but at lower concentrations. And so now you

had five more wells installed, or six more wells installed that showed that it was coming from the specific direction offsite.

Q. And do you agree that was kind of enough information so that you guys were confident that it was not the FUD site, and it was likely the BP site?

A. It was enough information to say that it was definitely not the FUD site. Because the on-site groundwater flow was up the bore holes, and you had artesian wells in the bedrock.

Q. What are artesian wells?

A. Wells that have hydraulic head above the upper limit of that unit.

Q. And you said there was some other circumstances in the past as well where you've done sort of alternative source type of demonstration or characterization?

A. It's possible. But, not as significant as that one was all of my design.

Q. Okay. And have you ever conducted an alternative source demonstration like under a landfill program?

A. No.

Q. Have you ever conducted one under the Federal CCR rules part 257?
A. No.
Q. And considering the rule was promulgated after you started working at IEPA, I assume the answer is no. But have you ever conducted one personally under part 845?
A. No.
Q. And when did you first review an alternative source demonstration as part of your professional career?
A. Review --
Q. An actual alternative source demonstration that's required under regulatory program?
A. That would be Newton.
Q. And other than, you may have already answered this, but I'll just ask one more time to clarify. Other than that FUD site, have you ever done any sort of forensic analysis to identify the source of an exceedance?
A. I mean, technically almost all environmental assessments or site characterizations fall under that. So yes, many.

Q. And in that circumstance, what do you typically decide? Or how do you typically decide what information to look at?

A. Well, you have to determine what media is present. And then you determine what needs to be characterized from there, depending on what kind of data is available already.

Q. And how do you decide what information not to look at?

A. If the media is not present, then you wouldn't look at it because you wouldn't be able to collect it.

Q. Let's go back to the FUD site for a second. Was there additional data that could have been collected as part of that analysis?

A. They had already done several previous investigations going in to that. So it became a -- we had already singled it out to be bedrock that needed to be investigated further. So, the soil and the shallow groundwater and all of that was well understood and characterized, if that makes sense.

Q. But no one ever did a direct characterization of what was coming off of the BP

site, correct?

A. No. That's not correct.

Q. Okay. Did someone then?

A. At some point, yes.

Q. Okay. Was there other information --

A. I was conflicted out of that, so I have no information on it. And I was not able to be involved in any kind of proposals or any data that came across as part of any kind of RFP or anything having to do with the investigation of it because of that.

Q. Okay. So you were only involved in a piece of the overall investigation, it sounds like?

A. Correct.

Q. Do you believe in those types of investigations that it's typical to look at every single source of data, even if you're already convinced of what the source of the exceedance might be?

A. Can you restate the question? Sorry. I'm getting lost on this.

Q. Okay. So, let's see. Let me phrase it in a way that's maybe a little bit better here.

So, if you're in a situation where a professional engineer or someone else has determined that they have collected sufficient data to support a conclusion, but there's still additional data that they could collect to further support that conclusion, do you believe that additional data should be collected?

A. It depends on the circumstances.

Q. Okay. So you think that there are circumstances where even if you're convinced based on existing data of a particular conclusion, you would still collect additional data?

A. Yes, because people can get lost in confirmation bias.

Q. Okay. What do you mean by that?

A. So, like we are tasked and most regulations are regulating like soil and/or groundwater. If you haven't fully -- like if you haven't collected all of that data, if you hadn't collected the soil, you wouldn't know how the groundwater could be impacted because of a flood or storm water infiltration or whatever. You don't know until you've actually collected those pieces.

So even if you see something in the groundwater, and you say you believe this is what's happening, you have to fully characterize it. So it just depends.

Q. Do you agree that there's a certain amount of professional judgment that's involved in the process?

A. Yeah.

Q. And how would you describe professional judgment? Like, what does that mean to you?

A. It would be I guess based on -- obviously it's based on your experience. But also if your peers and your senior technical review are in agreement, then, yeah.

Q. So taking a step back, just in preparation for this deposition today did you talk to anyone to help prepare for the deposition today?

A. I mean, we discussed that we were having a deposition, the general rules.

Q. Did you review any documents?

A. Yes.

Q. What documents did you review?

A. 845.

Q. The regulations?
A. Uh-huh.
Q. Did you review anything else?
A. No, not really.
Q. All right. I'm going to hand you a document that's been marked as exhibit 1. Have you seen this document before?
A. Is this the filing?
Q. Yeah, this is the subpoena for the deposition today.
A. Okay. Yeah.
Q. And could I ask you to turn to the second to last page.
A. Okay.
Q. Do you see, is this the subpoena that was directed to you?
A. Yes.
Q. Did you read the document request that were contained in the subpoena?
A. Okay. So --
Q. So the first request asks for any documents containing or referring to notes taken during any meetings, phone calls or discussions related to the review of the alternative source

demonstration.

A. Yeah, I didn't take any notes.

Q. All right. Then so you don't have any documents in response to the first request, is that correct?

A. Correct.

Q. All right. And I'll allow you a moment to review the second request. Just let me know when you're done.

A. Okay. So the number two, we had already submitted those as a part of the administrative record. I don't have anything else other than that.

Q. Okay. I'm going to hand you a document that's been, or Sam is going to hand you a document that's been labeled as Exhibit 2. This is record document number 12. I'll give you a moment to just take a look at what the document is. Do you recognize this document?

A. Yes.

Q. And what is it?

A. The Alternative Source Demonstration for Newton Power Plant.

Q. The one that they submitted on October

6th of 2023?

A. Yes.

Q. I'm just going to start with some baseline setting so that we're on the same page here today.

Do you agree that this document in the Alternative Source Demonstration presented with it relates to chloride in the well designated as APW15?

A. Yes.

Q. And do you agree that that well, APW15, was screened in the upper aquifer?

A. Is that included in here, because I do not know that.

Q. Okay. Well, if you would like, you can refer to the top of page five, or their well log starting on page 22 of the document.

A. Is that AP --

Q. W15?

A. I really, I can't see an actual boring ID on here.

Q. Well, why don't I refer you to the top of page five then of the document. So, at the top of the page the Bates number will read R0001613.

A. Okay.
Q. Do you see the description of the upper aquifer there?
A. Yeah.
Q. Okay. And the second sentence there reads, the top of the UA is highest in elevation in the north and east portions and then it slopes downward towards APW15. Do you see that statement?
A. Yeah.
Q. Okay. And the top of unit elevations range from approximately 482 feet in APW05 and APW10, to 425 feet (APW15); do you see that statement?
A. Yes.
Q. Do you believe this is indicating that APW15 is in the uppermost aquifer?
A. It's possible.
Q. Okay. Do you agree that the uppermost aquifer is made up of sand, silty sand, clay sand and gravel?
A. I am not really that familiar with Newton specifics, to be honest.
Q. Would the location of the well be

relevant to performing an Alternative Source Demonstration?

A. Yes.

Q. Have you heard of the term peer reviewed?

A. Yes.

Q. How do you define that term?

A. So, peer review would be like review with -- from peers that are independently, like, they're not I guess associated with you. So, yeah.

Q. Would it be fair to say when something has been reviewed by like independent experts?

A. Yeah.

Q. Are you, beyond what we just discussed, are you aware of any standards for what makes a document peer reviewed?

A. Um, being published I would say in a journal that's a peer reviewed by practice. It's objective and independent.

Q. Do you believe the EPA issues documents are peer reviewed?

A. By definition we wouldn't have that capability.

Q. What do you mean by that?
A. So we don't have one, we don't have that, like, ability to have independent review.
Q. Pardon me. I was talking about EPA, the United States Environmental Protection Agency. Are you aware, do you agree that the United States Environmental Protection Agency issues documents that are peer reviewed?
A. It's possible. I don't know what their process is. But, yes. I would believe that, it's a government agency. So --
Q. Is it always clear from the face of the document whether it's peer reviewed?
A. In what context? Because in a government document if they're following their quality procedures, they would have the signatures of the management and the peer review that happened. Versus a journal that's published is going to have peer review, but it's not going to be like signed off on like that.
But there is a whole quality management sign off on the government documents 'cuz that's a part of the quality management plan that we have to have one as well.

Q. Would that be located with the actual document?
A. Yeah. When it says issued with a document number, yeah.
Q. Sorry?
A. When it's issued with a document number, so there's a document control number. Then, yes. It would usually. Yeah.
Q. Okay. And with the journal articles you were just mentioning?
A. That's a separate process. So that's the difference between the government, versus like journals.
Q. Do you believe that there can be papers that are peer reviewed even if they don't come from an academic journal or from a governmental organization like USEPA?
A. I guess it's possible.
Q. I want to show you a document which we are going to mark as exhibit 18. It's record document number 1.
(Whereupon, Deposition Exhibit No. 18 was marked for identification.)
Q. Are you familiar with this document?

A. This is Fedder, I believe, is it? Or no.

Q. I believe if you're asking about the author, I believe it was listed in the table of contents of the record as coming from James Drevr, D-R-E-V-R.

A. Yeah.

Q. So are you familiar with this document?

A. Yes.

Q. And what is it?

A. I would need the actual, do we have the list of like what the names of them are? I believe this is the -- it's the groundwater resource, right, that we used?

Q. Well, I can give you a list of the table of contents if that's helpful. Unfortunately, I don't have copies of this. But it's the table of contents?

A. Specifically, yes, I am familiar with this. I am just double-checking that, yeah.

Q. Sure. No worries. Let me just pull this out for you.

A. Okay. Geochemistry of natural waters.

Q. Okay. So was this document provided

with Illinois Power's ASD submittal for Newton?

A. No.

Q. Was it provided to the agency by Illinois Power at all?

A. No.

Q. Where did this document come from?

A. This is in my, I guess professional collection of references that we have at the office.

Q. Is it like a hard copy reference?

A. Yeah.

Q. So, the first page has a heading -- well, first of all, do you agree that this is an excerpt from a larger document?

A. Yes.

Q. Okay. So the first page has a heading, it looks like the "B" is cut off. But it appears to say, Behavior of Specific Elements. Do you see that?

A. Yes.

Q. Is chloride among the elements discussed in this document?

A. It's not in the first section, but may be part of the contaminant transport in

groundwater and chemical evolution of groundwater, reaction path modeling and that kind of thing. Yeah. It may be part of that.

Q. Okay. All right. So it's not in that first part discussing the behavior of specific elements. Let's talk about that second part you were just talking about. The reaction path modeling?

A. Uh-huh.

Q. So, generally what is this dissection of this document talking about?

A. Groundwater modeling and specific groundwater model software.

Q. All right. So, are there specific modeling software packages that are discussed in the document?

A. Yeah.

Q. And have you ever used any of these groundwater modeling softwares?

A. No. Not, like, extensively. If I did touch on them, it would have been in grad school.

Q. Are you generally familiar with these groundwater modeling softwares?

A. Yeah.

Q. Are you aware of whether you would ever use any of these ground water modeling softwares for chloride?

A. I am looking at what would be R00008 or whatever. And it looks like that is --- chloride is a part of what was being evaluated in the model. But, I mean, that's an example.

So, this is basically giving bigger concepts, and that's what we use it for is just the bigger picture concepts then to back up the mass transport equation needs.

So, big picture, when we review these, the law of conservation of mass, which is in Fedder Chapter One, which is -- so, it is document eight, Fedder contaminant hydrogeology, Chapter One, I think it's Section 1.8, goes over the law of conservation of mass. So -- which is what drives the bigger or the greater need for source characterization and waste characterization that's required under 845.

So, that's kind of -- these are all supporting documents to that bigger concept that it has to be.

Q. So what's that law again? The law of

concentration in mass?

A. Law of conservation of mass.

Q. Law of conservation and mass?

A. "Of" mass.

Q. Okay. And what is that concept?

A. Basically what goes in either sticks or leaves. And so -- but mass doesn't actually change. So, you have, for instance, a good example would be that if you had a very low pH and it leached out metals from a specific like volume, you would still have the certain specific mass there. But also you would have this coming out. And this is a whole -- I guess what's coming in has specific qualities that will impact what goes out.

And so, yeah. It's -- it gets into very, very specifics. If you go, I'm sure you have it over there printed; the 268 pages of Fedder. So yes, so that's just the basics of it. It's just, what goes in must come out. Yeah.

Q. Okay. So, talking about chloride specifically, what chemical reactions would you expect chloride to undergo in groundwater?

A. Specifically, chloride is a known

corrosive. So there's many. So, I don't know that we can go into that.

Q. Would you expect it to precipitate?

A. I mean, I think there's conditions for any chemical or element to precipitate given the right conditions. But it just depends.

Q. And what conditions might impact chloride's ability to precipitate?

A. We would have to go look at what probably the USGS says about that.

Q. Okay. Would you expect chloride to dissolve?

A. It does.

Q. Are you familiar with the term redox reaction?

A. Yes.

Q. What does that mean to you?

A. It's the reduction of oxidation or reduction or oxidation of a specific thing. So, yeah.

Q. Does chloride undergo redox reactions?

A. Yes.

Q. Are you familiar with the term conservative solute?

A. I am. But not that familiar.
Q. Okay.
A. Geochemistry is not my thing.
Q. Do you have any understanding of like what the term conservative solute refers to?
A. It's been a long time.
Q. Okay. So, if I were to define it for you and say that a conservative solute means one where its mobility in water would be similar to that of water, meaning that it would be expected to move as the water moves with no extra complexities sort of impeding the transport of the constituent, with that sort of definition would you agree that chloride is a conservative solute?
A. I, again, I'm not a geochemist so --
Q. So you don't feel comfortable answering?
A. No.
Q. Beyond what you've already explained, is there any other way in which the agency relied upon this document in reaching its decision regarding the Newton ASD?
A. Not that I'm aware of.
Q. Let's move on to another document. This is record document number 4, which we will mark as

exhibit 19.

(Whereupon, Deposition Exhibit No. 19 was marked for identification.)

Q. Are you familiar with this document?

A. Somewhat.

Q. What is it?

A. It is the SW846 test method for liquid, solid partitioning as a function of liquid solid ratio for constituents in solid material using an upflow percolation column procedure.

Q. When you say you're somewhat familiar with the document, what do you mean by somewhat?

A. Somewhat in that, like, we as a team we're not as familiar with pore water because it is not a regulated, I guess, media because it's already a part of groundwater. And so there wasn't specific standards for it.

So we pulled that method of sampling and the other documents five, six and -- five and six to basically show what we could find as far as like what procedures were out there in SW846 on the methods that were provided under SW846, which is incorporated by reference in 845.

Q. Methods for what?

A. Sampling or analyzing.
Q. For analyzing what?
A. Pore water. Or pulling the pore water out of the material.
Q. Do you agree that this is a laboratory test?
A. Uh-huh.
Q. Referring still to this document that is marked exhibit 19?
A. Yes.
Q. It's not a method to directly sample pore water from a source, correct?
A. Correct.
Q. So what's your understanding of how this method in exhibit 19 is used to predict pore water source concentrations in a CCR surface impoundment?
A. I don't know that that has been fully vetted. And we were, again, just pulling the known test methods that were available for analyses. And then there is the -- so, there is the method for field sampling is also in our document list for pore water.
So, between the two, we were just

basically showing these are what we know to be the established procedures and methods for analyzing or collecting pore water. But, we do not have, I guess, a great deal of knowledge. Or I don't have a great deal of knowledge of what this method is about. And I could say that about pretty much any method in SW846 'cuz I've never worked in a lab.

Q. Sure. Okay. So that document, Exhibit No. 19, refers to something called a liiquid-to-solid ratio. Are you familiar with that term?

A. I mean, I understand what you're saying. But --

Q. Okay.

A. I understand ratios. And liquid and solid, yes.

Q. Okay. Are you familiar with the term eluate, which is used in that document?

A. No.

Q. So, going back to the liiquid-to-solid ratio term, does or do you, have you heard from anyone at the agency an opinion on what an appropriate liiquid-to-solid ratio would be for testing a CCR surface impoundment?

A. I don't know, and I don't know that that's been established.
Q. Does the CCR surface impoundment liiquid-to-solid ratio change over time to your knowledge?
A. I guess the liiquid-to-solid ratio would depend on the degree of dewatering that's occurred.
Q. Do you believe that the liiquid-to-solid ratio is the same across the entirety of the CCR surface impoundment?
A. I don't -- probably not, based on there's higher piles of CCR in certain areas, versus others, and over burden is going to squeeze it out more than places where there isn't any over burden.
Q. Do you agree that pH in field conditions may vary from pH in laboratory conditions?
A. Yeah.
Q. Are you familiar with the pH of rain water?
A. No. Again, I am not a geochemist, so sorry.
Q. No. Are you familiar with whether the

test methodology reflected in exhibit 19 accounts for any ponding of water?

A. I have no idea.

Q. Are you aware of whether the test method reflected in document 19 accounts for incoming groundwater?

A. I don't know.

Q. Are you aware of whether the test method reflected in document 19 accounts for any conditions that could dilute the leachate?

A. I don't know.

Q. Are you familiar with what volume of material is collected for a sample evaluated through the test method reflected in Exhibit No. 19?

A. I'm sure it says somewhere in here. But no, I'm not.

Q. Would you expect it to be a fairly small amount of material compared to the overall size of the source?

A. Typically, I would expect that. Yes.

Q. All right. Let's move on to another document. I'm going to mark this as exhibit 20.

(Whereupon, Deposition Exhibit No. 20

was marked for identification.)

Q. This is document number five in the record. We're going to take a break.

(A break was taken at 2:58 p.m.)

(The time is 3:04 p.m.)

CONTINUED EXAMINATION BY

MS. JOSHI:

Q. Going to give you a document which is marked as record document number 5 and exhibit 20.

And are you familiar with this document?

A. I am semi familiar with this document.

Q. What is it, to your knowledge?

A. It is the SW846 Method 1315 Mass Transfer Rates of Constituents in Monolithic Or Compacted Granular Materials Using a Semi-Dynamic Tank Leaching Procedure.

Q. Would you agree that this document describes a methodology for leach testing?

A. Yes.

Q. Can I direct your attention to the page where the top is marked as R000065?

A. Okay.

Q. Section 1.1 of the document. It says, this method is designed to provide the mass

transfer rates (release rates) of inorganic analytes contained in monolithic or compacted granule -- pardon me; granular material under diffusion controlled release conditions as a function of leaching time.

I want to direct your attention to the term, monolithic. Do you believe that the material contained in the Newton PAP is a monolithic material?

A. I can not speak to that.

Q. Why not?

A. Because I am not as familiar with Newton, and I -- or this document. And I did a broader review as the technical reviewer for this ASD.

Q. Okay. Do you understand what, or to you, what does monolithic material mean?

A. Potentially I'm thinking -- I'm not 100 percent sure, but I'm thinking it's consolidated basically bedrock. It's a solid piece.

Q. And what does the term, compacted granular material mean to you?

A. Compacted granular material is just granular material such as sand or gravel that's

been compacted, I guess, artificially. So with a compactor, or has consolidated over time.

Q. Do you believe the material in the Newton PAP is a compacted granular material as defined in this document?

A. Some of it may be, yes. Just by the fact that it's been there for so long.

Q. And how so? Just because it's been there for a long time? Or is there anything more to that assumption of yours?

A. So, the deeper the material, it has more over burden. So there is compaction over time from consolidation because of that over burden weight. So I'm saying it's possible.

Q. Do you believe that CCR surface impoundment generally behaves more like a porous medium or a monolithic compacted granular material?

A. I'm not actually sure.

Q. And to your knowledge, does the method discussed in this document marked as exhibit 20 simulate water movement through a porous medium?

A. Compacted granular material would still be a potentially porous media in some cases. So,

it could be.

Q. Do you believe this test method is meant to address water movement through a porous medium?

A. It could be.

Q. Why did the agency include this document in the record?

A. For the same reasons I stated before. That it was a way of testing the liquids that came out of a solid or pore water. Or to our understanding at the time. But we had very little time to get things together as far as these documents go. So, that would also apply to document six.

Q. Okay. Great. Let's talk about document six then next. This is going to be marked as Exhibit 21 for the deposition.

(Whereupon, Deposition Exhibit No. 21 was marked for identification.)

Q. Are you familiar with this document?

A. Somewhat.

Q. Okay. Do you agree that that document describes a methodology for leach testing?

A. I am not sure. It doesn't seem to be necessarily very specific up front. And, yeah.

It doesn't seem to be necessarily very specific, so I'm not sure.

Q. Why did the agency include this document in the record?

A. Basically because it seems like it had to do -- it was a method that had to do with the testing or analyzing of the liquids that were within a solid material, and what comes out of it.

Q. Is what comes out of that material usually called leachate?

A. That depends on how I guess you're looking at it. Sometimes that can be interpreted as pore water, and we do pore water extraction in situ, and sometimes it's leachate because for whatever reason I think that's a different -- I don't know the specifics of why they make that determination.

Q. Okay. Do you agree that the methodology reflected in Exhibit 21 is a methodology that's conducted within a lab?

A. Yes.

Q. Again, if you go to, say, page two of this document at the top that's Bates numbered 4000103. And just look at, say, Section 1.1,

you'll see the term liquid-to-solid ratio there. Do you see that term?

A. Yes.

Q. All right. Again, how do you determine an appropriate liquid-to-solid ratio for a particular CCR surface impoundment under this methodology?

A. I don't know.

Q. Do you have any understanding of what type of pH might exist under the laboratory conditions used for this method?

A. No.

Q. Does this test methodology in Exhibit 21 to your knowledge account for any ponding of water?

A. I don't know.

Q. To your knowledge, does the test methodology in Exhibit 21 account for incoming groundwater?

A. I don't know.

Q. To your knowledge, does the test method reflected in Exhibit 21 account for any other conditions that could dilute the leachate?

A. I don't know.

Q. Are you familiar with the volume of material that's conducted for sampling under this method?
A. No.
Q. So for the last three documents that we just talked about, which have been marked as exhibits 19, 20 and 21, do you agree that they all reflect different SW846 methodologies?
A. Yes.
Q. Do you agree that each of the methodologies are conducted under laboratory conditions?
A. Yes.
Q. Do you believe that any of these methodologies are representative of field conditions of a CCR surface impoundment?
A. I wouldn't know.
Q. Do you agree that there's variability that could impact leaching of the unit over time? For example, weather conditions like rainfall?
A. It's possible. Yes.
Q. Could the topography of a unit impact leaching?
A. Yes.

Q. Could different permeability in different areas of the unit impact leaching?
A. Yes.
Q. Do you believe that any of the methods discussed in exhibits 19, 20 and 21 are a better indication of current impacts on groundwater than actual in-field pore water sampling?
A. I don't know.
Q. Did IEPA conduct any investigation into whether the methodologies reflected in documents 19, 20 and 21 are appropriate for a CCR surface impoundment?
A. No, we didn't have time.
Q. Did the agency look into any drawbacks or flaws from these methodologies as they might be applied to CCR surface impoundment?
A. No.
Q. All right. I'm going to give you another document that's been marked as exhibit 5.
Are you familiar with this document?
A. Yes.
Q. What is it?
A. The USEPA pore water sampling procedure.
Q. Is this a document that the agency

independently pulled in its review of the Newton ASD?

A. Yes.

Q. Did you review it in connection with the Newton ASD?

A. We reviewed the basics of it, and then looked for evidence in the ASD that these methods were followed. But we did not see that information.

Q. And generally do you consider USEPA to be a trustworthy source?

A. Yes.

Q. Does the agency regularly pull and review USEPA documents?

A. Um, with respect to some procedures, yes, we do.

Q. Do you believe that the pore water sampling methodology represented in that document is appropriate for CCR surface impoundments?

A. I do.

Q. Why so?

A. Because you can use these push points very easily in the field, and there are methods to be able to reshift load to be able to move out

into the CCR surface impoundments to get samples. So, yes. And I've used the hydropunch, which would fall under the push point or similar sampler, prior to my time at the agency. So we weren't collecting pore water though. That's not what we would call it though, I don't think. Again, this is a whole new thing that's not even in our regulation; pore water, the term.

Q. So, you're just saying you use a particular instrument that they refer to in that document?

A. Yeah.

Q. But you've never used it to collect pore water?

A. When you read this document and the way that it's supposed to be collected, it looks like what we were saying was a groundwater grab from a hydropunch or a push sampler way back in the day.

Q. Okay. A hydro what?

A. Hydropunch.

Q. Punch. Okay.

A. So, I guess I'm not sure what the difference is between a groundwater grab where you are just opening the slot and you're letting the

water come in from the pores, versus, and we were calling it groundwater at the time, versus now we want to call it pore water. But, groundwater is what's regulated. So we had to stick with that.

Q. Is pore water sampling in a stream sediment to your knowledge the same as pore water sampling for a CCR surface impoundment?

A. It would be very similar, honestly.

Q. Okay. And what would be the similarities?

A. In a stream, the sediment is laid down by active flow of water. In a CCR surface impoundment the CCR was laid there by active flow of the fluids into that impoundment and the settling of that sediment. So, which is the CCR. So, it's -- one is manmade and the other is natural. But it's the same process of settlement.

Q. Okay. And earlier in the deposition you referred to observing some pore water sampling, was it in a bay?

A. Yeah, it was in the Waukegan Harbor.

Q. Or harbor. Pardon me. Do you believe that pore water sampling of a CCR surface impoundment is similar to pore water sampling of a

harbor?

A. I feel like -- I'm not really, really 100 percent sure on the whole sediment in a harbor versus sediment in a CCR surface impoundment, to be honest. I have no idea.

Q. But you do believe that this document is relevant to pore water sampling of CCR surface impoundments?

A. I do.

Q. Let's move on to record document number 19. We're going to mark this as Exhibit 22.

(Whereupon, Deposition Exhibit No. 22 was marked for identification.)

Q. All right. Are you familiar with this document?

A. Yes.

Q. What is it?

A. It's an e-mail from myself to Lynn, Heather, Justin, Matt and I cc'd Mike Summers. And it is regarding the ASD for Newton and the ASD for JOPPA. And a list of what we needed to discuss.

Q. Okay. Are there three items listed there for discussion?

A. Yes.
Q. What's that first item that's listed?
A. Geochemistry.
Q. What is that intended to mean?
A. So, this e-mail, because it's addressed to our junior staff, was meant to bring everybody together to have a discussion on the general subjects that they were going to be encountering as they reviewed ASDs, because I'm the only one with a master's in hydrogeology and Heather is the only one with a master's in geochemistry. And the two other folks have a bachelor's and a collective three years of experience between the two of them.

So, we were trying to get people more familiar with just the basics of these items since they're coming up. So, it was less about specifically Newton, and I guess JOPPA, and more of like a training.

Q. Okay. So, is the geochemistry on here meant to reflect anything about geochemistry at the Newton PAP?
A. If we were talking about it, it would be Heather talking about it; the geochemistry, if that makes sense. So, and the specifics of that.

And like walking people through like what you -- how we would look at it or analyze it.

Q. Okay. So as an agenda item, to your recollection you did not intend to discuss anything specific to the Newton PAP geochemistry?

A. I was intending to have Heather walk through the Newton PAP geochemistry as an example and explain.

Q. Okay. And explain what?

A. What was being presented. Like she understands from her professional experience and understanding; that kind of thing.

Q. Okay. The second item on here reads, alternative source data submittal requirements. Do you see that?

A. Yes.

Q. What is that intended to mean?

A. That is intended to mean the agreed-upon data requirements that we needed for alternative source demonstrations to be considered complete.

So, we needed source characterization of the actual CCR source. And then also CCR surface impoundment of the alternative source.

Q. Was the discussion of alternative source

data submittal requirement general to all ASDs, or specific to the Newton and JOPPA ASDs?

A. Generally to all.

Q. And did the agency reach any conclusions at this meeting or at any other time on what is required for an alternative source data submittal?

A. Not necessarily at this meeting. But yes, we did. Because -- so, I basically asked if there was source characterization, both of the alternative source and then also of the CCR at Newton, so that was because it was the first one -- it was the first one that got discussed. And I took that to Mike Summers. And he said correct; if there's no source characterization of both, then we do not concur.

And so that was kind of the end of that.

Q. Okay. And what is the scope of source characterization that would be needed of let's start with the CCR surface impoundment?

A. So, according to Mike Summers, it was determined that we needed a ten percent source characterization of the CCR surface impoundment. So, that was basically ten borings with a sample in the upper one-third of the boring, the middle

one-third of the boring, and the lower one-third of the boring. And that's -- yeah.

Q. And did you have a discussion as to why that was needed?

A. We had a discussion about the fact that source characterization needed to occur. We had thrown out -- I had thrown out ideas on what we could do, or to just establish a baseline for all of them. And that is what management decided.

Q. And did you discuss what method had to be used for that source characterization?

A. Well, it was source characterization per the rule, which is that the solids have to be characterized.

Q. And when you say, per the rule?

A. 845.

Q. And what portion of 845 are you referring to?

A. Hold it. I have it marked. Okay. So, source characterization is required in 845.230(a)15. That's all initial operating permits.

Q. Does it -- are there any -- is there any specificity in 845.230(a)15 on what needs to be

done for source characterization?

A. No. Not in 230, no.

Q. All right. So, what regulation, guidance or other document to your knowledge was the agency relying upon in reaching the conclusion that it needed this ten percent source characterization that you referred to?

A. That was the professional judgment of Mike Summers.

Q. And then going to the second piece of characterization that you were talking about, the characterization of the alternate source, are you aware of whether the agency concluded what information would be required for characterization of that alternate source?

A. Well, our management has agreed that one sample is not sufficient to characterize any media because SW846 specifies that you must have a sampling rationale and that must include more than one sample.

Our interpretation as an agency is that you have to have sampling of the alternative source here, and it's in 845.650(e), right, is it? Yeah, 650(e).

Q. Can you point me to where in 845.650(e) it discusses requiring sampling of the alternate source?

A. So, we are interpreting, the agency interpreted the submit a demonstration to the agency that a source other than CCR surface impoundment caused the contamination, and CCR surface impoundment did not contribute to the contamination to mean that you had to have data to substantiate that claim that it came from an alternative source. So that would require an analysis of samples from the alternative source.

Q. So --

A. Because without data, you're making -- you're just making -- it's just an opinion.

Q. Do you agree that there can be data other than direct sampling that could support the conclusion that something is coming from an alternative source?

A. There has to be data. Now, the media that gets sampled for the alternative source may depend on availability of the media or field conditions.

Q. Going back to that FUD site where you

were investigating TCE, you said you came in sort of towards the end of that process?

A. Uh-huh.

Q. Okay. Do you have any idea how long it took to try to figure out the source there as part of that process that you were involved in?

A. It was upwards of ten years likely.

Q. Going back to the document, Exhibit 22, going back to Exhibit 22, that item number three reads, other items the team is curious about or needs to brush up on. Do you see that?

A. Uh-huh.

Q. What is that referring to?

A. That's just an open, like, dialogue for any other things that have come up in any of their work, if they needed to have that conversation while we're having a conversation about data and geochemistry. So --

Q. Did any of that discussion relate to the Newton ASD?

A. I'm sure some of it did. But, I don't know about number three though. Yeah, I don't recall.

Q. Okay. Going to move on to another

document that's already been marked as Exhibit No. 7.

Are you familiar with this document?

A. Yes.

Q. What is it?

A. It is the ASD nonconcurrence letter from the agency.

Q. Were you involved in drafting this letter?

A. Yes.

Q. What portions of it did you draft?

A. I helped draft one, two and three.

Q. So, do you mean the items that are listed here as one, two and three?

A. Uh-huh. Yes.

Q. Okay. Did anyone else help you draft items one, two and three?

A. I -- in what manner? Because I asked questions, and then they told me. Like, we had an open dialogue. Basically I was like, here's what we need for an ASD. And then, yeah. Then we got that approval from Mike. And then had the conversation about what was there and what wasn't.

Q. And who did you have the conversation

with, other than Mike Summers?

A. Heather Mullenax.

Q. And did Mr. Summers sign off on the language in here before he signed the letter?

A. Yeah.

Q. Did he do any editing to the portion that you wrote prior to sending the letter?

A. I don't recall.

Q. Is this generally consistent with what you presented, though, or originally drafted?

A. Generally, yes.

Q. What was the scope of discussion that you had with Mr. Summers about whether or not to include each of these data gaps in this letter?

A. So, the first one, source characterization, he agreed that the mass transport equation has to be answered. We have to have waste characterization or source characterization to be able to talk about whether or not the CCR surface impoundment has or does not have the potential to provide or contribute to the contamination as specified here in 650(e).

Additionally, it was our agency position that they had to have sampling from the

alternative source of some kind.

And then for number two, hydraulic conductivities from the laboratory or in-situ testing. We felt that there needed to be better characterization of the bedrock unit, that's fracture flow. If you're -- yeah; bedrock wells can not be installed in just solid rock. And not have a hydraulic conductivity and be used to say that there is nothing going on without substantial bedrock characterization showing there is not actual -- the secondary flow path, which is the primary flow path really of fracture flow. And those have to be captured. Does that make sense? Am I making sense?

Q. Let's talk about this. Let's take a step back and talk about them one at a time, all right?

So, for number one, it says source characterization of CCR at the Primary Ash Pond must include total solid sampling in accordance with SW846, right?

A. Yes.

Q. Okay. First off, what do you mean by source characterization in accordance with SW846?

A. Okay. So, SW846 has methods for testing or analyzing a solid sample. It's incorporated by reference in 845. We're saying source characterization of the CCR must be total solids based on what is required in 230, what's required for the corrective action modeling for closure modeling, which is FATE and transport. For transport modeling calculations, you're going to need that source characterization or the waste characterization as it's stated in 845.230.

Q. Okay. So --

A. Go ahead.

Q. I was just going to ask a follow-up question there. So 845.230, that relates to what goes into your operating permit application, right?

A. Correct.

Q. And you're saying that that's useful information for sort of the life of the unit?

A. Correct.

Q. As it's closing and maybe needs to undergo corrective action?

A. Yes.

Q. How is it specifically helpful for

determining whether a particular exceedance from a particular quarter is being caused by the CCR surface impoundment?

A. So, the source characterization or the waste characterization of the solids will show what metals are actually present in the CCR.

If, say, chloride was not present in the total CCR solids, but it was still in your well, and you're saying it's there because it's from an alternative source, but there's no existence of it in the source, then we could say okay, yeah. That's like an example. It's like, any constituent that's not in the CCR, because not all CCR is going to have the same metals in it because it depends on the parent coal that was used and burned, plus the processes that they go through to -- yeah, utilize the coal for energy.

Q. Okay. Do you agree that a way to find that out is also by doing pore water sampling?

A. No.

Q. Why not?

A. Pore water sampling is a snapshot in time of a very specific portion of the groundwater. It does not fully characterize the

groundwater. It does not fully characterize the total solids. And -- yeah.

Q. Again, so, I guess what I'm trying to get is what's the difference between the life of the unit versus what's happening right now? And for an ASD, do you need to be worried about what's going to happen over the whole life of the unit, or do you need to worry about what's happening right now?

A. So, the source characterization provides what is the actual potential for that CCR?

If you don't have that, then you can't say even what's happening right this second is accurate except for that one second, I guess. And not even that when it comes to pore water because it's not actually like the whole groundwater, if it's being collected as a groundwater graph. So we didn't have the documentation with the ASD to say this was done low flow and it's actually groundwater, and etc. If it's a groundwater grab, that's even less accurate.

Q. Do you agree that if there was -- leach testing would also just be discrete samples collected from around the CCR surface impoundment?

A. It's possible, but leach testing, again, wouldn't replace the total solid source characterization that needs to be done to be able to start that mass transport equation conversation. And that's where you -- that's a missing link.

Q. Okay. So, taking a step back then, when you're talking about total solid sampling in data gap one, what method are you referring to?

A. So, any of that are appropriate for total solids of those metals constituents, and I know that metals has a number of different analyses that are approved depending on the constituent. So we just said SW846 instead of parsing which methods.

Q. Okay. Did you mean to refer -- was this meant to refer to the SW846 methodologies we discussed earlier in this deposition?

A. No.

Q. Okay. It was meant to refer to something other than that, is that right?

A. Correct.

Q. Okay. Do you agree that pore water collection and sampling is a way to characterize

the source?

A. I don't think that it characterizes, fully characterizes the source adequately for the mass transport equation.

Q. Again, can you refer me to any specific method in SW846 that the agency would be looking for when it comes to the total solid sampling characterization?

A. I would have to go through SW846 and pull up the various constituents that are being tested to make sure all of them are covered. Because heavy metals has one, and generally speaking I know mercury is always separate and has a different test method. So there's a number of test methods under SW846 for solid sampling that you would have to do to do all of the constituents under 845.600.

Q. And you're not referring to other leach testing methods like, what is it? SPLP? I don't know if I'm saying that --

A. SPLP would be something that you do after you've done the total solid sampling. So you would do total solid sampling. You would see what's there. Then if you want to know if it's

leaching, then you would see for those specific constituents that are detected what they actually leach at.

Q. Okay. So, again, going back to data gap one, is the agency just looking for that initial total solid sampling? Or is it looking for anything further than that such as that second step of conducting a leach test?

A. I think that you will likely need the leach test to say for the things that are present this is not going to leach. You're going to have to do a leach test to make sure that it's not leaching.

Q. Okay. And do you believe that that leach test would be more accurate than a pore water test?

A. Yes, because you can adjust the pH in the lab to simulate various scenarios.

Q. But don't you agree that pore water sampling is conducted in, in-field conditions, which would be reflective of in-field PH?

A. Yes. But, other pHs could occur, or could have occurred in the past that created this down gradient plume.

Q. Going to refer you to what's been marked as Exhibit 8.

This is an excerpt from record document number 33. Have you ever reviewed this document before?

A. What is this document? I mean, it's possible that I've seen it.

Q. Sure.

A. I'm not sure.

Q. This is an excerpt from record document 33, which is Illinois Power's petition in this case.

A. Okay. No, I have not been able to get that far into that.

Q. Okay. Can I direct your attention to, please, paragraph four of that declaration.

And would you just take a moment to review that paragraph and just let me know when you're done.

A. Okay.

Q. So, the first sentence there says, performing source characterization of the CCR at the Newton Primary Ash Pond using total solid sampling techniques under SW846 would require

drilling within the Newton Primary Ash Pond up to ten borings using specialized equipment to collect 20 samples. Do you agree with that statement?

A. Well, it would be 30 samples; if you do one-third in the upper, one-third in the middle, one-third at the bottom. That's 30, not 20. But generally, yes.

Q. And why are you saying -- are you saying 30 samples is what the agency believes is appropriate?

A. Yeah. We were saying 30 samples, not 20. But yeah, ten borings with three samples at each one.

Q. The next sentence reads, it would further require complete laboratory analyses, data evaluation and reporting for these samples.

Do you agree that it would involve that process?

A. Yeah. Yes.

Q. The next sentence reads, assuming a driller is readily available, which is not always the case, this process would likely take approximately 21 to 42 weeks to complete.

Based on your experience, do you agree

with that statement?

A. Yeah.

Q. All right. Moving back to exhibit 7. Let's talk about that second listed data gap. Can you describe what information this data gap is referring to?

A. In our review, we determined that the hydraulic conductivity of the bedrock unit had not been presented with ASD.

Q. So, what hydraulic conductivities is this referring to? Just the bedrock unit?

A. It is, yeah.

Q. What type of in-situ hydraulic tests are you thinking would be necessary?

A. In-situ hydraulic tests can be anything from a spinner or some kind of down hole geophysical method that engages flow within the bedrock, or you can also do packer testing. There's -- yeah, there's various methods.

Q. Do you believe any of those methods you just listed would be appropriate?

A. It's possible, but it would depend on the conditions after it was properly logged with discontinuities logged and understood better.

Q. Why are you asking for a hydrogeologic characterization of the bedrock unit?

A. Okay. So, at the time I believe we're thinking that it was connected to the unit. And so we were looking at that as well.

Q. When you say, at the time, why do you use that phrase, "at the time"?

A. Because I don't recall the specifics of what went into the specific decision. It has been and primarily was and is a source characterization issue in the mass transport equation that went into the reason for the letter.

Q. And what regulation, guidance or other document leads you to believe that this type of characterization presented in data gap two is necessary to prove that the PAP is not the source of the chloride exceedance?

A. Hydraulic conductivities to bedrock is required as a part of 845.620, I believe. Yeah. 620. And so which is supposed to be -- so, if this was all working the way that it should, we would have an initial operating permit and the ASD would be requested after you had this piece that is supposed to be submitted with the operating

permit and approved by the agency.

So yes, it would be one of those pieces that all go into the bigger picture setting. So that when we're making these more minute decisions that are very specific, like we have all of the background data. But that is not the case here.

Q. So you agree here that IPGC has started to conduct monitoring under its ground water monitoring programming, correct?

A. Yes.

Q. Okay. And that was due to a request from the agency to start monitoring before the operating permit was approved?

A. Correct.

Q. Okay. And so as a result, the agency doesn't necessarily have the benefit of all of the information that would be in like an approved operating permit, is that correct?

A. Correct.

Q. And how long does it take, or how long did an owner/operator have to submit an operating permit application to the agency if you recall, or just generally?

A. Like a year and a half I think after the

rule was enacted. Somewhere around there.
Q. And how many rounds of sampling were typically conducted before an owner/operator submitted a ground water monitoring plan under its operating permit application?
A. At least eight.
Q. And how much time does an owner/operator have to put together an ASD?
A. Very little. It's something like 60 days, I believe. Or 90.
Q. I'll let you refer to 845.650, and I have a copy if you'd like a copy here.
A. Yes, it is 60 days after confirmed detected exceedance of the groundwater protection standard.
Q. Okay. Are you familiar with what a confining layer or aquatard is?
A. Yes.
Q. What is it?
A. It is a unit that impedes, stops, or slows the flow of ground water down into a lower aquifer.
Q. How is it different from an aquifer?
A. An aquifer has a hydraulic conductivity

that is conducive to ground water flow, and the aquatard or confining unit, again, slows down the flow of ground water or stops it.

Q. As part of your professional life, have you ever installed a well or wells for purposes of investigating hydraulic conductivity?

A. Yes.

Q. Have you ever done so for purposes of investigating hydraulic conductivity of a confining layer?

A. Yes.

Q. Can you please describe when you did that?

A. Yes. As a part of nuclear siting licensing here in the United States, we were required to install wells per whatever plan that we had exactly the way that we said. And if you said it was 15 feet, then it was going in 15 feet regardless. And so we ended up with some dry wells.

Q. So, that project involved drilling for purposes of investigating hydraulic conductivity in an aquifer?

A. Yeah.

Q. Did it involve drilling for purposes of investigating hydraulic conductivity in the confining layer?
A. They wanted to know flow, yes. In the confining units, in the aquifer, and -- yeah.
Q. Did you run into any issues by drilling into the confining layer?
A. I mean, yeah.
Q. What kind of issues?
A. Dry wells. No samples. Yeah.
Q. As part of that experience, did you ever install a well screen into a confining layer?
A. Because it was required by the NRC, yes.
Q. Okay. Did it have any usefulness?
A. No. Other than you had a dry point. So I guess it is data.
Q. Have you ever conducted in-situ hydraulic conductivity testing of a confining layer?
A. Potentially perc tests, just to see what was going on.
Q. Perc tests?
A. Yes.
Q. That is the procedure that you used?

A. Uh-huh.
Q. Anything else?
A. No.
Q. Have you ever drilled through a confining layer such that the aquifers above and below became connected hydraulically?
A. No.
Q. Moving on to the third data point here on exhibit 7.

What is the scope of characterization this data point is seeking?

A. 845.640(a) 1, 2, 3, 4 and 5.

So, if you go back to 640(a)1, at sample collection you basically have documentation reading sample collections, sample preservation, and shipment. Again, that's documented on your chain of custody. Your analytical procedures generally are in your laboratory report and your chain of custody. Quality assurance and quality control again are in there.

So, this would basically look like a laboratory report that includes your chain of custody, and also field documentation of your purge procedures, etc. And whatever field

procedures you used to collect the sample. Which was not in the actual submittal.

Q. Okay. So, the only portion of 845.640 this is meant to refer to is 845.640(a)?

A. Yeah.

Q. And what sampling is it referring to?

A. The sampling that was being provided. So, the sample collection that was presented in the ASD didn't have this documentation.

Q. Okay. So, for example, the pore water samplings that were conducted?

A. Yeah; so, whatever is being presented as a part of the ASD should have -- whatever data should be substantiated by the laboratory reports and the field collection procedures documentation.

Q. Okay. Data gap three only refers to the alternative source. Is it meant to refer to the alternative source?

A. Yes. I mean, because, again, ideally source characterization would have already occurred under an initial operating permit and you would already have that in the record. And we could just say, we would have already have said that that was acceptable and documented

appropriately, etc.

Q. Okay. Data gap three does not refer back to any other sampling results provided in the ASD, does it?

A. I don't know what you mean.

Q. Well, you were saying that it's meant to refer to samples that were provided with the ASD, is that right?

A. Yeah.

Q. Okay. I guess my question to you is, does it say that in your opinion? And if so, how?

A. So, yes, it does. And --

Q. Where?

A. It says that you have to have the characterization per 640. Well, it should be 640(a). For the alternative source, which is what would -- what was presented in the ASD was the alternative source data. But we didn't see the laboratory reports and we didn't see the documentation for how it was collected.

Q. So when data gap three refers to alternative source, what is it referring to?

A. Excuse me, what?

Q. When data gap three refers to

alternative source, what is that term referring to?

A. Your guys's proposed alternative source.

Q. Okay. So that's referring to the bedrock unit?

A. Whatever you were proposing was the alternative source.

Q. Okay. So, is it saying sample and analysis in accordance with 845 of what they were proposing, or what Illinois Power was proposing as the alternative source?

A. Correct.

Q. Is this referring in any way, or can you show me how it's referring in any way to sampling and analysis of the CCR surface impoundment?

A. Well, like I already said, the source characterization would have optimally already been completed and approved, but it wasn't so we needed that to actually go into the -- to feed into the mass transport equation or that whole discussion.

But, and that would have been sampled, again, per 845.640 as well. But, this point is specific to the data that was presented in the ASD, that it didn't come with laboratory reports

or field documentation.

Q. Okay. But, you just said that there wasn't data provided or sampling data provided related to the alternative source in the ASD?

A. No. I said that it didn't -- so, you have -- source characterization has to have -- for the mass transport equation you have to have the source characterization done so you can say that in fact this CCR surface impoundment doesn't have the ability to contribute to that contamination. And then you had this alternative source information that then says okay, yes, you have found the alternative source.

Q. Okay.

A. So, that's, yeah. You have to have both.

Q. Okay. So, data gap three, is it meant to refer to one of those two things or both of those two things?

A. It is meant to refer to the data that was presented in the ASD submittal.

Q. Okay. Can we take a short break?

(The time is 4:07 p.m.)

(The time is 4:17 p.m.)

CONTINUED EXAMINATION BY

MS. JOSHI:

Q. All right. So, going back to Exhibit No. 7, which is the denial letter, data point, or data gap three, it reads characterization to include sample and analysis in accordance with 35 I.A.C. 845.640 of alternative source must be provided with the ASD, correct?

A. Correct.

Q. It does not say characterization to include sample and analysis in accordance with 35 I.A.C. 845.640 of the CCR surface impoundment must be provided with the ASD, correct?

A. That's correct.

Q. I'd like to direct your attention back to Exhibit 8. And refer you to paragraph five. Give you a moment to review that, just let me know when you're done.

A. I'm done.

Q. The first sentence there says, conducting a characterization of the bedrock surrounding the Newton Primary Ash Pond in accordance with 35 Illinois Admin Code 845.640 would require drilling to bedrock, well

installation, solids and ground water sampling and analyses, and data evaluation and reporting.

Did I read that correctly?

A. You did read it correctly.

Q. Okay. Do you agree with the information in that sentence?

A. Typically you would not collect solids below the water table if you're not in like a source material that needs to be characterized.

Q. Okay. So, you would say that solid sampling and analysis perhaps would not be required for characterizing the bedrock?

A. If it's not a part of the source, correct.

Q. And is there anything else in that statement you disagree with?

A. Taken as a whole, the paragraph suggests that you would not actually be characterizing the bedrock in a manner that would be adequate to characterize fractures.

Q. Okay. So, do you think additional steps would be required?

A. Yeah.

Q. Okay. What additional steps?

A. Fracture analysis. Typically a bedrock well, and this is literally almost 15 years ago, costs 100 grand. So $150,000 would be one well. So no, it would not be sufficient to characterize bedrock. If you were going to have some kind of a monitoring network you would want to install the wells in the fractures. And again, that would require drilling where you could see where the fractures are, or doing some kind of down hole geophysics. So, it would cost more than that.

Q. So you are referring to the second sentence right now when you refer to the 150,000?

A. Yeah, I'm saying the second sentence suggests that the first sentence does not actually include everything; if that makes sense.

Q. It does not? Can you clarify what you mean?

A. So, $150,000 does not cover more than one well. And would not necessarily characterize a bedrock network if it's needed for Newton. So, I feel like the data evaluation and the bedrock characterization that would occur with drilling in the bedrock and well installation would not capture the fracture network.

Q. Okay. So, you're saying that the scope of --

A. At first glance, that was what came to me.

Q. I think you just said something along the lines of, if it's needed for Newton. What did you mean by that?

A. If, and again I did not do the initial operating permit review, and I'm not -- have not done that. So, I'm not familiar with whether or not they would need a network, a monitoring network for the bedrock. So, I'm saying that is not sufficient for the bedrock network.

Q. So, it may require drilling multiple wells?

A. Potentially.

Q. You are saying, and conducting ground water sampling of those multiple wells?

A. But I can't really say that right now.

Q. You can't say that right now. But it would require at least more than one?

A. I'm not sure. It suggests that -- yeah.

Q. It would require at least one though?

A. Yes.

Q. Okay. And going back to that second sentence, it reads assuming a driller is readily available, which is not always the case, this process would take approximately 20 to 30 weeks. Do you agree with that statement if we were talking about, say, one well?

A. Potentially, yes.

Q. Okay. And if we were talking about more wells than one, would you agree with that statement?

A. No.

Q. Okay. And do you believe it would require more time?

A. Yeah.

Q. Okay. And going back to confirm, you would also agree that the costs would probably be greater than the $150,000 represented in this document?

A. Yes, that's an extremely low number.

Q. Okay. All right. I'm going to hand you a document that's been marked as exhibit 9. This is an excerpt of record document number ten, which is the operating permit application that was submitted for the Newton PAP.

A. What document is Attachment C a part of?
Q. The operating permit itself.
A. Okay.
Q. So this is Attachment C of the operating permit. I'd like to refer you to the first page of Attachment C.
A. Okay.
Q. The first sentence reads, in accordance with 35 I.A.C. 845.230(d)(2)(C). Do you see that language?
A. Where?
Q. I'm sorry?
A. Am I supposed to be on 622?
Q. Yes. The page with 622 at the top.
A. All right. Okay.
Q. Do you see that language at the top that says, in accordance with 35 I.A.C. 845.230(d)(2)(C) IPGC is submitting available/existing analyses of the chemical constituents of all streams, chemical additives and sorbent materials entering or contained in the CCR surface impoundment on the Ash Pond.
A. Yes, I see that it says that.
Q. Can you turn to the next page, which has

a title that says Appendix A?

A. Okay.

Q. Do you agree that Appendix A provides information regarding the chemical constituents contained in the Newton PAP?

A. So, it has -- this is 845 and 620 constituents, first of all. And it is liquids or surface free liquids concentrations, and not totals.

Q. What do you mean by not totals?

A. Not total solids, sorry.

Q. Okay. But this includes for pollutants, total and dissolved results, right? Total for some, and dissolved for others? In the pollutant list?

A. Yes.

Q. Okay. And the third column says surface free liquids average concentration. Do you see that?

A. Yeah.

Q. What do you understand that to be referring to?

A. I have no idea what that means.

Q. Okay. And going to the next column, it

says subsurface free liquids average concentration. Do you see that?

A. Yeah.

Q. Do you understand what that means?

A. I don't know what it refers to, no.

Q. Okay. Did you review this document in connection, or rather did you review this Appendix A of Attachment C of the initial operating permit application as part of your review of the Newton PAP ASD submittal?

A. We did take a look at it. However, we need the actual data laboratory reports for the constituents that were collected for it to be considered. But it was still not total solids as agreed upon with management approval. So we were unable to accept it as source characterization.

Q. Okay. But you do agree that this provides some information about the chemical constituents contained in the Ash Pond?

A. I agree that it provides information about chemical constituents of the water in the Ash Pond.

Q. Moving on to Appendix B. All right. Do you agree the first table of Appendix B provides a

list of chemical additives that are located in the Newton PAP?

A. I agree that that is what is presented.

Q. Do you agree that the second table in Appendix B presents a list of waste streams that are in the Newton PAP?

A. I agree that that's what is presented.

Q. I'm going to refer you to another document that's been marked as exhibit 10.

This is another excerpt from record document number 10, the operating permit application. This is Attachment H to the operating permit application, and it is excerpts from Attachment H. And the cover pages are included in the exhibit for your reference.

A. Okay.

Q. Are you familiar with this document?

A. No, I have not seen this one.

Q. Okay. I'd like to refer you to the page with the record Bates number 696 at the top. Do you see that?

A. Okay.

Q. All right. So, do you see that this is the cover page of the hydrogeologic

characterization report for the Newton PAP?
A. Yes.
Q. Going to the very last page of this exhibit, table 2-2?
A. Yes.
Q. To confirm, you haven't seen this table before?
A. I don't believe so.
Q. Looking at this table now then, do you agree that it reflects solid sampling conducted of the Newton PAP?
A. I would agree that it potentially does, but it doesn't have laboratory reports or sample collection in accordance with 845.640. So, that would be a comment that we would have provided or will provide on the initial operating permit that this would be submitted with.
Q. Assuming that there are -- sorry; you just said the laboratory reports and what else?
A. The field collection documentation.
Q. Okay. So, assuming there was laboratory results and field collection data to back this information up, would you agree that this presents solid sampling conducted of the Newton PAP?

A. Yes.
Q. I'm going to provide you with a document that has been marked as exhibit 15.
Does the agency consider -- well, to go back for a moment. The agency considers documents outside of those just provided by Illinois Power in connection with the Newton ASD submittal, correct?
A. To an extent, yes.
Q. So, for example, you looked at EPA guidance?
A. Yes.
Q. Okay. You looked at some maybe academic references? Is that a fair characterization?
A. Yeah, possibly.
Q. How did you determine what other documents to review and consider?
A. So, I basically had the conversation with Heather Mullenax and asked her for the specifics that go into source characterization.
So, I asked her if there was any source characterization. And then we went through like what was missing. And so these pieces that are in the letter are not actually in the submittal. And

so we just, yeah, we went through that process of just asking those questions.

Q. So, referring to this document that's in front of you right now; have you ever seen this document before?

A. Yes.

Q. Okay. What is it?

A. It's 40 CFR part 257. The USEPA CCR rule, or at least the preamble, it looks like. I'm not sure. Or the proposed rules. I'm not really sure.

Q. Okay.

A. How you, like, interpret all of that. But, yes, it goes -- this seems to go through 107, 257, 107, I don't know.

Q. So do you agree it's an EPA rule making?

A. Yes.

Q. Or it's a proposed rule from the United States Environmental Protection Agency, agreed?

A. Yes.

Q. You agree it's authored by EPA?

A. Yes.

Q. Would you have this document in your possession when you were reviewing the Newton ASD

submittal?

A. Do you mean did I look at this specifically during my review?

Q. Could you have looked at it?

A. I could have, yes.

Q. Did you consider this document in connection with the Newton ASD submittal?

A. Indirectly, yes. Directly, no.

Q. Okay. Can you go to page 11588 of this document.

A. 115 what?

Q. 88. It's like a few pages in.

A. Okay.

Q. Do you see highlighted language in the third column there?

A. Yes.

Q. Okay. I'm going to read the first sentence of the highlighted language: Quote, "out of all the coal ash constituents modeled by EPA, boron has the fastest travel time, meaning boron is likely to reach potential receptors before other constituents." End quote.

Do you agree with that statement?

A. Yes.

Q. I'm going to read the second sentence that's highlighted there. Quote, "therefore, boron is expected to be one of the earliest constituents detected if releases to groundwater are occurring." The sentence then continues, "consequently, EPA reasoned that retaining boron on Appendix III was more appropriate as it would function as a signal constituent that would ensure that assessment monitoring was quickly triggered in response to any release."

Did I read that correctly?

A. Yes.

Q. Do you agree that boron is expected to be one of the earliest constituents detected if releases to groundwater are occurring?

A. Yes.

Q. Do you agree that boron can serve as a, or that boron would function as a signal constituent?

A. Yes, it could.

Q. Okay. And what do you understand the term signal constituent to mean as it's used here?

A. Basically, it's one of the first to appear, which is why it's Appendix III, and in the

detection monitoring versus assessment monitoring for this part.

Q. Were there exceedances to your recollection at Newton, at the Newton PAP other than the chloride exceedance that's the subject of this ASD?

A. I don't know. We'd have to look at that. I think there was ones that you've submitted in there, wasn't there?

Q. Let's look at Exhibit 2, which is the ASD submittal.

And if you could just turn to the page that has R0001611 at the top.

A. Okay.

Q. All right. And then going maybe two-thirds of the way down the page. Do you see the paragraph starting, "the most recent quarterly sampling event"?

A. Yes.

Q. Okay. The last sentence of that paragraph reads, "the statistical determination identified the following GWPS exceedances at compliance groundwater monitoring wells." Do you see that language?

A. Yes.
Q. Okay. And so does that then list several wells at which there were groundwater protection standard exceedances?
A. Yes.
Q. Okay. So, do you see the listing for chloride in APW15?
A. Yes.
Q. And are there other listings on there?
A. Other listings of what?
Q. Other wells where there were exceedances of groundwater protection standards?
A. For chloride or for others?
Q. For anything?
A. Yes.
Q. Okay. So, do you see a listing here for lithium at well APW02?
A. Yes.
Q. And then do you see sulfate exceedances listed for four different wells?
A. Yes.
Q. And then do you see TDS, or total dissolved solids, listed as exceedances in three other wells?

A. Yes.
Q. Okay. And then I would like to point your direction to the last sentence on that page, which says lithium, sulfate and TDS exceedances will be addressed in accordance with 35 I.A.C. 845.660.
A. Okay.
Q. Do you see that sentence?
A. Yes.
Q. What do you understand that to mean?
A. That means that only chloride is being addressed here.
Q. Okay. And what does that mean for the other exceedances?
A. That they're going to assessment of corrective measures.
Q. Do you have any understanding of what boron concentrations were in the wells that are undergoing an assessment of corrective measures?
A. No.
Q. Do you have an understanding of what sulfate concentrations were in the wells that are undergoing --
A. No.

Q. -- an assessment of corrective measures?
A. No.
Q. I'm going to direct your attention to another document, which has been marked as exhibit 16.
Are you familiar with this document?
A. I am familiar with the part 257, not 261.
Q. Okay. Do you agree that this is a final rule making related to part 257?
A. It seems to be.
Q. Okay. Have you reviewed this document before?
A. I have reviewed part 257. I, again, am not familiar with 261.
Q. Okay. Would you have reviewed the portions of this document related to part 257?
A. To some extent, but not in total.
Q. Okay. Do you agree this document is authored by EPA?
A. Yes.
Q. And when I say EPA, I mean the United States Environmental Protection Agency?
A. Yes.

Q. Is this a document that IEPA would have had access to when it was reviewing the Newton ASD?
A. Yes.
Q. Did you consider this document in connection with the Newton ASD?
A. Indirectly, yes. Directly, no.
Q. Indirectly how so?
A. Indirectly, the 845 is written to be as protective as or more protective than 257. So --
Q. Is part 845 meant to address similar risks as 257 is meant to address?
A. To my understanding, yes.
Q. I'd like to refer you to page 21441 of this document. And it's a bit of a ways through the document. All right. In the third column at the very top of the third column do you see a section starting, EPA response?
A. Yeah.
Q. Okay. The first sentence there reads, "the use of pore water data is still considered the most appropriate approach to estimate constituent fluxes to groundwater for CCR surface impoundments." Did I read that correctly?

A. Yes.
Q. Do you agree with that statement?
A. Yes.
Q. The second sentence reads, "this is because pore water better represents the leachate seeping from the bottom of the impoundment than impoundment water samples." Do you see that sentence?
A. Yes.
Q. Did I read it correctly?
A. Yes.
Q. Do you agree with that statement?
A. Yes.
Q. Okay. Are you aware of any EPA or other documents that state that LEAF testing or other leach tests are better than measurements taken in the field?
A. I am not familiar with LEAF testing enough to make a statement on that.
Q. I'm going to show you a document that's been marked as exhibit 17.
Are you familiar with this document?
A. Yes.
Q. What is it?

A. It's the Human and Ecological Risk Assessment of Coal Combustion Residuals From December 2014 done by the USEPA.
Q. Have you reviewed this document before?
A. Yes.
Q. In what context?
A. Just in general, how it pertains to CCR and --
Q. Do you agree that it's authored by the United States Environmental Protection Agency?
A. Yes.
Q. Is this a document that IEPA had in its possession when reviewing the Newton ASD?
A. Yes.
Q. Did you consider this document in connection with the Newton ASD?
A. Indirectly, yes.
Q. And indirectly how so?
A. In that I have reviewed it. I agree with what it says in respect to -- well, in total. But also, like, it doesn't contradict the mass transport equation and does still require source characterization is what we were asking for. So, it doesn't contradict what our request is. So,

yes.

Q. Okay. Can I refer your attention to page 4-5 of this document?

A. Okay.

Q. Do you see the section that's listed as 4.2.1?

A. Yes.

Q. All right. I'm going to read the first sentence there: It says, "similar to the screening analysis described in Section 3, EPA relied on pore water concentrations to characterize leaching from impoundments." Do you see that sentence?

A. Yes.

Q. Do you agree I read it correctly?

A. Yes.

Q. Do you agree with that statement?

A. Yes.

Q. Do you agree that under the risk assessment presented in this document, EPA relied upon pore water concentrations to characterize leaching from CCR surface impoundments?

A. Yes.

Q. The second sentence reads: "These

concentrations are collected from the interstitial water between the waste particles in surface impoundments as it occurs in the field, and best reflect leachate as it is released into underlying soils." Did I read that sentence correctly?

A. Yes.

Q. Do you agree with that statement?

A. Yes.

Q. Going to direct your attention to page 5-17 of this document.

All right. Let's turn it around here. Can you read the first sentence there under Section 5.1-3. Do you see the section titled, representativeness?

A. Yes.

Q. Could you read the first sentence there:

A. "Pore water data were determined to be the most representative data available for impoundments because these data are field-measured concentrations of leachate present at the bottom of these WMUs."

Q. First off, are you familiar with the acronym WMUs?

A. No.

Q. Okay. Do you agree that it might be referring to waste management units?
A. It's possible, yeah.
Q. All right. Assuming that WMUs is referring to waste management units, do you agree with the statement in the sentence you just read?
A. Yes.
Q. All right. I'm going to go back to Exhibit 2, which is the original ASD submittal.
Actually, can we take a short break?
(The time is 4:52 p.m.)
(The time is 4:58 p.m.)
CONTINUED EXAMINATION BY
MS. JOSHI:
Q. All right. So, I'd like to refer you back to what's been marked as Exhibit 2. And I'd like to refer you to the third page of the document, which has the record Bates number 1608 at the top.
All right. Do you agree that this page includes a certification from a professional engineer?
A. Yes.
Q. Do you agree that this page includes a

certification from a professional geologist?
A. Yes.
Q. If you could move to page three of the actual document, meaning the actual substance of the document. So, page title Introduction. Do you see that? It's R1611?
A. Okay.
Q. The second to last paragraph says, "pursuant to 35 I.A.C. 845.650(e) the lines of evidence (LOEs) presented in Section 3 demonstrate that sources other than the PAP are the cause of the chloride GWPS exceedance listed above." Do you see that sentence?
A. Yes.
Q. What do you understand the terms, lines of evidence analysis to mean?
A. It means this is the lines of evidence being presented, the data that's being presented; and analysis.
Q. Are you familiar with the lines of evidence analysis generally?
A. Not really, actually.
Q. Okay. Have you ever performed a lines of evidence analysis?

A. No.
Q. Have you reviewed the lines of evidence provided in this document?
A. Briefly in more of a big picture overview of whether or not there was a -- whether or not the data inputs into the mass transport equation were there or not.
Q. Okay. Like to refer you to the page that's numbered 1615 at the top right-hand corner.
And Section 3.1, do you agree that Section 3.1 sets forth the first line of evidence presented in this document?
A. I'm sorry, come again?
Q. Sure. You've reviewed this document, yes?
A. In a brief overview.
Q. Okay. Did you take a look at section 3.1 as part of your review?
A. I believe that, it's been several months, that I more focused on whether or not the source characterization of the total solid was included in this document. And therefore the mass transport equation was being implemented adequately to be able to start these lines of

evidence.

Q. What do you mean by, to be able to start these lines of evidence?

A. Going back to the law of mass conservation, the mass transport equation is basically that you have X amount of mass, and then on the other end of the equation is the same mass. And so if you don't have the one side, you can't say what's on the other side of that equation.

And so it's kind of what I've been saying the whole time. So we're back to, it's -- we have to have the total amount potential that's going into this, or could be leachable to be able to say what's actually potential and what's not.

Q. Potential, correct? Is the term you just used?

A. Yeah.

Q. So you did not review the first line of evidence in any detail?

A. Not in any detail, because again, it had to comply with 845.650(e).

Q. And in what way does the first line of evidence not comply with 845.650(e)?

A. Go back to 650(e). Again, the ASD task

is that you have to show that the CCR surface impoundment did not contribute to the contamination. And if you do not have that adequately characterized, thus the source characterization, mass transport equation, on the one side, then you can't say what's on the other side of that equation.

Q. Does 845.650(e) specifically refer to a source characterization?

A. In my technical interpretation, yes.

Q. Where?

A. Again, in the first sentence where it says, "and the CCR surface impoundment did not contribute to the contamination."

Q. Okay.

A. If you don't have the data, then you can't make the assumption.

Q. Okay. But again, what data are you talking about there?

A. The total solids data.

Q. And does 845.650(e) refer to total solid sampling anywhere?

A. It doesn't have to. The technical, the law of mass conservation and the mass transport

equation are the technical bases of making those statements. And without that data, you can't make this jump.

Q. Is that your opinion?

A. No, it's the law of conservation of mass. But --

Q. Is the law of conservation of mass a theoretical principle?

A. Yes.

Q. So it's a scientific principle?

A. Yes.

Q. Okay. So, you are saying that it should apply in this circumstance, correct?

A. Yes; and management agree.

Q. And by management, to whom are you referring?

A. Mike Summers.

Q. Anyone else?

A. No, he's the one that signed off on this.

Q. Okay. So, let's look at 845.650(e), and I actually have a copy we can enter into the record as an exhibit. We are on exhibit 23.

(Whereupon, Deposition Exhibit No. 23

was marked for identification.)

Q. Okay. So first of all, do you agree that this, looking at 845.650(e), all right? You agree that this section refers to alternative source demonstration?

A. Yes.

Q. Do you agree that this section requires an ASD submittal within 60 days after the detection of an exceedance of a groundwater protection standard?

A. Yes.

Q. Do you agree that it requires a submission of a demonstration to the agency?

A. Yes.

Q. And do you agree that that demonstration has to -- that that demonstration is that a source other than the CCR surface impoundment caused the contamination, and the CCR surface impoundment did not contribute to the contamination?

A. Yes.

Q. Okay. I want to -- well, I want to refer you to the last sentence of this Section e.

A. Okay.

Q. It says, "either type of ASD must

include a report that contains the factual or evidentiary basis for any conclusions and a certification of accuracy by a qualified professional engineer." Do you see that?

A. Yes.

Q. Okay. Did Illinois Power provide a report for the Newton PAP ASD submittal?

A. They provided a report, but they did not provide the data required under SW846 Chapter 1 to make regulatory decision, which is why the nonconcurrence letter said the source characterization was not complete.

Q. Okay. Going back to 845.650(e), does it make any reference to SW846?

A. No, SW846 is incorporated by reference, and it applies to all of 845.

Q. You believe that SW846 applies to all of 845?

A. In that all of our regulatory decisions have to be based on data, yes.

Q. Okay. Are there specific sections of 845 that specifically mention SW846?

A. The incorporation is by reference.

Q. So, for example, can you turn to 845.640

in your regs there?
A. Okay.
Q. And the very last section of 845.640?
A. Okay.
Q. Is that subsection, what is that j?
A. Yeah.
Q. Okay. Does that refer to SW846?
A. Yeah.
Q. Okay. Does 845.650 refer to SW846 anywhere?
A. So, j refers to 845 -- SW846 test methods, not to Chapter One.
Q. Okay.
A. 650 -- hold on. 650 does not refer to it directly, but Chapter One applies to across-the-board regulatory decisions.
Q. And what is your basis for saying that?
A. Because S40 -- S846 Chapter One in the first, like, introduction it says that all regulatory decisions must be supported by environmental data.
Q. Okay. Is SW846 law in Illinois?
A. No, but you can't just make decisions on opinions.

Q. Okay. Well, let's go back to this last sentence of Subsection e. So, you agree that a report was submitted?

A. Correct.

Q. It may not have included the information you wanted to see, but you agree that a report was submitted?

A. Correct.

Q. Do you agree that that report contained facts?

A. I agree that that report contained what was stated to be fact. However, the laboratory result, like laboratory reports and the field documentation substantiating that it is fact, were not provided.

Q. Okay. Did you ask for that data during your discussions?

A. I believe so, but I am not entirely sure.

Q. Okay. Do you agree that the report includes an evidentiary basis for the conclusions in the report?

A. I feel that if you do not have the substantial, like, evidence that this is in fact

data that is fact, then it undermines the whole entire document.

So, I don't agree that it would be evidence if it's not substantiated as fact. So, if you don't have the facts, then you don't have the evidence. One can not be by itself.

Q. Are there any facts presented in Exhibit 2 that you can point to, and tell me that you disagree with?

A. I did not review it enough to give an opinion on that specifically agree or disagree on the geochemistry; because again, I am not the geochemist. I was just agreeing based on the mass transport equation and the law of conservation of mass.

Q. So because there was no -- they didn't do those two things, you disagree with the ASD?

A. Correct.

Q. And you did not review any of these lines of evidence in detail?

A. Not in detail. I am not a geochemist.

Q. And sitting here today, you couldn't tell me whether you disagree with any of the facts in this ASD?

A. Well, if in fact they are substantiated as facts by the laboratory reports documentation.
Q. Sitting here today, do you disagree with any of the information presented in the ASD?
A. I can't say whether or not I do.
Q. Can we break really quick? I want to check on time.
(The time is 5:13 p.m.)
(The time is 5:13 p.m.)
CONTINUED EXAMINATION BY
MS. JOSHI:
Q. I'd like to refer you to page ten of Exhibit 2, the top is R0001618.
Did you review this section of the ASD submittal?
A. No, I did not.
Q. Did you review any of the references listed in the reference section of this document, which is on this page and also the following page, just so you know?
A. No.
Q. Why did you not review any of these documents?
A. Again, I was leading the technical

review and asking the questions of Heather Mullenax.

Q. Are you familiar with whether anyone from IEPA reviewed any of the reference documents listed here in connection with the Newton ASD?

A. I don't know that.

Q. All right. I'm going to refer you to one last document here, exhibit number -- it's been marked as Exhibit No. 14.

Are you familiar with this document?

A. I am not necessarily. Yeah, I'm not familiar.

Q. Did you review this document in connection with the Newton PAP ASD?

A. No.

Q. I'm going to refer you to R001941 of the document.

A. Okay.

Q. Do you see that section entitled, references?

A. Yes.

Q. Again, can you take a look at the references listed there, and let me know whether you reviewed any of the documents listed there in

connection with the Newton ASD submittal?

A. Not in particular.

Q. What do you mean by, not in particular?

A. I didn't review this page. But yes, I mean, I think I reviewed a few of these documents potentially for other purposes. But --

Q. Okay. Which of those documents would you have reviewed for other purposes?

A. Inasmuch as I've already said the initial operating permit, if I have done any review of that specific part of the document that we were looking at earlier that was part of the initial operating permit. And, I mean, the USEPA monitoring natural attenuation of Superfunds -- I may have reviewed that at a past time, but not in the course of this. So, otherwise none of this looks familiar.

Q. Okay.

A. Well, 846, yeah, obviously. But, yeah.

Q. And then turning back a couple pages from this reference section to page 1938.

Just want to confirm whether, did you look at this particular letter and the information contained within it as part of your review of the

Newton ASD?

A. I do not believe that I looked at this.

Q. Okay. Can we pause?

(The time is 5:19 p.m.)

(The time is 5:23 p.m.)

MS. JOSHI: We're all set. No more questions. Thank you.

THE WITNESS: Thank you.

MS. MEADE: No questions from us. Reserve signature.

(The time is 5:24 p.m.)

COUNTY OF CHAMPAIGN)

I, DEANN K. PARKINSON, a Notary Public in and for the County of Champaign State of Illinois, do hereby certify that LAUREN HUNT, the deponent herein, was by me first duly sworn to tell the truth, the whole truth and nothing but the truth in the aforementioned cause of action.

That the foregoing deposition was taken on May 28, 2024.

That said deposition was taken down in stenographic notes and afterwards reduced to typewriting under my instruction and said transcription is a true record of the testimony given; and that it was agreed by and between the witness and attorneys that said signature on said deposition would be not waived.

I do hereby certify that I am a disinterested person in this cause of action; that I am not a relative of any party or any attorney of record in this cause, or an attorney for any party herein, or otherwise interested in the event of this action, and am not in the employ of the attorneys for either party.

In witness whereof, I have hereunto set my hand and affixed my notarial seal June 2, 2024.

DISCOVERY DEPOSITION

The deposition of HEATHER MULLENAX taken on behalf of the Petitioner at 133 South 4th Springfield, IL on May 28th, 2024, before Deann K. Parkinson, Certified Shorthand Reporter of the State of Illinois. Deposition taken pursuant to the discovery provisions of the Illinois Code of Civil Procedure and the Rules of the Supreme Court promulgated pursuant thereto.

(The time is 8:57 a.m.)

HEATHER MULLENAX,

the deponent herein, called as a witness, after having been first duly sworn, testified as follows:

EXAMINATION BY

MS. JOSHI:

Q. Hello, good morning. My name is Bina Joshi from Arentfox Schiff LLP representing Illinois Power Generating Company in this matter. Ms. Mullenax, would you please state your name and business address for the record?

A. My name is Heather Mullenax. I work over at the Illinois EPA, which is on North Grand Avenue in the Bureau of Water.

Q. So Ms. Mullenax, you're giving testimony under oath today. I'm going to start by just going over a few sort of ground rules and like basis setting for the deposition before we kind of get into questions.

So, first of all, you are giving testimony under oath today as you know, by the fact that you were just sworn in by Ann here.

Is there anything that might impact your

ability to answer truthfully today?
A. No, ma'am.
Q. Are you aware of anything that would preclude your ability to understand my questions this morning?
A. No, ma'am.
Q. Are you aware of anything that might affect your memory?
A. No, ma'am.
Q. Could you please, you probably already know this, but give verbal answers to my questions, since we'll have a transcript, and they can't pick up head nods and things like that.
A. Yes, ma'am.
Q. Please, let me finish my questions before you answer a question. Let me know if you don't understand a question that I ask this morning, and I will do my best to try to rephrase it or to clarify.
Let me know or let us know if you need a break at any time. If there is a question pending, you will need to complete the response before we take the break. But, if you just need a minute, need to use the restroom, whatever, please

just speak up and we can take a break.

Do you understand these instructions?

A. Yes, I do.

Q. And I'll also start by going over some shorthand for this morning. So, I may refer to Illinois Power Generating Company this morning as Illinois Power or IPGC. I may refer to the Newton Power Plant as Newton. I may refer to the Newton Primary Ash Pond that was the subject of the alternative source demonstration at issue in this appeal as the PAP, or the Newton PAP.

When I use the term ASD, I'm referring to, again, Newton Alternative Source Demonstration for chloride that's the subject of this proceeding.

When I refer to IEPA, or the agency, I'm referring to Illinois EPA. And when I refer to part A45, I'm referring to the regulations located at Title 35 Illinois Administrative Code part 845. Does that all make sense to you?

A. Yes.

Q. I'm sure those are acronyms that you are very familiar with.

A. I understand.

Q. All right. So I'll start by asking you just a few questions about your background. Where did you get your bachelor's degree?

A. I received my bachelor's of arts in earth science at the Western Kentucky University. It was in earth science. And a minor in environmental science and sustainability.

Q. Do you have a Master's degree?

A. I do.

Q. And in what subject is your Master's degree?

A. My Master's of science is in earth science from the University of Memphis.

Q. Do you have any other degrees of a collegiate level or higher?

A. No, I do not.

Q. And then I'd like to talk briefly about your employment history. So, what, you said you currently work in the Bureau of Water at IEPA?

A. Yes.

Q. What is your position in the Bureau of Water?

A. My current position is the environmental protection geologist two.

Q. And what are your responsibilities just generally in your current role?
A. My current responsibilities are to overall look at coal combustion residuals, otherwise known as CCR. I look over bacteria results of other sites. And primarily look at chemistry of exceedances with other water qualities as sites.
Q. What types of other water quality sites?
A. They are usually spray irrigation sites, or usually like waste management sites. They submit water quality info to the agency to test for exceedances.
Q. And sort of in what way do you review those submittals? Just to make sure they're accurate?
A. Yes. To make sure they're accurate with the regulation of whatever class they are under; whether it's 620 class one, class two, or 845.
Q. Did you hold any positions at IEPA prior to your current position?
A. No, I did not.
Q. Did you hold any employment prior to starting at IEPA?

A. I did have prior employment.
Q. And what was that?
A. I was a substitute teacher back in Paducah, Kentucky.
Q. Did you have any other employment prior to that?
A. No, I did not.
Q. Are you licensed as a professional engineer?
A. No.
Q. Are you licensed as a professional geologist?
A. No.
Q. Are you a hydrogeologist?
A. I'm in earth sciences.
Q. Okay. Have you yourself ever performed total solid sampling of CCR surface impoundment?
A. No.
Q. Have you ever coordinated the schedule for performing total solid sampling for a CCR surface impoundment?
A. No.
Q. Have you yourself ever performed a characterization of bedrock?

A. No.
Q. Have you ever coordinated a schedule to conduct a bedrock characterization?
A. No.
Q. Have you ever prepared an alternative source demonstration?
A. No.
Q. Have you ever assisted in preparing an alternative source demonstration?
A. No.
Q. When did you first review an alternative source demonstration or an ASD?
A. The Newton Primary Ash Pond was the first one.
Q. Have you ever done a forensic analysis to identify the source of an exceedance in any context?
A. Yes.
Q. Okay. And when so?
A. It was back in 2022 when I was a research assistant with the University of Memphis. I looked at the source characterization or the -- for exceedances in a well field.
Q. Okay. And what kind of well field? Can

you give me a little more description of what the circumstance was of the characterization?

A. Yes. It was a water treatment plant looking at modern water leakage.

Q. And what was the scope of the source characterization that you did?

A. Modern water leakage.

Q. Can you explain to me, a non-geologist, what that means?

A. It is to determine whether new water is coming in to the well field, and therefore contaminating or causing exceedances in the well field.

Q. Okay. And what methods did you use for this characterization?

A. We use the EPA low flow sampling methodology. And we use radioactive isotopes. So, I'm not exactly sure of the EPA number for that sampling.

Q. Okay. And what was the scope of sampling that was conducted for this investigation?

A. To determine if there was modern water leakage in the well field using cation and anion

sampling.

Q. So, when you say -- sorry, can you repeat that?

A. Cation, C-A-T-I-O-N, and anion, A-N-I-O-N.

Q. And by scope, I mean how many wells were installed for the purposes of the sampling, do you recall?

A. I do not recall.

Q. And over how many sampling events occurred for the characterization, do you recall that?

A. I do not recall.

Q. When you were doing this characterization, how did you decide what information to look at?

A. I was asked by my adviser to look at the chemistry of the site. And that is looking at the, what I mentioned before, cation and anion elements. And compared them over a period of time to understand the exceedances.

Q. Compared them to what?

A. Previous historical data.

Q. And where was the historical data from?

A. From the University of Memphis.
Q. Okay. And was it historical data from that same site?
A. Yes.
Q. And you said over a period of time; what was that period of time, do you know?
A. Over a couple of years.
Q. So you were working on this project over a couple of years?
A. I was working on it a total of two years.
Q. So, it sounds like your professor sort of gave you direction on what to look at; how did, I guess how did you guys come to a conclusion on the process that you would use in order to do the comparison of conditions then, versus the historical conditions?
A. We looked at, we came to the conclusion, based on previous other well fields in Memphis, Tennessee, who have also done the same research. And my previous, the well field that I was under, had not gone through that historical comparison.
Q. And did you determine that it was being influenced by other sources?

A. We did not.
Q. And what led to that conclusion?
A. This was due to faulting in the Memphis, Tennessee, area, which did not allow for modern water to enter the well field.
Q. How did you know that faulting was occurring?
A. Based on historical data.
Q. And that historical data was what exactly?
A. It was maps made by USGS and the University of Memphis when they used geographical information systems; GIS.
Q. Moving on, did you do anything to prepare for the deposition today Ms. Mullenax?
A. Besides reviewing the submittal.
Q. Okay. So, by reviewing the submittal, what do you mean by the submittal?
A. The record that was submitted to everyone here.
Q. Okay. So, you reviewed the record prior to coming here today?
A. Yes.
Q. Okay. Did you review the entire record

or were you focused on particular documents in the record?

A. I focused on the alternative source demonstration. My notes that were submitted. And the meetings that were submitted in the -- as invites.

Q. And did you have discussions with anyone prior to your deposition today regarding the deposition?

A. No.

Q. I'm going to hand you a document, which we're going to mark as Exhibit 1.

(Whereupon, Deposition Exhibit No. 1 was marked for identification.)

Q. If you could pass the copy over there. Have you seen this document before?

A. Yes.

Q. If you could turn the page and look at the section where you were asked to bring certain documents to this deposition. I believe that would be page four of the document. Try to keep this double sided.

Did you review these requests for documents before you came here today?

A. Yes.
Q. Do you have any documents to provide in response to that first request for documents?
A. No.
Q. Do you have any documents to provide in response to the second request for documents?
A. No.
Q. Have you provided any correspondence you had internally or externally regarding the Newton ASD as part of the record in this proceeding?
A. Yes.
Q. Have you provided any notes that you made regarding the Newton ASD in the record in this proceeding?
A. Yes.
Q. I'm going to hand you another document here. This is record document number 12. Which is the original ASD submittal.
(Whereupon, Deposition Exhibit No. 2 was marked for identification.)
Q. Which I'm going to mark as Exhibit 2. Are you familiar with this document?
A. Yes.
Q. Okay. I'm going to start with just some

baseline setting for our discussion today. Do you agree that the ASD that's at issue in this proceeding relates to chloride in a well designated as APW15?

A. Yes.

Q. And do you agree that this well was screened in the upper aquifer?

A. Yes.

Q. Do you agree that the upper aquifer where this well was screened is made up of unconsolidated materials, such as sands, silts and clays?

A. Yes.

Q. Ms. Mullenax, have you heard of the term peer review before?

A. Yes.

Q. How do you define that term?

A. I define peer reviewed as journals or articles that are reviewed by multiple people or multiple organizations, and are backed by scientific records before.

Q. And where does your understanding of that definition come from?

A. From what I learned in my degree.

Q. Would you consider documents published by EPA to be peer reviewed?
A. Yes.
Q. Do you agree that a document may be peer reviewed even if it's not published in an academic journal?
A. I would say it would depend if it's clearly marked or clearly stated being peer reviewed.
Q. Can you always tell from the face of a document whether it's been peer reviewed?
A. No.
Q. So, what did you mean by your last statement about whether it was clearly marked as peer reviewed?
A. What I mean is, usually in a summary or a conclusion I have seen where they have stated, it has been peer reviewed by X number of people, or by whoever the, or by multiple out source.
Q. Is that statement always in a peer-reviewed article?
A. No.
Q. All right. I'm going to move on and show you another document. This is marked as

record document number three, and I'm going to mark it as Exhibit 3 for your deposition here.

(Whereupon, Deposition Exhibit No. 3 was marked for identification.)

Q. I'll give you a moment to take a look at the document. Are you familiar with this document?

A. Yes.

Q. All right. What is it?

A. This is my textbook called Geochemistry, the Principles of Geochemistry.

Q. When you say my textbook, do you mean that you own this textbook?

A. Yes.

Q. Do you agree this document was submitted with the ASD submittal?

A. Yes.

Q. Or included with the ASD record?

A. Yes.

Q. And do you agree that the pages that are included in the record consist of excerpts from a larger document?

A. Yes.

Q. I'd like to direct your attention to

page 366 of this document. Towards the end. Do you see on the left side of the page down at the bottom there's a section that starts, Cl and Br.

A. Yes.

Q. Do you agree that Cl stands for chlorine there?

A. It stands for chloride.

Q. Oh, chloride?

A. Yes.

Q. Okay. So, and just so we can also base that here, what is the difference between chlorine and chloride?

A. Chlorine is -- all right, let me -- chlorine is what would be considered what chloride is a part of. Chloride is what I would consider a small section of a chemical equation.

Q. So, would you agree chlorine is like an atom, while chloride is like an ion?

A. Yes.

Q. So, I want to read the first sentence of that section there. It says chlorine and bromine both have natural and anthropogenic sources. Do you see that language?

A. Yes.

Q. Okay. Do you agree with that statement?
A. Yes.
Q. And do you agree that the statement is true for both chlorine and chloride?
A. Yes.
Q. I want to direct your attention to some language that starts about halfway through that same paragraph. Do you see the sentence starting, hydrochemical characteristics?
A. Yes.
Q. Okay. I'm going to read that statement as well. Hydrochemical characteristics of both compounds are one, low concentration in most rock forming materials. Two, high solubility of most nonsilicate compounds. Three, virtually no absorption by particles. Four, lack of volatile compounds. And five, generally low bioconcentrations in aqueous systems.

Because of these characteristics, both elements behave as conservative species and they have been widely used as tracers in hydrological systems. Do you see that language?
A. Yes.
Q. Do you agree I read it correctly?

A. Yes.
Q. What do you understand the term, conservative species to mean as used in that statement?
A. They can be used to define a characteristic of a site or an exceedance.
Q. And why can a conservative species be used to help, to do that?
A. They're considered to be nonreactive. They, while other elements would be more reactive in a situation, conservative ones allow things to be easier to define.
Q. So, do you agree that chlorine is a conservative species?
A. Yes.
Q. And do you agree that chloride is also a conservative species?
A. Yes.
Q. Okay. I'm going to move on to another document. This is record document number 24. Which I'm going to mark as exhibit 4.
(Whereupon, Deposition Exhibit No. 4 was marked for identification.)
Q. Ms. Mullenax, are you familiar with this

document?
A. Yes.
Q. And what does it reflect?
A. This is my notes during a meeting.
Q. And notes regarding what?
A. A meeting with the IEPA and Illinois Power.
Q. And what was that meeting regarding?
A. This meeting was regarding the IEPA's decision on what was considered to be missing in the alternative source demonstration. And that we would be nonconcurring. And the response of what they would have to do.
Q. What do you mean by, the response of what they would have to do?
A. It stated either they would appeal, or go through corrective measures.
Q. If you look on these notes, the second to last bullet point there; could you read that for me. The one that starts, "use of"?
A. Use of aerial photos in order to determine pore water.
Q. Okay. Can you explain what you meant by this bullet point?

A. This was an explanation that was given through Illinois Power that they used aerial photos to determine their pore water samples.
Q. And why did you make note of that fact?
A. Because this was something the IEPA would have to discuss further based on what pore water was, and whether we would accept.
Q. Did IEPA discuss further?
A. Yes.
Q. And what did they conclude?
A. The conclusion was based on the IEPA pre water -- or my apologies; the USEPA pore water, and we could not accept the use of pore water.
Q. Can you explain that further? What do you mean by, it was based on the use of USEPA pore water?
A. USEPA had a guidance document that was stating of what pore water was. And because part 845 does not have standards for pore water, we were unsure of the validation with the chemistry.
Q. What do you mean by you were unsure of the validation with the chemistry?
A. Part 845 lines out groundwater standards in part 600. And because pore water is not a part

of that, we would have to -- we did not have a standard to look at.

Q. Again, when you say you did not have a standard to look at, you meant that 845 -- I'm just trying to understand what you are saying. Are you saying that 845 doesn't have a standard for sampling pore water?

A. Yes.

Q. And so then you were looking at USEPA standards for sampling pore water?

A. We used the USEPA guidance document to understand what pore water was.

Q. What guidance document is that?

A. It's a recent document from 2019, I believe. I did not find this document. This was -- I did not find this document.

Q. Is this a document that was provided with the record?

A. Yes.

Q. Okay. I'm going to hand you a document I'm marking as exhibit 5.

(Whereupon, Deposition Exhibit No. 5 was marked for identification.)

Q. Can you tell me if this is the document

to which you are referring to?
A. Yes.
Q. Okay. And do you believe that that document applies to pore water sampling of CCR surface impoundments?
A. That was my understanding.
Q. Okay. And how did you use this document to review the Newton alternative source demonstration?
A. This was our background document of what pore water was because we did not understand how the sampling of pore water does occur.
Q. Okay. And then again, after reviewing this document did you come to any conclusions regarding the Newton -- the pore water sampling that was conducted for the Newton alternative source demonstration?
A. No.
Q. Okay.
MR. HENDERSON: I'm sorry, would it be possible to get a read back of that last question?
(At this point the court reporter read the requested portion of the record.)
BY MS. JOSHI:

Q. What was your -- so, beyond understanding how pore water sampling occurs, did the agency use what has been marked as exhibit 5 for any purposes in reviewing the Newton ASD?

A. Would that be, besides coming to our conclusion to not use pore water overall in alternative source demonstrations?

Q. How did the agency use what's been marked as Exhibit No. 5 to come to the conclusion that pore water sampling could not be used in alternative source demonstrations?

A. It was our understanding that pore water had a specific sampling regimen that we did not see provided in the ASDs. And that because pore water has a specific sampling method, that we would need to see how that was done in the alternative source demonstration.

Q. Did the denial of the alternative source demonstration include the lack of information regarding the pore water sampling regime as a basis for denial?

A. No.

Q. And again, I just want to understand and clarify. Are you saying that the agency could not

accept the pore water sampling as a way of conducting source characterization of the CCR?

A. Yes.

Q. And the reason the agency couldn't do that is because the pore water sampling that was conducted differed from the regime that's in this particular USEPA guidance document?

A. We did not have that provided to us. That's why it was a data gap.

Q. But, we just established that wasn't listed as a data gap, right?

A. Yes.

Q. Okay. So, and what information was it that you did not have, that you would have liked to have seen regarding the pore water sampling?

A. This would be a documentation of the sampling, whether this was laboratory documents or the sampling methodology.

Q. And what kind of information would you have liked to have seen related to the sampling methodology?

A. This is for both the characterization and the groundwater that was provided, just an explanation of how the sampling occurred, and what

steps were provided. Plus, field methods.
Q. Did you review any other resources for how pore water sampling is conducted to inform your decision?
A. We looked at the USEPA LEAF guidance.
Q. LEAF testing is a type of leach testing, do you agree?
A. Yes.
Q. It's not a method of pore water sampling?
A. No.
Q. Sorry. Let me phrase that in a way so it's clear on the record.
Is LEAF testing a method of pore water sampling?
A. No.
Q. All right. I'm going to hand you another document, which is record document number 31. Which we will mark as exhibit 6.
(Whereupon, Deposition Exhibit No. 6 was marked for identification.)
Q. Are you familiar with this document?
A. Yes.
Q. And what is it?

A. My notes on the additional information that was provided during public comment from Illinois Power.
Q. Did you take these notes during the meeting?
A. No.
Q. What did you take these notes based off of?
A. The PDF document that was given as additional information from Illinois Power.
Q. So, this is based on additional information from Illinois Power that was provided during the public comment period?
A. Yes.
Q. And what is your understanding of why Illinois Power provided that information?
A. This was during our meeting from October 31st of the data gaps they did have. And what else could be provided.
Q. Okay. So, do you think -- so, again, I won't ask you to speculate why Illinois Power did something. But was it your understanding that they were providing this information in response to that earlier meeting regarding additional

information the agency wanted to see?
A. Yes.
Q. Okay. On the first line here there's -- well, not the first line. But do you see that first star that's listed on the document? Okay.
Can you read what that first star says?
A. Provided hydraulic conductivities for GW, groundwater, wells.
Q. I think you missed one part there?
A. It's ten to the negative eight.
Q. And what is that, provided hydraulic conductivities ten to the negative eight, intended to mean?
A. It is to the bullet point that is at the very bottom; the ten to the negative eight for the confining unit.
Q. Yes, but what does that ten to the negative eight, I guess, reflect? Or let me take this back. Why did you make note of that?
A. It was our understanding that a confining unit such as bedrock would have this hydraulic conductivity or be around this.
Q. And when you say "this", what are you referring to? The ten to the negative eight?

A. The ten to the negative eight, yes.
Q. The second star here says, no bedrock well logs. Correct?
A. Yes.
Q. What is that referring to?
A. There were no bedrock well logs that went directly into bedrock.
Q. Do you believe that bedrock well logs were needed with the ASD submission?
A. Yes.
Q. Why?
A. Because the alternative source was given as bedrock. And to understand how the bedrock is used in Newton, having the bedrock well log would help us understand if there is a bedrock unit, and how the -- how it reacts to the nearby geology.
Q. Can you tell me what is written on the line that starts, need for explanation?
A. Need for explanation and proof.
Q. So that's an "and" symbol there?
A. Yes.
Q. And then there is what appears to be an arrow to that note? Do you see that?
A. Yes.

Q. And I guess, what was your point of -- well, I guess first of all, what is that arrow referring back to?

A. This arrow is referring to the, because there was no bedrock, there's no lab reports that would be needed for an explanation to the alternative source or proof.

Q. Okay. So it's referring back to the no bedrock well logs bullet there and the no geochem lab reports bullet?

A. Yes.

Q. And first of all, is geochem short for geochemical?

A. Or geochemistry.

Q. Or geochemistry. Okay. Do you believe that geochemistry lab reports were needed for the ASD submission?

A. Yes.

Q. Why?

A. This is to prove the summary charts that were provided in the alternative source, just for validation purposes and quality control so that we can check the groundwater analytical report.

Q. And what summary charts are you

referring to?

A. I am referring to the alternative source demonstration submittal that was provided as one of the attachments that was in the alternative source.

Q. Which attachment are you referring to? And if you want to take a look at I believe what's been marked as Exhibit 2, feel free to go ahead and take a look.

A. This was marked as Appendix C.

Q. So, you believe that the geochemical lab reports were needed to provide additional data in support of the information in that appendix?

A. The validation of what was submitted into Appendix C.

Q. So you believe that the geochemical lab reports were necessary to -- the geochemistry lab reports were necessary to validate the information that's in that appendix?

A. Yes.

Q. Outside of the lack of perhaps what you consider validation, is there anything -- sorry; you said that was Appendix C?

A. Appendix C.

Q. Okay. Beside perhaps what you consider the lack of validation, is there any information that would lead you to disagree with the information that's in Appendix C?

A. By having the lab reports, it is to double check that the information provided was correct.

Q. So you didn't believe you had the information to double check that information?

A. Yes.

Q. But do you have any other reason to disagree with the information?

A. Could you clarify that?

Q. Sure. Yeah. Is there anything, other than perhaps the fact that you didn't have the information to double check the information that's in that appendix, did you see any information or evidence that would lead you to believe that that information is incorrect?

A. No.

Q. All right. Let's move on. I'm going to hand you another document. This is record document number 32, which we will mark as exhibit 7.

(Whereupon, Deposition Exhibit No. 7 was marked for identification.)

Q. It's double sided.

Are you familiar with this document?

A. Yes.

Q. What is it?

A. This is our letter to Illinois Power of the nonconcurrence to the Newton alternative source demonstration.

Q. Were you involved in drafting this document?

A. Yes.

Q. Okay. And what role did you take in drafting it?

A. To write the letter.

Q. Did you write all of the letter?

A. No.

Q. Okay. What portions did you write?

A. The portion of the first paragraph stating the purpose of the correspondence, the paragraph that is, "if you have any questions, please contact." And then the address and titles of what is stated on the document.

Q. Okay. So, you did not draft the three

data gaps that are located in the middle of that document?

A. No.

Q. Who drafted that?

A. Lauren Hunt.

Q. Okay. As you can see, this document is signed by someone named Michael Summers. Do you see that?

A. Yes.

Q. Did you have any discussions with Mr. Summers regarding the document?

A. Yes. We did.

Q. What discussions did you have?

A. The discussion with what data gaps we should move forward with.

Q. And how did you decide to move forward with these three data gaps?

A. During our groundwater meeting, Lauren came up with these data gaps, and we discussed with Mike Summers, or Michael Summers, who is our manager, and he agreed with these data gaps to be put in the letter.

Q. Was there any information presented in that meeting for learning the data gaps?

A. The Newton alternative source submittal.
Q. Did Mr. Summers offer any opinion, other than agreeing with including these three data gaps during that meeting?
A. He agreed that, of those submittals.
Q. And again, Lauren Hunt is the person who drafted these three data gaps that are in this document, correct?
A. Yes.
Q. And to clarify, is Lauren Hunt the person who determined that these three data gaps -- let me take a step back.
Is she the one who suggested that these three data gaps be included in this letter as part of that meeting that you had with Mr. Summers?
A. Yes.
Q. Did Mr. Summers have any role in drafting this document?
A. He reviewed the letter to make sure it matched with our, the data gaps we discussed, but that was it.
Q. Was there anyone else who had to weigh in on these, on this letter, prior to it being sent out?

A. Lauren also looked at this for the majority of edits.

Q. Was there anyone else who had to sign off on the data gaps presented in this letter before the letter was sent out?

A. No.

Q. Okay. So, to be clear, Lauren reviewed it, Lauren Hunt, and Michael Summers reviewed it; was there anyone else who reviewed this letter before it went out?

A. Lynn Dunaway did minor edits.

Q. Anyone else?

A. No.

Q. The first data gap listed on this letter states, source characterization of the CCR at the primary ash pond must include total solid sampling in accordance with SW846.

What does this mean?

A. This is, with the response to the alternative source, that it does not come from the CCR in the surface impoundment. And the characterization would provide that; would provide the explanation of it not coming from the CCR impoundment.

Q. Can you clarify what you mean by that? So, was IEPA looking for any particular type of source characterization through this first data gap?

A. No particular.

Q. Okay. So, what information is IEPA looking for?

A. In 845 it asks for characterization of CCR in waste streams under 230. And which would be provided. We would ask for this type of documentation to be given in the ASD as well.

Q. Okay. Did IEPA have a copy of the Newton PAP operating permit application when it reviewed this ASD?

A. Yes.

Q. And does 845-230, that section you just referred to, is that a section that relates to information that needs to be provided with an operating permit application?

A. Yes.

Q. Is there any section of 845 that requires this information being provided as part of an alternative source demonstration?

A. No.

Q. And when you say that IEPA was looking for a discussion of waste streams in accordance with 845-230, what kind of information related to waste streams?

A. This would be the channels that would be going in or out of the surface impoundment.

Q. What do you mean by channels?

A. This would be the way that CCR would flow into the impoundment, or the water from the CCR would flow out of the surface impoundment.

Q. Do you understand that any CCR is flowing into this impoundment?

A. We -- to be honest, I do not recall.

Q. Do you agree that pore water collection is a way to characterize waste that is flowing out of an impoundment?

A. Yes.

Q. So is there any particular type of method of investigation that IEPA was looking for the source characterization that's listed in data gap one?

A. We, in accordance with SW846.

Q. Any particular SW846 method?

A. I do not remember the exact chapter that

we would refer to.
Q. Okay. Was the intention, was IEPA's intention to suggest that leach testing in accordance with SW846 was required?
MR. HENDERSON: I'm going to object to foundation.
Q. You can answer the question.
A. For SW846 was incorporated into 845. We just see that as a methodology to be used for sampling.
Q. Do you agree that SW846 includes a lot of different types of methodologies?
A. Yes.
Q. And in this particular data gap in this letter, are you aware of whether IEPA was referring to any specific methodology in SW846?
A. I do not recall.
Q. Do you understand the difference between leach testing data and pore water sampling data?
A. I do.
Q. Do you believe that leach testing data is superior to pore water sampling data?
A. I'm not sure how you want me to answer that 'cuz --

Q. In your opinion, is leach testing data superior to pore water sampling data?
A. I find them equal ways of sampling.
Q. I would like to show you a document that is part of record document number 33, which we will mark as Exhibit 8.
(Whereupon, Deposition Exhibit No. 8 was marked for identification.)
Q. Are you familiar with this document?
A. Yes.
Q. Okay. I'd like to refer you to paragraph four of this document. Well, first of all, what is it, if you have reviewed it? What is it?
A. It was a declaration of Cynthia, who was over the Newton Primary Ash Pond alternative source demonstration.
Q. So, is Cynthia Vodopivec, do you agree she prepared this declaration on behalf of Illinois Power Generating Company?
A. Yes.
Q. And this declaration was attached to the petition that was filed in this matter?
A. Yes.

Q. Okay. So, if you could just take a moment to review paragraph four of this document to refresh your recollection on it.

A. Okay.

Q. In paragraph four, Cynthia states that using total solid sampling techniques under SW846 would require drilling within the Newton primary ash pond with up to ten borings using specialized equipment to collect 20 samples.

Do you agree that that would be required in order to conduct solid sampling in accordance with SW846?

A. Yes.

Q. And that next sentence reads, it would further require complete laboratory analyses, data evaluation and reporting for those samples. Do you agree that solid sampling under SW846 would require those steps?

A. Yes.

Q. The next sentence reads, assuming a driller is readily available, which is not always the case, this process would likely take approximately 21 to 42 weeks to complete. Do you agree with that statement?

A. I would -- yeah, I would agree.
Q. All right. Let's go back to what I believe has been marked as Exhibit 7, which is the denial letter.
Referring to the second data point on here. Can you please describe what information the agency is looking for through the second data gap?
A. This is the data reports of hydraulic conductivity within the wells, which would include bedrock wells.
Q. Okay. Let's break this down a little. What hydraulic conductivities is this referring to? Conductivity of what unit or units?
A. This would look at multiple units with the primary focus of bedrock.
Q. Okay. Any other units?
A. No.
Q. So just bedrock?
A. Yes.
Q. So, this is looking for the hydraulic conductivity of the bedrock?
A. Yes.
Q. And what type of in-situ hydraulic test

is the agency thinking is necessary for data gap two?

A. I do not know the specific.

Q. And what is the agency asking for through the phrase, hydrogeologic characterization of bedrock units?

A. This would include the bedrock well logs, and the well construction logs.

Q. Anything else?

A. No.

Q. Why do you believe such a characterization is necessary?

A. This is for our full understanding of how the bedrock is reacting in the Newton area.

Q. And what regulation, guidance or other documents leads you to believe this type of characterization is necessary to prove that the Newton PAP is not the source of the chloride exceedance?

A. This would overall be the alternative source, the characterization of that. But, it would refer back to 620 being the hydrogeologic characterization of the site.

Q. Sorry, when you say 620, what are you

referring to?

A. 845-620. Apologize.

Q. And when you refer to the 845-620 hydrogeo characterization of the site, are you referring to the hydrogeologic characterization that an owner/operator is expected to provide with its groundwater monitoring plan?

A. Yes.

Q. Okay. Is there a requirement to provide a hydrogeologic characterization with an alternative source demonstration in the regulations?

A. Not specifically.

Q. Moving on to the third listed data gap, or the third point here on this letter.

Characterization to include sample and analysis in accordance with 35IAC845640 of alternative source must be provided with the ASD.

What characterization is this meant to refer to?

A. This is to refer to the geochemical lab reports and the chain of custodies.

Q. And geochemical lab reports for what?

A. The data that was provided with Appendix

C.

Q. And chain of custody for what?

A. Appendix C.

Q. Is this meant to refer to anything else?

A. No.

Q. So, to confirm, was the agency seeking any additional sampling through this data gap?

MR. HENDERSON: I'm just going to repeat my previous objection.

Q. You can answer.

A. Could you repeat the question?

Q. Sure. Data gap three says, characterization to include sample and analysis in accordance with 35 I.A.C. 845.640 of alternative source must be provided with the ASD.

So, was the agency looking for any sampling through this data gap? I'm just trying to understand what this data gap means.

A. I -- to my understanding, as this was Lauren who made this, the additional sampling would refer to item number one, not item number three.

Q. Okay. All right. So, is there any information outside of the geochemical lab reports

and chain of custody that you believe the agency was looking for through data gap three?

A. I do not believe so.

Q. Okay. And just based on your understanding. Okay. Thanks.

All right. If we could turn back to what I believe is marked as Exhibit 8.

Cynthia Vodopifec's declaration. Could I refer you to paragraph five of that declaration?

A. Okay.

Q. And I'll give you a moment to review if you want to read over that paragraph, just let me know when you're done.

A. Okay.

Q. All right. You had a moment to read paragraph five. Is the agency looking for what she has stated in this paragraph through this third data gap?

A. Not with the third data gap.

Q. No? Okay. Was the agency looking for the information in this paragraph in connection with its denial of the Newton ASD?

A. Yes, with the second data gap.

Q. Oh, the second data gap.

A. Yes.
Q. Okay. All right. Well, then looking at paragraph five, do you agree that conducting a characterization of the bedrock surrounding the Newton Primary Ash Pond in accordance with 35 Illinois admin code 845.640 would require drilling to bedrock, well installation, solids and groundwater sampling and analyses and data evaluation and reporting?
A. Yes.
Q. Then that next sentence reads, assuming a driller is readily available, which is not always the case, this process would take approximately 20 to 30 weeks. Do you agree with that statement?
A. Yes. And I would also like to rephrase to your question; it would be for data gap two, and then would conjoin with data gap three. It's not, I guess my understanding was specifically just data gap three.
Q. Would you agree that data gap two and data gap three both are referring back to like characterization of the bedrock unit?
A. Yes.

Q. Okay. And through both those data gaps we're looking for ground water sampling, geochemical lab reports, and chain of custody, as well as perhaps some other things?
A. Yes.
Q. Are you familiar with 845640 generally?
A. Generally, yes.
Q. Okay. How many rounds of sampling would the agency have wanted to see for the bedrock unit?
A. Usually, it's eight quarters.
Q. And do you agree that eight quarters of sampling usually provides you with enough data to determine whether an exceedance is statistically significant?
A. Yes.
Q. And if I may just ask the question; if they were to drill wells for the bedrock unit, say, even when doing this initial ASD for the Newton PAP, there's no way they could have had eight rounds of sampling data before they had to submit the ASD. Do you agree with that?
A. Yes.
Q. Is it your understanding that an owner

and operator always has to identify the alternative source in connection with an alternative source demonstration?

A. Yes.

Q. Is this true even if there's clear evidence that the CCR surface impoundment is not contributing to the exceedance?

A. It is my understanding it would either -- it would not be the CCR impoundment, and there would be an alternative source.

Q. Right. So if there's clear evidence that the CCR surface impoundment is not contributing to the exceedance in a particular well, then does an owner/operator still need to identify what the alternative source is?

A. Yes, with an exceedance.

Q. Okay. And what's your basis for this understanding?

A. The alternative source would show that an exceedance is not with the impoundment, and therefore the owner/operator might not have to do corrective measures for the --

Q. What's your basis for the understanding that even if it's clear that a CCR surface

impoundment is not contributing to an exceedance, that the owner/operator still has to identify what the alternative source is?

A. My understanding is that's how 845 was regulated. Beyond that, I am not sure.

Q. Okay. Are you basing it on any particular provision or guidance?

A. No.

Q. And what is your understanding of the degree of provision -- sorry. What is your understanding of the degree of precision with which the alternative source must be identified?

A. My understanding is there is clear proof that it is not coming from the impoundment, and then the alternative source is proven--whatever the source may be--is proven through different methods.

Q. Okay. And what methods would be required for identifying the alternative source?

A. I believe that's up to the owner and operator because it's not clearly stated in to the alternative source.

Q. So, it wouldn't necessarily always mean testing the alternative source?

A. The 845 regulation says they have to, if they do an alternative source, they have to show that it is the alternative source. So my understanding would be there is, there would have to be testing or an explanation to that.

Q. Okay. And what section of 845 were you just referring to? Or was it 845.650 that you were referring to?

A. Yes. I believe so.

Q. Okay.

A. Also, can I get a water? That would be great.

Q. Can we take a quick break.

(The time is 10:10 a.m.)

(The time is 10:17 a.m.)

CONTINUED EXAMINATION BY

MS. JOSHI:

Q. So we were just talking about whether or not an owner/operator always has to characterize an alternative source and the extent to which characterization is required.

So, going back I just want to clarify. So, is it your position that the owner/operator has discretion to decide for themselves, sort of

the scope of characterization that might be needed for the alternative source?

A. Yes.

Q. All right. Let's move on to another document. This is an excerpt from record document number 10, which is the operating permit application, and is very large so we're only going to provide an excerpt here. This is going to be marked as exhibit 9.

(Whereupon, Deposition Exhibit No. 9 was marked for identification.)

Q. The first few pages are just the cover pages for document number ten. And then you'll see a few pages in there is the start of something called Attachment C. Do you see that?

A. Yes.

Q. Are you familiar with this document?

A. Yes.

Q. Have you reviewed this document before?

A. Yes.

Q. I'd like to refer you to Appendix A of Attachment C. Do you see that?

A. Yes.

Q. Do you agree that this Appendix A

provides information regarding the chemical constituents contained in the Newton Primary Ash Pond?

A. Yes.

Q. And then on Appendix A, you'll see there's a table. The first column reads pollutant, agreed?

A. Yes.

Q. The second column reads units, agreed?

A. Yes.

Q. The third column reads surface free liquids average concentration; do you agree?

A. Yes.

Q. Okay. What do you understand that to mean?

A. These are what is at the surface level of the impoundment. This is what would be considered liquid that is just at the top of the impoundment.

Q. Okay. And then the next column, or final column here reads, subsurface free liquids average concentration. Do you agree?

A. Yes.

Q. And what do you understand that to mean?

A. That could be the liquids that would be found under the subsurface of the impoundment, or what is beneath the impoundment.

Q. Okay. And so what is reflected then in the final column of this chart?

A. This would be the -- what would be considered in the surface impoundment, or like the state of the chemicals in the surface impoundment.

Q. So it's a reflection of the chemicals in the surface impoundment?

A. Yes.

Q. And if you could flip over two pages to the chart that's marked Appendix B. Do you see that?

A. Yes.

Q. Okay. Do you agree that the first table of Appendix B provides a list of chemical additives that are located in the Newton PAP?

A. Yes.

Q. And do you agree that the second table in Appendix B provides a list of waste streams that are in the Newton PAP?

A. Yes.

Q. I'd like to refer you to another

document which we will mark as exhibit 10.

(Whereupon, Deposition Exhibit No. 10 was marked for identification.)

Q. This is another excerpt from that same document that's in the record. The operating permit application. Are you familiar with this document?

A. Yes.

Q. All right. What is it?

A. This is the hydrogeologic site characterization of the Newton Primary Ash Pond.

Q. And that hydrogeologic characterization was provided with the Newton Primary Ash Pond's operating permit application?

A. Yes.

Q. And you've reviewed this document before?

A. Yes.

Q. If you could go to the last page of this document, you'll see that there's a table there marked 2-2. Are you familiar with this table?

A. Yes.

Q. What is it?

A. This is sampling of, or I should say, a

summary of the sampling analytes for the ash in the impoundment.

Q. Do you agree that that table reflects solid sampling conducted of the Newton PAP?

A. Yes.

Q. Going to move on to another document. This is record document number 16. Which I will mark as exhibit 11.

(Whereupon, Deposition Exhibit No. 11 was marked for identification.)

Q. Give you a moment to just look at it. Are you familiar with this document?

A. Yes.

Q. What is it?

A. The JOPPA East Ash Pond Alternative Source Demonstration.

Q. Why was this document included in the record for the Newton ASD?

A. We were reviewing both the Newton ASD and the JOPPA one at the same time.

Q. Did the agency rely upon or consider this document in any way when reaching its decision on the Newton ASD denial?

A. No.

Q. All right. Going to hand you record document number 22, which I will mark as exhibit 12.

(Whereupon, Deposition Exhibit No. 12 was marked for identification.)

Q. Are you familiar with this document?

A. Yes.

Q. What is it?

A. The IEPA's letter for the JOPPA ASD nonconcurrence.

Q. Why was this document included in the record?

A. Since they were, since Newton and JOPPA were viewed at the same time, we had them both in the record.

Q. Did the agency rely upon this document at all in reaching its decision for the Newton ASD?

A. No.

Q. And did the agency consider this document at all in reaching its decision on the Newton ASD?

A. No.

Q. One last document for this line of

questions. This is record document number 26. Which we will mark as exhibit 13.

(Whereupon, Deposition Exhibit No. 13 was marked for identification.)

Q. Are you familiar with this document?

A. Yes.

Q. What is it?

A. This is an e-mail correspondence with Lauren about the JOPPA West Ash Pond adjusted standards.

Q. And are you copied on this e-mail?

A. Yes.

Q. Okay. Why was this document included in the record?

A. This was included as the documentation of what the IEPA would request as the CCR characterization.

Q. Okay. Can you point me to what portion of this document you're referring to when you say that this reflects what IEPA would sort of rely upon for a CCR source characterization?

A. Yes, I can. This would -- the line that is stated, IEPA also asks for CCR characterization. JOPPA provided the six CCR

samples, analyses. Would you want me to read the entire paragraph?

Q. Or you could just show me where it ends, if it is easier.

A. It would end where the SPLP analysis is in accordance with SW846 using the lowest pH of the site of frequent five.

Q. So, you just read the term SPLP. What do you understand that to mean?

A. I understand that as a leaching test that was brought up as an example to be used.

Q. Okay. So, again, before when we were talking about CCR source characterization, you said that there wasn't any one particular method that would be required, correct?

A. Yes.

Q. Okay. But, is the agency looking for a leaching type test, like SPLP for source characterization?

A. I believe this is a suggestion that as one of the ways to do this. And this is how we would analyze the characterization.

Q. Okay. And the information in this paragraph that you just referred me to here, in

that second paragraph starting, please provide further CCR solids. Do you see that language?

A. Yes.

Q. Okay. It goes on to read, please provide further CCR solid sampling and analysis to include a minimum of: One sample location per ten percent of the total cubic yards of CCR, with three samples collected from each location. This language regarding one sample per ten percent of the total cubic yards of CCR; is that meant to refer to a leach type of test, or a leach test?

A. I believe so.

Q. Okay. Do you believe that the number of samples required might differ based on the type of testing that is occurring?

A. Yes.

Q. Do you believe that the number of samples would differ if it was a different method of leach testing that was occurring?

A. I would believe so.

Q. The last sentence says: The SPLP analysis in accordance with SW846 using the lowest pH on site of 3.5. Is it your opinion that a leach test would typically be done using the

lowest pH that's been found at the site?

A. Yes, that's my understanding.

Q. So, in what way did the agency, if at all, rely upon this document in reaching its decision on the Newton PAP ASD?

A. This is our understanding of what source characterization for CCR would be at most sites. This was kind of a general consensus with the groundwater section for this type of explanation when talking to the companies.

Q. When you say companies, who are you referring to?

A. Owners and operators of CCR surface impoundments.

Q. Does that include owner and operators other than IPGC?

A. Yes.

Q. Let's go back to Exhibit 2, which is the ASD, the original ASD submittal.

It's document 12 marked as Exhibit 2.

A. Yes.

Q. And to confirm, you have reviewed this document before, correct?

A. Yes.

Q. Okay. Can I refer you to the third page of the document? The one that has certifications at the top? Do you see that?
A. Yes.
Q. Okay. Sorry, I meant the third physical page of the document, not the page marked page three.
All right. Do you agree that this page includes a certification from a professional engineer?
A. Yes.
Q. Do you agree that that page includes a certification from a professional geologist?
A. Yes.
Q. Now, if you could move on to the actual page three of the document, which is at the top. The Bates number for the record is R001611.
Do you see that?
A. Yes.
Q. I'd like to refer you to the second to last paragraph of this page that says, pursuant to 35 I.A.C. 845.650(e), the lines of evidence (LOEs) presented in Section 3 demonstrate that sources other than the PAP were the cause of the chloride

GWPS exceedance listed above. Do you see that sentence?

A. Yes.

Q. Did I read that correctly?

A. Yes.

Q. Okay. So, I just referred to something called a lines of evidence evaluation. Are you familiar with lines of evidence evaluations?

A. Well, do you mean prior to, or just overall?

Q. Just -- well, sure. Prior to reviewing the Newton ASD, were you familiar with the concept of a lines of evidence evaluation?

A. No, I was not.

Q. Did you become familiar with it after?

A. Yes.

Q. Okay. What do you understand a lines of evidence analysis to mean?

A. I understand lines of evidence to be the explanation of evidence that would be for, in this case, an alternative source, and the reason of why it would not be the surface impoundment.

Q. Okay. Are you familiar with the fact that a lines of evidence analysis is used in

various different circumstances for a forensic analysis?

A. I did not know.

Q. Okay. You said you engaged in sort of a forensic analysis before, right, to determine whether outside water was impacting a particular site?

A. Yes.

Q. Okay. In that type of situation, if you reached a point where you had data that supported your conclusion, but there was still additional data you could collect to further support your conclusion, did you end up collecting that additional data?

A. We just stated what -- we stated what additional data could have been had.

Q. Okay.

A. If it was not readily available.

Q. Have you reviewed the lines of evidence that are in this document?

A. Yes.

Q. Okay. Let's go to page seven of the document.

Do you agree that this is the start of

the more in depth discussion of the lines of evidence in this document?

A. Yes.

Q. Okay. I'm going to refer you first to the information related to the first line of evidence in section 3.1. Do you see that?

A. Yes.

Q. Okay. Do you agree that header reads, LOE number one: The PAP is separated from the UA at APW15 by a thick layer of low permeability glacier till. And then you've got the term in parentheses (UCU)?

A. Yes.

Q. Did you review the information that's contained here within this first line of evidence?

A. Yes.

Q. Is there any information presented here in this first line of evidence that you disagree with?

A. No, not disagree.

Q. Can I point you to the second line of evidence there at section 3.2. Have you reviewed the second line of evidence?

A. Yes.

Q. Is there any information presented here in the second line of evidence that you disagree with?
A. The need of laboratory data as just validation would make me unsure.
Q. Can you clarify what you mean by that?
A. For this line of evidence, by having the laboratory data, it validates the issue of giving a summary chart to make sure it matches with the laboratory reports, just as validation.
Q. So, outside of maybe not having that laboratory data, do you agree that the evidence provided showed that boron concentrations in APW15 are below background?
A. Yes.
Q. And do you agree that the information in here shows that sulfate concentrations in APW15 are below background concentrations?
A. Yes.
Q. And if CCR was the source of the chloride exceedance in APW15, how would you explain a lack of boron above background?
A. My understanding is looking at the chemistry of the impoundment, while boron is a

main constituent that would be used to identify the CCR, if there are other issues such as chloride being really high, while pH is very low, then CCR could flow through the impound -- flow through more quickly than usual.

Q. But wouldn't that CCR contain boron?

A. Yes.

Q. All right. Let's go to the third point of evidence, which is on the next page, page eight, section 3.3.

Have you reviewed this third line of evidence?

A. Yes.

Q. Is there any information presented in the third line of evidence that you disagree with?

A. No.

Q. Do you believe that the data set forth in IEPA's denial letter would have changed the ultimate determination of the Newton PAP ASD?

A. Yes.

Q. How so?

A. By having the full scope of the three data gaps that were provided would help the understanding of the entire CCR, versus what would

be the alternative source. And have a, I would say, a more complete understanding for the IEPA and for the public.

Q. You would believe it would provide a more fullsome picture?

A. Yes.

Q. Do you believe that any of that data would end up changing the ultimate conclusion that the Newton PAP is not the source of the chloride exceedance?

A. It would depend on the -- the characterization of the CCR, and the laboratory data. If it did show that the characterization was low, and the laboratory data that is given validates or is the same as the analytical data that was given, then yes.

Q. Then "yes" what?

A. Then yes, we could see that as the -- that the surface impoundment was not the cause of the chloride exceedance.

Q. I'm going to refer you to page ten of this document.

Do you see that section titled, references?

A. Yes.
Q. All right. Did you review this page of the document?
A. Yes.
Q. Did you review any of the references listed in this document?
A. No.
Q. Did you search for any of the references listed in this document?
A. No, I did not.
Q. Did you ask Illinois Power for any of the documents listed in this reference section?
A. No. I didn't.
Q. But, let's just go down, let's say, to the fourth item from the bottom. Do you see that Ramboll Americas Engineering Solutions 2021 Hydrogeologic Site Characterization Report. Correct me if I'm wrong, but you have reviewed that document?
A. Yes, I have.
Q. Can I give you a moment to just review this list and let me know what it is that you have reviewed and haven't reviewed?
A. Yes. Okay.

Q. Go ahead. Could you now walk me through what it is you have reviewed and have not reviewed? Why don't we just go with what you have reviewed.

A. Yes. The AECOM 2016 drawing that was included in the construction permit application. The HDR 2022 closure drawing that was also included in the construction permit application.

And then the Ramboll Hydrogeologic Site characterization, the groundwater monitoring plan that were also included into the operating permit. And those were the ones that I reviewed during the ASD.

Q. And did you review any after the ASD denial letter was issued?

A. The Ramboll detected exceedances quarter to Primary Ash Pond.

Q. Right above the Ramboll Engineering Solutions there's a document called Panno, do you see that? It starts with Panno SV 2018?

A. Yes.

Q. Have you ever reviewed this document?

A. I believe that I have heard. I did not review it.

Q. Okay. And if I could just have you flip the page because there are three more citations on the next page. If you could take a look, and again let me know whether you have reviewed any of these documents.

A. No, I did not review these.

Q. And did you ask for any of these documents from Illinois Power?

A. No.

Q. Did you independently go and look for or obtain these documents?

A. No.

Q. I'm going to hand you another document, which we will be marking as exhibit 14.

(Whereupon, Deposition Exhibit No. 14 was marked for identification.)

Q. This is record document number 29. Are you familiar with this document?

A. Yes, I am.

Q. What is it?

A. This is the additional information that Illinois Power provided us before the -- or on November 3rd.

Q. And additional information related to

what?

A. The alternative source demonstration data gaps.

Q. Did you review this document prior to IEPA issuing the denial of Newton's ASD?

A. Yes.

Q. I'm going to ask you to turn to, and just so you know this is towards the back of the document. The page that is Bates numbered with the number R001941.

Would you have reviewed this page as part of your review of this document?

A. Yes.

Q. Did you review any of the references listed on this page?

A. I have reviewed the Burns & McDonnell operating permit. The Ramboll Hydrogeologic Site Characterization. The USEPA LEAF document. And that is it.

Q. Okay. The USEPA LEAF document, you mean the USEPA 2019 Leaching Environmental Assessment Framework, how-to guide document?

A. Yes.

Q. Thank you. Did you ask for any of these

documents to review as part of your review of the Newton ASD?

A. No.

Q. And did you seek out or review any of these documents as part of your review of the Newton ASD?

A. There was a discussion with Mike Summers and Lauren Hunt about the Electric Power Research Institute that we had a discussion on that. But I did not go out and look for these references.

Q. And so there was a discussion regarding the Electric Power Research Institute; which document? The 2017 document that's listed here?

A. The 2022 document.

Q. Okay. And that discussion was in relation to the Newton ASD submittal?

A. The Newton ASD, and ASDs going forward with this reference.

Q. And do you recall the scope of that discussion?

A. The discussion was on the validation of EPRI, our Electric Power Research Institute, between Lauren and Mike Summers.

Q. What do you mean by the validation of --

A. According to Mike Summers, there were articles of EPRI that are not peer reviewed, and that was his position to me and Lauren.

Q. Did you confirm whether or not this EPRI reference or any of the other EPRI references listed here were in fact peer reviewed?

A. I did not confirm them.

Q. The agency considered documents outside of those provided with, or referenced in IPGC's ASD submittal when reviewing the Newton PAP ASD, correct?

A. Can you please repeat that?

Q. So, for example, earlier we talked about a textbook that you referenced when reviewing the Newton PAP ASD, correct?

A. Yes.

Q. Okay. So, you didn't just look at references that were cited to you in the Newton ASD when reviewing and considering the ASD submittal, correct?

A. Yes, that's correct.

Q. Okay. You also referenced EPA pore water sampling guidance that you reviewed to, correct?

A. Yes.
Q. How did you determine what documents to review?
A. These were given as our background documentation of my understanding or, like, well the documents that I reviewed are my background documentation. So --
Q. Okay. You started by saying these documents were given; what do you mean by given?
A. Well, my textbook was one that I have already had. The pore water documentation was found by Lauren Hunt.
Q. Why did you decide to refer to that particular textbook?
A. That, the geochemistry textbook is my background in my Master's degree. And to document the basis of my understandings.
Q. Okay. And when you say, and the textbook we're talking about, can you confirm that's the document that's been marked as Exhibit 3 on the record?
A. Yes. That's correct.
Q. Okay. Did you ever think about pulling any other reference materials?

A. Not at the time of the Newton ASD.
Q. Have you pulled any additional reference materials for ASDs you've reviewed since the Newton ASD submittal?
A. Yes.
Q. Can you provide me with examples?
A. We've pulled more like recent guidance documents instead of ones that are in 2017. We're looking more at the 2022 or 2023.
And then that's typically with the other ASDs, what we've done.
Q. Recent guidance related to what?
A. The USEPA typically, yes.
Q. And what is the subject matter of the guidance?
A. The pore water or leaching testing, just so we have the most up to date.
Q. Do you happen to recall specifically what any of these documents are right now?
A. No, I do not recall.
Q. But, they are guidance documents from USEPA, correct?
A. Yes.
Q. And they relate to pore water or leach

testing?
A. Yes.
Q. And were they available at the time you reviewed the Newton PAP ASD?
A. I believe so.
Q. Do you review federal rule makings related to CCR surface impoundments as part of your job?
A. Yes.
Q. And it sounds like yes, but do you review EPA guidance documents as part of your job?
A. Yes.
Q. I'd like to direct your attention to a document which I will mark as exhibit 15.
(Whereupon, Deposition Exhibit No. 15 was marked for identification.)
Q. Are you familiar with this document?
A. No. I'm not familiar.
Q. Okay. Do you see the title of the document there, Hazardous and Solid Waste Management System: Disposal of Coal Combustion Residuals From Electric Utilities: Amendments to the National Minimum Criteria, Phase One, Proposed Rule?

A. Yes.
Q. Okay.
A. I see that.
Q. Do you agree that this is a rule making related to coal combustion residuals from electric utilities?
A. Yes.
Q. Is this the type of rule making document from EPA you might review as part of your job?
A. Yes.
Q. Do you have any recollection of actually reviewing this document as part of your job ever?
A. No.
Q. Okay. I'd like to refer you to page 11588 of this document.
It's the fifth page of the document. You'll see some highlighted language there. So, this document in the third column here, the highlighted language; well, first of all, do you agree there's some highlighted language there?
A. Yes.
Q. Do you see it?
A. Yes. I do.
Q. So, it reads, out of all the coal ash

constituent modeled by EPA, boron has the fastest travel time, meaning that boron is likely to reach potential receptors before their constituent. Do you agree with that statement?

A. Yes.

Q. The next sentence reads, therefore, boron is expected to be one of the earliest constituents detected if releases to groundwater are occurring. Do you agree with that statement?

A. Yes.

Q. And then that sentence continues to say, consequently, EPA reasoned that retaining boron on Appendix III was more appropriate as it would function as a signal constituent that would insure that assessment monitoring was quickly triggered in response to any release. Do you agree with the portion of that statement that says that boron can function as a signal constituent?

A. Yes.

Q. So, generally, do you agree that boron can serve as a signal constituent?

A. Generally, yes.

Q. And what do you understand the term, signal constituent to mean?

A. I understand that as to be a primary indicator when it comes to CCR, or the coal combustion.

Q. And could you explain what you mean by primary indicator?

A. The boron would be generally noticed first as an exceedance, or a large amount of it, in groundwater.

Q. Did you review or consider this document in connection with the ASD?

A. I did not.

Q. Did anyone else you're aware of review this document in connection with the ASD?

A. I'm not sure.

Q. Is this a document that IEPA would have had in its possession when reviewing the Newton ASD?

A. We would have had the final rule of 257. I am not 100 percent sure if we have this one.

Q. Okay. Do you typically review proposed rules related to CRR? You or other folks at IEPA?

A. I believe so.

Q. I'd like to refer you to another document. This will be marked as exhibit 16.

(Whereupon, Deposition Exhibit No. 16 was marked for identification.)

Q. Give you a second to look at it. Are you familiar with this document?

A. I am not.

Q. So, over there, do you agree that it's a USEPA rule making?

A. Yes, I do.

Q. Do you agree that it's a rule making that was published in the Federal Register?

A. Yes.

Q. Do you agree that the title of this rule making is Hazardous and Solid Waste Management System Disposal of Coal Combustion Residuals From Electric Utilities?

A. Yes.

Q. Do you agree that this is a final rule?

A. Yes.

Q. Have you ever reviewed this document?

A. I do not believe so. Not this document.

Q. Do you agree that it's authored by EPA?

A. Yes.

Q. I would like to direct your attention to page 21441 of this document. Apologize, it's

long.

Just let me know when you're there.

A. 21441.

Q. Yes. Okay. In the third column of 21441 do you see at the top section that starts with EPA response, colon.

A. Yes.

Q. The first sentence there after EPA response says: The use of pore water data is still considered the most appropriate approach to estimate constituent fluxes to groundwater for CCR surface impoundments. Do you see that sentence?

A. I do.

Q. Do you agree with that sentence?

A. I do.

Q. The second sentence there reads: This is because pore water better represents the leachate seeping from the bottom of the impoundment than impoundment water samples. Do you see that sentence?

A. Yes, I do.

Q. Do you agree with that sentence?

A. I do.

Q. And if I were to just tell you generally

that this is the 2015 Federal CCR rule, would that refresh your recollection as to whether you've ever reviewed this document before?

A. I would still say I believe I have not reviewed this one.

Q. Okay. So, again, did you consider this document at all when reviewing the Newton ASD submittal?

A. No.

Q. Is this a document that IEPA would have had in its possession when reviewing the Newton ASD submittal?

A. I believe so.

Q. Are you aware of whether anyone else at IEPA reviewed this document in connection with the Newton ASD submittal?

A. I am not aware.

Q. I'd like to direct your attention to an additional document which I will mark as exhibit 17.

(Whereupon, Deposition Exhibit No. 17 was marked for identification.)

Q. Are you familiar with this document?

A. I have heard of it. I have not

reviewed.

Q. Okay. When you say you've heard of it, in what context?

A. Lauren Hunt had mentioned about the human and ecological risk assessments. And that there was documentation. I did not see this, I should say.

Q. Okay. Do you have familiarity generally with what this is?

A. A very general --

Q. Sure. How would you describe what it is?

A. Whether the coal combustion residuals are at risk to the human health or the ecological health.

Q. Do you agree that this is a document authored by the United States Environmental Protection Agency?

A. Yes.

Q. So, would it be fair to categorize this as a risk assessment conducted by the United States Environmental Protection Agency related to coal combustion residuals?

A. Yes.

Q. So, I would like to direct your attention to page 4-5 of this document. At the bottom right-hand corner of the page. Do you see the section that starts, surface impoundments? Section 4.2.1?

A. Yes.

Q. Okay. The first sentence of that section reads, similar to the screening analysis described in section three, EPA relied on pore water concentrations to characterize leaching from impoundments. Do you agree that this sentence is saying that EPA was relying on pore water data to characterize CCR surface impoundment leaching?

A. Yes.

Q. The second sentence reads: These concentrations are collected from the interstitial water between waste particles and surface impoundments as it occurs in the field, and best reflect leachate as it is released into underlying soils. Do you see that sentence?

A. Yes, I do.

Q. Do you agree with that sentence?

A. Yes.

Q. Do you agree with the fact that pore

water concentrations best reflect leachate as it's released into underlying soils from a CCR surface impoundment?

A. I do.

Q. I'd like to refer you to page 5-17 of this document.

There's some highlighted language there. Do you see that?

A. I do.

Q. Okay. The highlighted language reads: Pore water data were determined to be the most representative data available for impoundments because these data are field measured concentrations of leachate present at the bottom of these WMUs. Do you see that sentence?

A. I do.

Q. What do you understand the term WMUs to mean?

A. I understand that as a waste management unit.

Q. Do you agree with the statement in that sentence that I just read?

A. I do.

Q. Did you review or consider this document

in connection with the Newton ASD submittal?
A. I did not.
Q. Are you aware of whether anyone else at IEPA reviewed or considered this document in connection with the Newton ASD submittal?
A. I am not aware.
Q. Would this document have been in IEPA's possession prior to its review of the Newton ASD submittal?
A. I would guess so.
Q. Can we take a short break?
(The time is 11:16 a.m.)
(The time is 11:25 a.m.)
CONTINUED EXAMINATION BY MS. JOSHI:
Q. Ms. Mullenax, can you refer back to what's been marked as Exhibit 2 in this deposition. It's the Newton ASD submittal, record document number 12.
And go to Appendix C of this document. I think you had referred to this appendix previously, correct?
A. Yes.
Q. What do you understand this appendix to

reflect?

A. I see this appendix as a summary of the groundwater in there, specifically the boron chloride sulfate in the Newton Primary Ash Pond.

Q. Do you agree that it reflects pore water sampling of the Newton Primary Ash Pond?

A. This is groundwater sampling, as this is the groundwater analytical data.

Q. So let's go, if you go to the very first page of the document, or you'll see that the first column is titled well ID. Do you agree with that?

A. Yes.

Q. Okay. Then the second column is titled, well type.

A. Yes.

Q. Okay. Do you see sort of the first set of well types, let's say maybe until two-thirds of the way down in the document, it says, compliance. Do you see that?

A. Yes, I do.

Q. Okay. And then eventually, and the well ID associated with those well types are all APW15, do you agree with that?

A. Yes, that is.

Q. Okay. And then about two-thirds of the way down in the document, do you see where well ID XPW01 starts?
A. Yes, I do.
Q. What type of well type is listed for that?
A. Pore water.
Q. And do you agree that this document -- so, sort of looking there, let's just start with that very first line for XPW01. Pore water. Do you see the date of 2-17-2021?
A. I do.
Q. Okay. The fourth column down that is titled parameter, agreed?
A. Yes.
Q. Okay. And what does parameter appear to be referring to?
A. The analyte that is being sampled.
Q. Okay. So for that 2-17-2021 data that we were just looking at, what is the parameter that is being sampled for?
A. Boron.
Q. Okay. And then going down the page a little bit more; do you see the next entry for

2-17-2021 on that page?

A. Yes. I do.

Q. Okay. Again, is that for well ID XPW01?

A. It is.

Q. And is that for pore water well type?

A. Yes, that's correct.

Q. Okay. And is the parameter listed there chloride?

A. Yes. That's correct.

Q. Okay. And going down through the rest of the entries on this first page, are those all, do those all have the same well ID?

A. Yes.

Q. Are they all listed as pore water for the well type?

A. Yes.

Q. Do you agree that they all have different date listed?

A. Yes.

Q. Okay. And then do you agree that the parameters for all of them are chloride?

A. Yes.

Q. Okay. And then the fifth column titled results? Do you see that?

A. Yes.
Q. What do you understand that to reflect?
A. This would be whatever the analytes total is in being sampled.
Q. And the very last column unit, what do you understand that to reflect?
A. This is the measurement of the unit, this one being in milligrams per liters.
Q. And going on to the second page of the document, or this appendix, second page of Appendix C. Do you agree that that page contains additional data regarding pore water for various well IDs?
A. Yes.
Q. Okay. And do you agree that it includes data under the parameters for chloride, sulfate and boron?
A. Yes.
Q. Okay. Going on to the next page of this appendix, page three. Do you agree, again, that this page contains various well IDs on it? It looks like XPW03 and XPW04 might be reflected on this page. Do you agree?
A. Yes.

Q. Do you agree that the well type listed on this page all consists of pore water?
A. Yes.
Q. And then do you agree that parameters listed on this page include boron, chloride and sulfate?
A. Yes.
Q. Moving on to the very last page of this appendix, page four. Do you agree that the first column reflects the well ID, and in this case this is for well ID XPW04?
A. Yes.
Q. Do you agree that the second column again indicates the well type as pore water?
A. Yes.
Q. And do you agree that the fourth column includes sulfate as a parameter?
A. Yes.
Q. Okay. And again, the parameters, the constituent being sample four, do you agree?
A. Yes.
Q. Going back to something you had mentioned earlier today, you had mentioned wanting information to validate the data provided in

Appendix C, is that correct?

A. Yes.

Q. And what kind of information were you looking for there again to validate the data here?

A. In supporting this, would be the laboratory documentation and the chain of custodies.

Q. And what laboratory documentation?

A. Whatever lab that Ramboll or Illinois Power sampled or went with.

Q. So, just the name of the lab or something more than that?

A. The documentation that the lab provides, which would describe the analytes and the result.

Q. If IEPA had received that information related to Appendix C, meaning one, the laboratory documentation as you just described it. And two, the chain of custody information, do you believe IEPA would have still included data gap number one in its denial letter? And if you need to refresh your recollection on data gap number one, please feel free to do so. That would be in exhibit 7.

A. I would believe so. I'm not sure.

Q. Okay. Why are you not sure?

A. This, again, the first data gap was not my decision. It was Lauren Hunt's. So, that's where I don't know exactly what she would --

Q. And to confirm, was Lauren Hunt sort of the final decision maker for all three of the data gaps?

A. Yes. Before Mike Summers.

Q. Okay. And Mike Summers then signed off on the three data gaps that Lauren presented, correct?

A. Yes.

Q. Okay. No further questions. Thank you very much for your time today.

MR. HENDERSON: Just a couple of questions.

EXAMINATION BY
MR. HENDERSON:

Q. So, we've just been discussing, or we were just a moment discussing Exhibit 2, which is the alternative source demonstration submittal. So I'm just going to stay with that, and direct your attention to page R0001616. Which is page eight of the ASD.

And it says, I'll read from the bottom;

analytical data to support summary statistics presented in Table A are included in Appendix C.

So, is it your understanding from reviewing this document that the pore water statistics that you've just reviewed with opposing counsel are summarized in Table A on this page?

A. Yes.

Q. Okay. So these include composite pore water readings, or composite pore water concentrations for chloride, is that correct?

A. Yes. That's correct.

Q. Can you explain -- well, I'm sorry. And it was Illinois EPA's position that these were not sufficient, correct?

A. Yes, that's correct.

Q. So, can you explain why that was, those pore water concentrations were not sufficient?

A. We would need the data or the laboratory documentation, with the statistical information that what is being summarized in Appendix C and Table A were valid in Illinois Power's submittal.

MR. HENDERSON: No further questions.

MS. JOSHI: May I ask one clarifying question? You just referenced statistical

information that you would need which I don't think you had referenced before. What do you mean by statistical information?

THE WITNESS: This, as a data gap, it is kind of the analyses information of statistics, which usually is a company's -- how they do statistics for a more further explanation.

MS. JOSHI: Is that reflected anywhere in the denial letter?

THE WITNESS: No.

MS. JOSHI: Nothing further. Thanks.

MR. HENDERSON: We would not waive signature.

(The time is 11:38 a.m.)

STATE OF ILLINOIS)

COUNTY OF CHAMPAIGN)

I, DEANN K. PARKINSON, a Notary Public in and for the County of Champaign State of Illinois, do hereby certify that HEATHER MULLENAX, the deponent herein, was by me first duly sworn to tell the truth, the whole truth and nothing but the truth in the aforementioned cause of action.

That the foregoing deposition was taken on May 28, 2024.

That said deposition was taken down in stenographic notes and afterwards reduced to typewriting under my instruction and said transcription is a true record of the testimony given; and that it was agreed by and between the witness and attorneys that said signature on said deposition would be not waived.

I do hereby certify that I am a disinterested person in this cause of action; that I am not a relative of any party or any attorney of record in this cause, or an attorney for any party herein, or otherwise interested in the event of this action, and am not in the employ of the attorneys for either party.

In witness whereof, I have hereunto set my hand and affixed my notarial seal June 2, 2024.

Guidelines for Development of Alternative Source Demonstrations at Coal Combustion Residual Sites. EPRI, Palo Alto, CA: 2017. 3002010920.

ABSTRACT

EPRI's guidance for alternative source demonstrations (ASDs) was developed to provide environmental managers at electric utilities with a list of alternative sources to check as well as a standardized, defensible approach for building and documenting an ASD when there are exceedances of one or more benchmarks established within a groundwater monitoring program. This guidance is designed for statistical benchmarks, in specific, statistically significant increases (SSIs) or statistically significant levels (SSLs) for groundwater monitoring under the federal Coal Combustion Residuals (CCR) rule and/or state regulations, but the guidance also applies to exceedances of other types of benchmarks such as groundwater quality standards.

The guidance provides information to help identify when a cause other than a release from the facility is the likely source of an SSI during detection monitoring or an SSL during assessment monitoring along with a checklist-based framework for developing a defensible ASD. The guidance covers ASDs developed in response to sampling causes, laboratory causes, statistical evaluation causes, natural variation, and alternative anthropogenic sources, with emphasis on development of an ASD when an SSI, SSL, or other exceedance is due to natural variation or an alternative anthropogenic source.

Keywords

Alternative source demonstration (ASD)
CCR Rule
Coal combustion residuals
Groundwater monitoring
Statistically significant increase (SSI)
Statistically significant level (SSL)

Deliverable Number: 3002010920

Product Type: Technical Report

Product Title: Guidelines for Development of Alternative Source Demonstrations at Coal Combustion Residual Sites

PRIMARY AUDIENCE: Electric utility environmental managers interpreting and responding to groundwater data collected under the Coal Combustion Residuals (CCR) rule and/or state rules

SECONDARY AUDIENCE: Consultants working for electric utilities with responsibility for responding to potential exceedances of benchmarks or criteria established for utility groundwater monitoring programs

KEY RESEARCH QUESTION

Groundwater monitoring programs developed for compliance with the federal CCR rule, and some state rules, use statistical analysis to determine whether or not individual results represent exceedances, which are often termed statistically significant increases (SSIs) over background in detection monitoring or statistically significant levels (SSLs) relative to a groundwater protection standard in assessment monitoring. However, the statistical methods are subject to false positive results, where a value that is not a true exceedance is flagged as such. Furthermore, there are literally dozens of causes related to sampling, laboratory analysis, natural variation, and other anthropogenic sources that can trigger an exceedance that is not due to a release from the monitored unit. When an exceedance is triggered due to a cause other than a release from the facility, federal and state regulations allow for an alternative source demonstration (ASD). At present, however, there are no criteria for how to develop and document an ASD.

RESEARCH OVERVIEW

This research provides guidance for identifying when an ASD is needed, evaluation techniques that can be used to support the demonstration, and a standardized checklist-driven approach for documenting a defensible ASD. The guidance is based on experience developing ASDs in states that have long used statistical analysis to determine compliance with groundwater quality benchmarks and is tailored for application in CCR monitoring programs.

KEY FINDINGS

- Potential sampling, laboratory, and statistical causes that can trigger an exceedance that is not due to a release from the CCR facility are described in Section 2. Checklist 1 outlines a methodology for demonstrating these causes.
- Natural variation can trigger an exceedance if there are changes in mineralogy along a groundwater flow path, changes in pH and/or redox over time or along a flow path, changes in groundwater elevation over time, and/or changes in groundwater flow direction over time (Section 4).
- Potential anthropogenic sources at a power plant that can trigger an exceedance at one or more monitoring locations include, but are not limited to, spills of petroleum or other materials, road salt, leakage of runoff from coal management areas, overspray of leachate used for dust control, accumulation of blowing dust near monitoring wells, leakage from leachate conveyance pipelines or tanks, and releases from other CCR units (Section 5).

- Potential off-site anthropogenic sources include, but are not limited to, agricultural activities, road salt, coal mining, brines associated with oil and gas production, leaking underground pipes, pumping-induced brackish water, septic systems, and industrial or municipal waste management (Section 5).
- An ASD due to natural variation or an off-site or on-site anthropogenic source will be strongest if multiple lines of evidence are developed. Key lines of evidence include a lack of exceedances and a lack of increasing trends for primary indicators of the CCR, leachate concentrations for the affected constituent that are lower than concentrations observed in groundwater, major ion chemistry in the affected monitoring well that does not represent mixing of leachate with background groundwater, tritium age-dating showing that the groundwater is older than the CCR unit, and isotopic data showing that the groundwater at the affected monitoring well is not a mixture of background groundwater and leachate (Section 6).

WHY THIS MATTERS

False identification of an SSI can trigger assessment monitoring, and false identification of an SSL can trigger corrective action, either of which can increase the cost and manpower resources needed for groundwater compliance at CCR sites. An ASD can be used to demonstrate that these incremental increases in resource allotment are not necessary if the statistical exceedance is not due to a release from the facility. ASDs may be reviewed by state regulators and the public, and this guidance provides a standardized, checklist-driven approach for documenting a strong ASD.

HOW TO APPLY RESULTS

Users of this guidance can begin by reviewing Sections 2, 4, and 5 to determine whether or not an ASD is appropriate, and if so, the potential alternative causes that may explain the ASD. Section 3 describes evaluation techniques that can be used to support the ASD. The user can then use the checklists described in Section 6 and provided at the end of the document in Appendix B to build the ASD.

LEARNING AND ENGAGEMENT OPPORTUNITIES

- Statistical analysis used in CCR groundwater monitoring programs is described in *Groundwater Monitoring Guidance for the Coal Combustion Residuals Rule*. EPRI, Palo Alto, CA: November 2015. 3002006287.
- Techniques for evaluating groundwater quality data are described in *Groundwater Quality Signatures for Assessing Potential Impacts from Coal Combustion Product Leachate*. EPRI, Palo Alto, CA: October 2012. 1017923.
- Methodologies for application and evaluation of isotopic analysis are provided in *Application of Isotopic Methods to Coal Combustion Residual Groundwater Quality Investigations*. EPRI, Palo Alto, CA: December 2017. 3002010911.

1
INTRODUCTION

Scope of Guidance

This guidance for alternative source demonstrations (ASDs) was developed to provide environmental managers at electric utilities with a list of alternative sources to check, and a standardized, defensible approach for building and documenting an ASD when there are exceedances of one or more benchmarks established within a groundwater monitoring program. The guidance is designed for statistical benchmarks, specifically statistically significant increases (SSIs) or statistically significant levels (SSLs) for groundwater monitoring under the Coal Combustion Residuals Rule (CCR Rule)[1] and/or state regulations, but the guidance is also applicable to exceedances of other types of benchmarks such as groundwater quality standards.[2]

The guidance provides information to help identify when a cause other than a release from the facility is the likely cause of an SSI during detection monitoring or an SSL during assessment monitoring, and a framework for developing a defensible ASD.

As provided for in the CCR Rule,[3] an alternative source demonstration can have a variety of causes:

- Sampling causes (ASD Type I)
- Laboratory causes (ASD Type II)
- Statistical evaluation causes (ASD Type III)
- Natural variation not accounted for in the basic detection monitoring or assessment monitoring statistics (ASD Type IV)
- Potential alternative sources (ASD Type V)
  - Anthropogenic impacts
  - Natural sources

Potential alternative sources, both anthropogenic and due to natural environmental influences, are the main focus of this report.

The scope of this document does not include guidance for performing a site investigation or establishing a groundwater monitoring system. Readers can refer to EPRI (2015) and a variety of other documents, many of which are listed in EPRI (2015), for such information.

[1] 40 CFR 257 Subpart D; published in 80 FR 21302-21501, April 17, 2015.

[2] The remainder of this document will primarily reference exceedances of SSIs or SSLs even though the methodology applies to exceedances of all types of benchmarks.

[3] 40 CFR 257.94(e)(2) for detection monitoring; 40 CFR 257.95(g)(3)(ii) for assessment monitoring.

2
TYPES OF ALTERNATIVE SOURCES

As stated in the CCR Rule at 40 CFR 257.94(e)(2), "The owner or operator may demonstrate that a source other than the CCR unit caused the statistically significant increase over background levels for a constituent or that the statistically significant increase resulted from error in sampling, analysis, statistical evaluation, or natural variation in groundwater quality. The owner or operator must complete the written demonstration within 90 days of detecting a statistically significant increase over background levels to include obtaining a certification from a qualified professional engineer verifying the accuracy of the information in the report." This section describes the five types of ASDs, provides example causes, and presents examples for how those causes might be identified.

Potential causes or investigation paths associated with each of the alternative source categories identified in the CCR Rule are listed in Table 2-1 and are discussed below. Anthropogenic sources are further discussed in Section 5, and natural variation is discussed in Section 4.

Table 2-1
ASD Types and Causes

Sampling Causes (ASD Type I)	Laboratory Causes (ASD Type II)	Statistical Evaluation Causes (ASD Type III)	Natural Variation (ASD Type IV)	Alternative Sources (ASD Type V - Natural and Anthropogenic)
• Sample mislabeling • Contamination • Change in technique • Excessive suspended solids or turbidity • Other sampling anomalies	• Analytical method • Calibration • Analytical technique • Contamination • Interference • Recording • Dilution errors • Digestion methods	• Lack of statistical independence • Outliers • Trends • Non-detect processing • False positives • New background data	• Geology • Precipitation • Seasonality • Water level • Changes in pH and/or ORP • Biological activity • Time of travel	• See Tables 2-2 and 2-3

Sampling Causes (ASD Type I)

- Sample mislabeling: One form of sample mislabeling is sample switching. Sample switching can be identified by sudden changes in concentration for the same constituent at two monitoring wells (Figure 2-1). Multiple constituents will be affected when this occurs, although it would only be evident for constituents with large differences in concentration

between the two monitoring wells. The multiple constituents will come from the same type of sample bottle (e.g., metals, IC analysis) if only one sample bottle is switched, and can come from multiple bottles if all bottles for two samples are switched. If analysis results suddenly differ from normal for a particular well, look for similar anomalies at other wells for patterns that could indicate swapped identification.

Another form of mislabeling can occur if the sample is taken from a different monitoring well than listed on the label (e.g., MW-01b instead of MW-01a), when the other monitoring well is not in the sampling program. In this case, only one monitoring well will show an anomaly for multiple constituents. This anomaly should affect all sampled constituents, although it will only be evident for constituents where concentration is different in the sampled well, relative to the well that should have been sampled. This case is more difficult to identify and demonstrate than the case of the switched sample. If all concentrations in a resample return to previous levels, then it is a possible explanation.

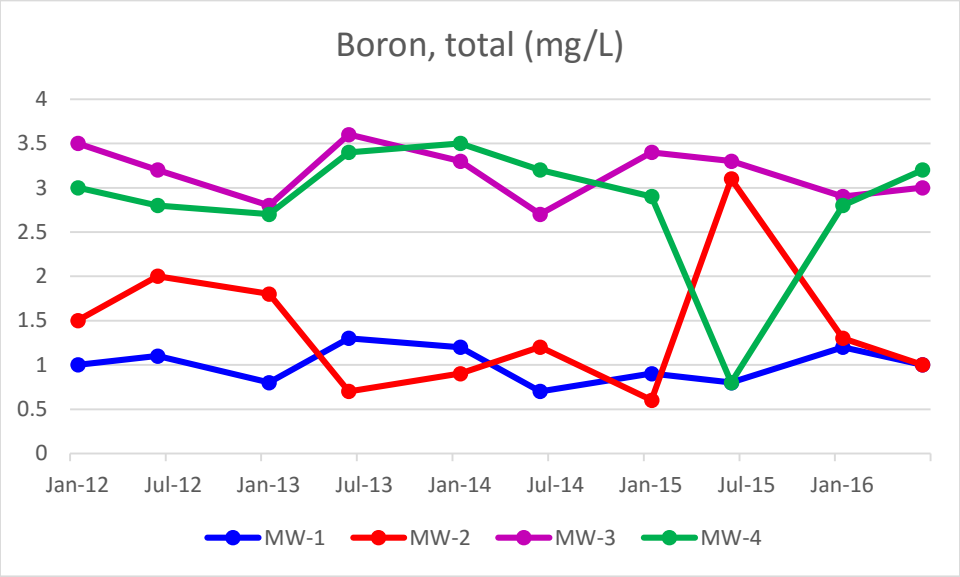

Figure 2-1
Time series plot showing potential sample mislabeling (switching)

- Contamination: If non-dedicated sampling devices are used to collect samples, contamination from the sampling equipment could potentially cause unrepresentative, elevated concentrations that could trigger an SSI/SSL. This type of sampling error is more likely to affect trace elements such as those found in Appendix IV of the CCR Rule than higher concentration elements such as those listed in Appendix III of the CCR Rule. An equipment blank (also called a rinsate blank) is a field quality control sample consisting of the rinsate from equipment used to collect the sample. Check the equipment blank analytical results to assess the potential for cross contamination, which will be evident by elevated concentration in the equipment blank. A field blank is a sample of deionized water from the laboratory that is opened in the field to assess the potential for field contamination. Field blanks are not always used for groundwater sampling at CCR sites. If field blank analytical results are available, check to assess the potential for field contamination unrelated to the sampling equipment.

- Sampling technique: A change in sampling technique, whether planned or due to an error, can have an influence on resulting concentrations if it affects the amount of sediment, as measured by turbidity, in the sample. See the next bullet for turbidity effects.
- Turbidity: Sudden increases in total dissolved solids and/or trace element concentrations can sometimes be associated with an increase in suspended solids/turbidity in a sample, relative to previous samples. Because the CCR Rule requires collection and analysis of unfiltered samples, elements comprising or attached to the particulate matter that causes turbidity are digested and analyzed along with the dissolved elements in the sample. Therefore, a turbid sample can yield higher concentrations for the elements that make up or are attached to the particulate matter. Evaluate the sampling technique used and the field analytical results, particularly the turbidity value if available, to assure that low-flow sampling procedures were properly followed. If the field analytical results do not indicate that stabilization of the field parameters (pH, temperature, specific conductance, dissolved oxygen, redox potential, and turbidity) was achieved, then sampling technique may be a defensible cause for an SSI/SSL. Some facilities establish sampling protocols that include collection of replicate filtered samples whenever a sample location has a turbidity greater than 10 to 20 NTU to allow comparison of analytical results between filtered and unfiltered samples. If filtered results are available, and are considerably lower than the unfiltered results, then turbidity resulting from differences in sampling technique, a screen failure in the monitoring well, or a need for redevelopment may be defensible alternative causes.
- Sampling anomalies: Review field documents (chain of custody form, calibration logs for field equipment, field notes, and field data) to see if any issues were encountered during the sampling event that could potentially affect the sample integrity. Potential anomalies may include improper bottles or preservation, inadequate calibration of field instruments, failure to achieve stabilized field parameters prior to sampling, use of non-dedicated or improperly cleaned equipment, improper labeling, etc.

Laboratory Causes (ASD Type II)

There are opportunities for potential contamination or errors associated with laboratory procedures, equipment decontamination and calibration, and sample handling and analysis. In addition to the analytical results, laboratory reports include documentation of methods and data qualifier flags to indicate potential issues that may affect the accuracy of results. The following are common data qualifiers for inorganic constituents sanctioned by USEPA:

- U = Reading was less than the method detection limit (MDL).
- J = Reading was less than the contract required quantitation limit but greater than or equal to the MDL.
- B = Analyte was found in the method blank as well as in the sample. Indicates possible/probable blank contamination.
- E = Reported value is estimated due to the presence of an interference. Look for comments.
- N = Spiked sample recovery not within control limits.
- * = Duplicate analysis not within control limits.
- D = The reported value is from a dilution.

The B, E, N, *, and D flags all indicate potential for laboratory errors that may have triggered an SSI/SSL, and warrant a closer look at the results to determine if the reported results may be invalid and if resampling and/or an ASD should be considered.

Potential errors associated with laboratory handling and analysis include:

- Calibration: Use of poorly or inadequately calibrated instruments may cause elevated analytical results that are not representative of the water quality at the sampling location. If results for a particular analyte in multiple samples, particularly if all were analyzed on the same day (laboratories typically recalibrate their instrumentation daily), are higher than the norm, then poor calibration of analytical equipment may be a potential cause. Consider reviewing instrument calibration records to see if poor calibration is a defensible alternative source for the SSI or SSL.
- Contamination: One or more samples may be contaminated by improperly cleaned and/or prepared sample bottles, analytical equipment, calibration standards, reagents, or preservatives. This type of error is more likely to be evident for trace elements such as those found in Appendix IV of the CCR Rule than for higher concentration constituents such as those listed in Appendix III of the CCR Rule. If sample contamination is suspected, evaluate the analytical results for trip blanks (if available) and method blanks. Trip blanks are sample bottles filled with laboratory-prepared deionized water that accompany the samples to and from the field, without being opened. If trip blank results show detection of analytes, it is possible that the sample bottles may not have been properly cleaned or the deionized water may have been contaminated. Method blanks are analyte-free laboratory quality control samples subjected to the entire analytical process used to demonstrate that the analytical system did not introduce contamination. The method blank results should be below the method reporting limits. If they are not, then the analytical process may have introduced contamination. Look for "B" data qualifiers to determine if the analytes were detected in the method blank.
- Digestion Methods: Use of more aggressive digestion methods using hydrofluoric acid for total digestion rather than concentrated nitric and/or hydrochloric acids for "total recoverable metals" may result in higher trace element concentration results compared to results using "total recoverable metals" methods. USEPA requires digestion consistent with "total recoverable metals" methods under the CCR Rule. If more aggressive digestion methods were used, reanalysis (if there is any remaining undigested sample) or resampling is warranted to determine if the SSI/SSL result persists when total recoverable digestion methods are used.
- Dilution Corrections: If dilutions were necessary to overcome matrix interferences, then review analytical results to ensure that the analytical results were properly corrected and that the resulting detection levels are low enough to detect increases over background levels. Look for the "D" data qualifiers to determine if dilutions were used. If a sample result is suddenly higher (especially if it is close to an order of magnitude higher) than the norm at a sample location and dilution was used, it is possible that the sample results were not corrected for the dilution ratio (Figure 2-2). Use of dilution ratios typically increases the MDL. If the sample results are non-detect but the MDL is higher than the norm, erroneous statistical identification of increasing trends may occur, depending on how non-detects are handled in the statistical analysis.

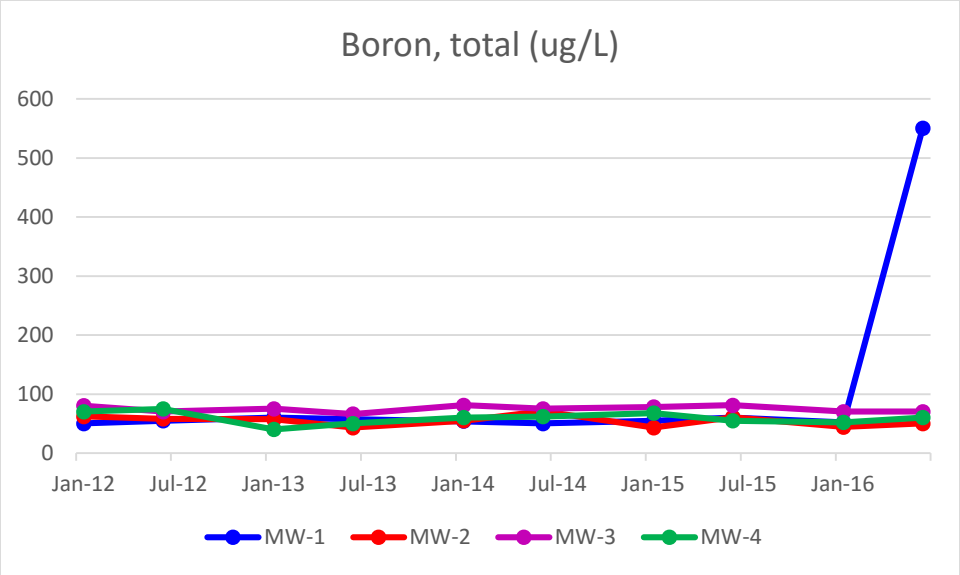

Figure 2-2
Time series plot showing potential dilution error

- Interference: Elevated analytical results may occur due to interference from other constituents present in the sample. If the laboratory identified interferences, the analytical report should include "E" data qualifiers. If interference was a problem, consider reanalyzing if there is sufficient remaining sample, and/or resampling and analyzing using methods that are less sensitive to interference from constituents of concern.
- Methods: Use of inappropriate methods or methods with reporting levels (RLs) or practical quantitation levels (PQLs) that are higher than background or maximum contaminant levels (MCLs) can result in erroneous analytical results or use of elevated non-detect values that can result in erroneous statistical determination of increasing trends. If use of inappropriate methods is suspected, verify that the methods used match those specified in the sampling and analysis plan, and are appropriate for the objectives of the groundwater monitoring program. Table 3-1 of EPRI (2015) shows methods, typical MDL and PQL capabilities, potential for interferences, and relative costs of test options for the CCR Rule Appendix III and Appendix IV constituents. This information can be very helpful in selecting and verifying that appropriate analytical methods were used.
- Technique: Poor analytical technique or use of poorly calibrated instruments (lack of quality control) can result in erroneous sample results. Check the laboratory report for data qualifiers ("B", "E", "N", "*") indicating that quality control may have been a problem.
- Transcription: Improper recording of results or mixing up results between samples can cause erroneous identification of SSI or SSL trends. If analytical results for two sampling locations are suddenly out of the norm, it's possible that the analytical results were transcribed to the wrong sampling locations. If a single location is suddenly out of the norm by an order of magnitude or more, it is possible that a transcription error such as inconsistency in units may have occurred.

Statistical Evaluation Causes (ASD Type III)

A primary challenge in statistical analysis is maintaining adequate statistical power while minimizing the false positive rate. While a detailed discussion of statistical methods and associated false positive rates is beyond the scope of this text, it is important to be aware that false positives can occur and are inherent in the statistical methods used for evaluation of groundwater quality data. See EPRI (2015) for guidance on statistical methods and recommendations for statistical approach under detection monitoring, assessment monitoring, and corrective action monitoring.

The following types of statistical errors could potentially falsely identify an SSI/SSL:

- Lack of statistical independence: The statistical comparison tests to determine if an SSI/SSL has occurred assume that the results are statistically independent. If samples are collected from the same well before the groundwater can flow through the well and be replaced with a fresh sample, then the samples are not physically independent and the comparison is not valid. As stated in the USEPA Unified Guidance (USEPA, 2009), the aquifer may "exhibit pockets or sub-zones of higher or lower concentration, perhaps due to location-specific differences in natural geochemistry or the dynamics of contaminant plume behavior over time." Generally, lack of statistical independence may be of concern if the groundwater velocity is less than 5-10 ft/yr. This type of statistical error is more likely to trigger an SSI during detection monitoring if a resampling protocol is included in the statistical plan, because the resample is collected more quickly after the original sample than the next regularly scheduled sample, and is therefore more likely to lack independence. This can be avoided by factoring groundwater flow rates into the timeframe calculation for resampling in a statistical analysis plan. Lack of independence is less likely to trigger an SSL during assessment monitoring due to the multiple sample design inherent with confidence intervals that are used in assessment monitoring statistics.
- Outliers: An outlier is a result that falls outside the typical range of values due to causes *other than* natural variability or a true change in concentration, and as such is not representative of groundwater quality. An analytical result that is suddenly much higher or lower than historical values represents a potential outlier, and there are graphical and statistical methods to identify such values. An SSI/SSL could be the result of an outlier due to transcription or typographical error, contamination, analytical interference, or other cause described under ASD Types I and II. Potential outliers need to be evaluated by reviewing sampling and laboratory documentation, and sometimes professional judgement needs to be applied to determine a) if the result is valid and should be included in the statistical analysis, b) if the result is due to an error and should be replaced with a corrected value, or c) if the value should be flagged and maintained in the database but not used in statistical calculations. If an outlier is confirmed, recalculation of the comparison to background or groundwater protection standard (GWPS) without the outlier can be performed to determine if the SSI or SSL determination was dependent on the outlier.
- False positives: A false positive is not an error per se; however, by statistical design, false positives can be expected to trigger a certain number of SSIs or SSLs under any statistical analysis plan. A false positive, also referred to as a Type I error, occurs when an SSI/SSL is falsely determined for a constituent at a compliance monitoring well relative to background groundwater quality (for SSIs) or a GWPS (for SSLs). The USEPA Unified Guidance

(USEPA, 2009) recommends that a statistical program be designed so that the site-wide false positive rate (SWFPR), which is the potential for one or more false positives on a site-wide scale, be 10% or less per year (5% per semi-annual sample event). See EPRI (2015) for a detailed discussion of statistical options and recommendations for balancing statistical power with false positive rates. Proving a false positive for an ASD may be challenging, and may require a weight of evidence approach as described in Section 6.

- Non-detect processing: Method detection limits change over time, although usually downward, or can suddenly increase by a factor of 10 or more when a laboratory dilution is used. If there is a dilution, or if MDLs increase (Figure 2-3), then an SSI could result if MDLs are used in statistical analyses. Potential for this type of statistical cause can be minimized by using set reporting limits for non-detect results and by using the double quantification rule when all background results are lower than the reporting limit.

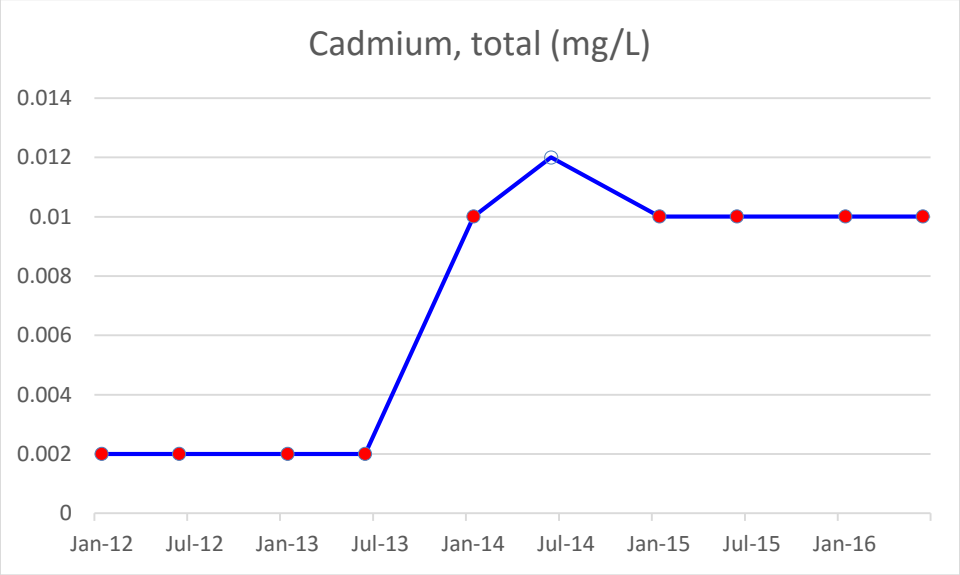

Figure 2-3
Time series plot of showing increasing trend associated with changing detection limits. Red markers indicate sample results below the minimum detection level associated with each respective sampling event.

Background Data: In the initial stages of detection monitoring, if there are numerous SSIs in the absence of a suspected release from the facility (e.g., a new lined landfill), then it is possible that background groundwater is not representative of downgradient groundwater due to spatial or temporal variability. The Unified Guidance (USEPA, 2009) states that a "high quality background dataset is the single most important key to a successful statistical groundwater monitoring program" and recommends a minimum of at least 8 to 10 independent samples for the initial background dataset before running most statistical tests.

Later on, apparent SSIs or SSLs can be triggered when new background data are added to an existing background dataset if that addition results in a change in statistical analysis method. This is particularly relevant if new data changes the distribution of the background dataset from parametric to non-parametric (Figure 2-4), because most non-parametric tests used in

groundwater analysis use the highest value as the upper limit (for detection monitoring) or GWPS (for assessment monitoring), and have a higher false-positive rate than their parametric counterparts.

Refer to Chapter 5 of the Unified Guidance (USEPA, 2009) for a thorough discussion of establishing background, reviewing and updating background, and effects of spatial and temporal variability on background.

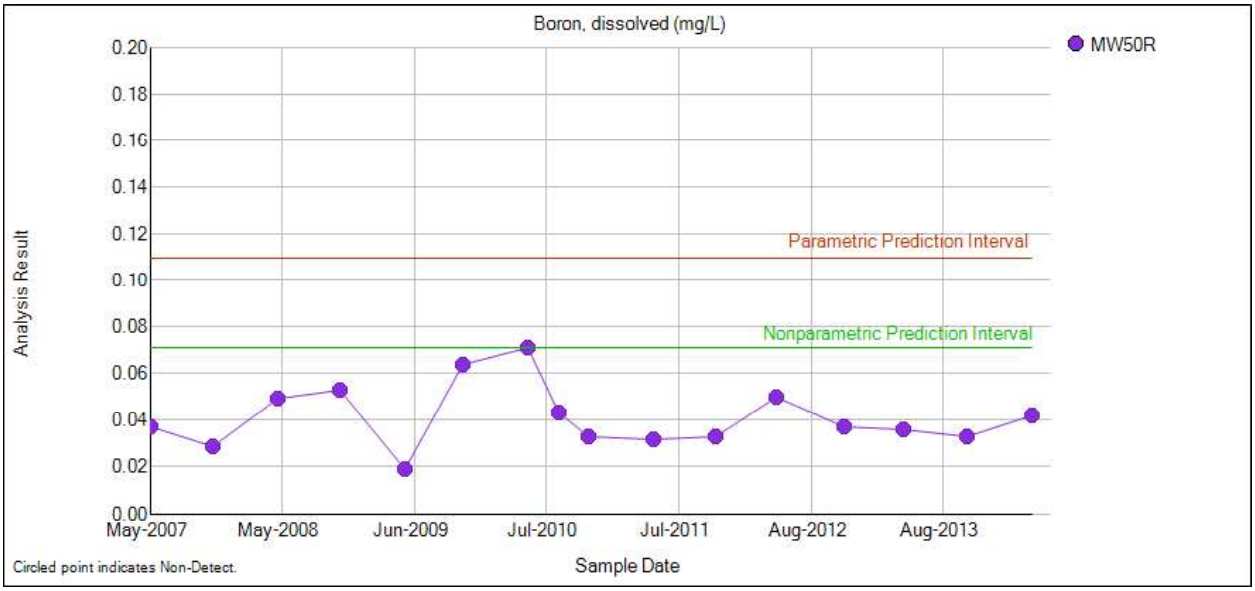

Figure 2-4
Background dataset illustrating the difference between a parametric and non-parametric upper prediction interval

Natural Variation (ASD Type IV)

Natural variation is recognized as a potential alternative cause of SSIs and SSLs under the CCR Rule. This category encompasses variability due to geologic influences such as dissolution of geomedia and natural ion exchange, changes in groundwater quality related to precipitation, seasonal changes in groundwater level or flow direction such as groundwater recharge and discharge fluctuations near surface water bodies, changing water levels in monitoring wells, time-of-travel for monitoring wells to detect upgradient changes, and influences related to changes in pH, oxidation reduction potential, and biological activity. These interactions and how they may affect groundwater quality are discussed in more detail in Section 4.

Alternative Sources (ASD Type V)

Sources for constituents dissolved in groundwater may come from both natural and anthropogenic sources. Natural sources include constituents present in groundwater from dissolution of minerals from the geomedia the groundwater has passed through. Anthropogenic sources can be complex and are too numerous to completely categorize, as many of them are likely to have source-specific signatures.

Table 2-2 provides information on natural and anthropogenic occurrence and typical behavior in groundwater for Appendix III and IV constituents as well as other constituents that may be helpful for identification of potential alternative sources. This table also identifies the relevance of the constituent as a CCR indicator for coal ash and FGD gypsum leachate.[4]

Table 2-3 provides an overview of common constituents that may be present in groundwater from a variety of anthropogenic sources. This information is intended to stimulate thought regarding constituents that *may be* present in groundwater, absent a release from the CCR site, if one of these activities is upgradient and has experienced its own release. Table 2-3 is not definitive; the information may be incomplete or not representative of actual anthropogenic sources near a particular site under evaluation. Site-specific investigation of nearby activities and history can be performed to verify groundwater impacts if an anthropogenic alternative source is suspected.[4]

A more detailed discussion of common groundwater impacts and contaminants associated with some of the more likely alternative sources is provided in Section 5.

[4] Tables 2-2 and 2-3 are also provided in Appendix A for easy reference with the ASD checklists.

Table 2-2
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix III Detection Monitoring Constituents								
Boron	Key Indicator	Yes if unwashed	17 / 35 / 82 ug/L	No	Very mobile	Boron-containing rocks (especially marine shales and clays), seawater, volcanic and geothermal activities, mined in arid regions of the United States (and other countries)	Fly ash leachate, may also be present in FGD leachate; sewage sludge, boron-containing fertilizers or herbicides, manufacture of glass, fiberglass, ceramics, soaps, detergents, bleach, fire retardants, and lubricants; used in control rods of nuclear reactors, and to produce a green color in pyrotechnics and flames; also used in the aerospace industry	Micronutrient for plants but may be toxic to some plant species in high concentrations. Boron deficiencies are more common than toxicities. Mobile in most hydrogeological environments, particularly sandy materials. Sorption to clay reaches a maximum in the pH range of 8-10.
Calcium	No	Yes	21 / 43 / 70 mg/L	CEC	Slightly mobile	Calcium carbonate rocks, limestone, calcium clay; fifth most common element in Earth's crust	Water softening wastes, soil acidity neutralization (lime additions to soil), calcium road salt, deicing, agriculture, cement and concrete, drying agents	Calcium carbonate is one of the most common calcium minerals. The concentration in groundwater may be limited by the solubility of calcium carbonate or calcium sulfate (gypsum). May be sorbed by ion exchange in soil and sediments but tends to be a reversible reaction.

Table 2-2 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix III Detection Monitoring Constituents								
Chloride	No	Yes if unwashed	3.1 / 8.6 / 23 mg/L	No	Very mobile	Salt water and brackish water sources; chloride anion is the most abundant element (other than hydrogen and oxygen) in Earth's oceans	Road salt, deicing, water softening wastes, sewage, septic effluent, livestock waste, oil-field brines, salt water intrusion (oil and gas well production), industrial emissions, incinerator ash, landfill leachate, aerospace industry, automobile industry, soaps and detergents, drying agents, flame retardants, flocculants, pharmaceutical and medical waste	
Fluoride	Yes for some coal ash	Yes for some FGD gypsum	<0.1 / 0.2 / 0.4 mg/L	No	Mobile	Natural weathering of fluoride-containing minerals	Steel, brick, and aluminum manufacturing; waste incineration, municipal water treatment	Occurs as fluoride anion at pH > 3, hydrofluoric acid at pH < 3. Can be sorbed by amorphous aluminum and iron oxides under strongly acidic conditions.
pH	No	No	6.9 / 7.3 / 7.6 SU	- -	- -	Oxidation/weathering of naturally occurring pyritic soils due to well installation or other excavation may cause low pH	Low pH: Oxidation/weathering of pyrite in coal or coal ash, leaking batteries High pH: Certain coal ash leachates may have high pH; cement and concrete manufacturing and use, soaps and detergents	Fly ash leachate pH may be acidic or basic depending on coal type. Bituminous coals tend to produce more acidic leachate, especially if comanaged with pyritic mill rejects, and subbituminous coals tend to produce more basic leachate. Important due to impact of pH on leachability of many trace elements.

Table 2-2 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25^{th} / 50^{th} / 75^{th} Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix III Detection Monitoring Constituents								
Sulfate	Yes for most coal ash	Key Indicator	4.7 / 14 / 36 mg/L	No	Very mobile	Sulfur is the 14th most abundant element in the Earth's crust; oxidation/ weathering of naturally occurring pyritic soils (such as iron sulfide)	Fly ash and FGD leachate, lead acid batteries, algaecides, gypsum mines, wood pulp production (paper mills), textile mills, tanneries, coal pyrite oxidation/weathering from mining or storage, industrial emissions and effluents, soaps and detergents, drying agents, flocculants, petroleum refining	Sulfate may precipitate with calcium, barium, and strontium. Not usually sorbed due to negative charge, but can be sorbed under acidic conditions by soils and sediments containing iron, aluminum, and manganese oxides with positive charges. May precipitate from solution as sulfides under strongly reducing conditions.
Total Dissolved Solids (TDS)	No	No	146 / 254 / 381 mg/L	- -	- -	TDS is largely based on concentration of major ions in groundwater (Ca, Mg, Na, K, carbonates, Cl, SO_4)		Refer to primary components.

Table 2-2 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25^{th} / 50^{th} / 75^{th} Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix IV Assessment Monitoring Constituents								
Antimony	No	No	<1 ug/L	No	Very mobile		Flameproof retardants, batteries, lead shot; metal and glass manufacturing	Usually soluble but may be sorbed by iron, aluminum and manganese oxides under acidic conditions (EPRI, 1987).
Arsenic	No	No	0.23 / 0.79 / 3.0 ug/L	Yes, pH and redox	Variable	May be present in sulfide minerals and in organic forms; concentrations can be naturally higher than typical under reduced conditions or if sulfide minerals are oxidized	Wood preservatives (chromated copper arsenate), feed additives, pharmaceuticals, electronic devices, metallurgical applications, metal mining and smelting, cemeteries; pesticides/herbicides/ insecticides (prior to 1960)	Arsenic occurs in the 5+ oxidation state as arsenate (AsO_4^{3-}) under relatively neutral pH and oxidized conditions, and as 3+ arsenite (AsO_3^{3-}) under reduced conditions. Arsenic fate and transport is complex due to sensitivity to pH and redox. Sorption usually increases with decreasing pH.
Barium	No	No	24 / 54 / 120 ug/L	Yes	Mobile	Weathering of sedimentary rocks	Well drilling mud or fluid, mining; manufacture of glass, paint, and rubber	Usually present as relatively insoluble barium sulfate in fly ash. Most barium compounds have limited solubility. Sorbed by clay, soils, and sediment.
Beryllium	No	No	<1 ug/L	Yes, pH	Immobile	Relatively scarce in Earth's crust	Electronic and electrical components, telecommunications and computer components, defense applications	Strong tendency to sorb at neutral to alkaline pH. Sorption may be reduced in the presence of humic acids.

Table 2-2 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix IV Assessment Monitoring Constituents								
Cadmium	No	No	<1 ug/L	Yes, pH	Slightly mobile	Minor component in Earth's crust, occurs in zinc minerals	Batteries, waste incineration, sewage sludge disposal, paint pigments, phosphate fertilizers, automobiles, electroplating and metal fabricating	Can be sorbed by clay, soil, and sediment at pH less than 8, but sorption decreases at low pH.
Chromium	No	No	0.68 / 1.2 / 3.0 ug/L	Yes, pH and redox	Variable	Primarily occurs as Cr(III) in soils and rocks	Electroplating, leather tanning, wood pulp production (paper mills), metal ore refining, wood preservatives, steel manufacturing, automobiles, electroplating and metal fabricating, paint and coatings	The solubility of Cr(III) generally increases at pH levels <6.5 and >11. Cr(III) is the predominant dissolved species under reducing to mildly oxidizing conditions. Cr(IV) is more soluble than Cr(III) at neutral to alkaline pH. Cr(VI) is soluble at alkaline pH and mildly to strongly oxidizing conditions.
Cobalt	No	No	0.063 / 0.17 / 0.48 ug/L	Yes	Variable	Relatively scarce in Earth's crust; usually occurs in combination with arsenic and sulfur in nature	Rechargeable battery electrodes, radial tires, drying agents, catalysts, paint pigments, medical wastes, automobiles	May be sorbed by mineral oxides (e.g., Fe and Mn), crystalline materials such as aluminosilicate, and natural organic substances in soil.
Lead	No	No	0.018 / 0.070 / 0.27 ug/L	Yes pH	Variable	Rare in Earth's crust	Smelting and mining, batteries, waste incineration, leaded gasoline (before 1996), lead-containing paint, glass manufacturing, ammunition, firing ranges, plumbing, automobiles	Sorption usually increases with pH.

Table 2-2 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix IV Assessment Monitoring Constituents								
Lithium	Yes for some coal ash	No	2.0 / 6.0 / 18 ug/L	No	Mobile	Rare in Earth's crust, dissolution of lithium-containing minerals	Glass and ceramics production, lubricants, greases, batteries, salt water intrusion	Reacts with sulfate ions to form lithium sulfate anion.
Mercury	No	No	NR	No	Slightly mobile	Occurs as HgS in nature; can be converted to methylated forms by anaerobic microbes	Waste incineration, mercury mining, metal recycling, fungicides, fluorescent lamps, batteries, thermometers/ thermostats/switches (electronic equipment), automobiles	Can be sorbed by iron, magnesium, silicon oxides, and organic matter.
Molybdenum	Yes for some coal ash	No	0.32 / 1.0 / 3.3 ug/L	No	Very mobile	Usually combined with sulfur or oxygen in natural minerals	Steel production, catalysts, lubricants, pigments, fertilizers, animal feed	Micronutrient for plants and animals; may be in fertilizers or animal feed. Peak sorption at pH <5 and limited sorption above pH 8. Phosphate and other oxyanions will depress sorption.

Table 2-2 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25^{th} / 50^{th} / 75^{th} Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix IV Assessment Monitoring Constituents								
Radium 226 + 228	No	No	NR / 0.28 / 1.2 pCi/L	Yes, CEC	No data	Natural decay product of uranium and thorium ores	Uranium mines, nuclear power, nuclear fuel and weapons manufacturing, uranium in coal	Radium decays to radon gas, so it is prevalent in locations where radon gas is a concern.
Selenium	No	No	0.12 / 0.34 / 1.0 ug/L	Yes, pH and redox	Variable	Usually occurs with silver, copper, lead, and nickel sulfide minerals; may exist in a variety of organic compounds	Metal mining and milling, industrial waste water, sewage effluent, waste incineration, saline agricultural waste waters	May exist as selenate (SeO_4^{2-}), selenite (SeO_3^{2-}), elemental selenium (Se^0), and selenide (Se^{2-}) in groundwater (shown in order from most to least oxic species). Since anionic selenium is the dominant form in groundwater, sorption typically is not significant. However, selenite can be sorbed by iron and aluminum oxides.
Thallium	No	No	<1 ug/L	Yes, redox	Mobile	Occurs in combinations with oxygen, sulfur, and halogens	Glass and electronic industries, iron and steel production, cement factories	May be immobilized under reducing conditions.

Table 2-2 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
Other Constituents								
Aluminum	No	No	0.98 / 3.0 / 4.9 ug/L	Yes, pH	Slightly mobile	Most abundant metal in Earth's crust; weathering of aluminosilicate minerals	Mining and industrial emissions and effluents; most abundant metal in coal ash, cement and concrete, drying agents, well drilling, flocculants, abrasives, aluminum manufacturing	Most soluble in water under acidic and alkaline solutions, essentially insoluble in near neutral water. May be sorbed by soils, sediments, and organic matter.
Bromide	Possible for certain coal ash	Yes if unwashed	0.02 / 0.04 / 0.09 mg/L	No	Mobile	Brackish groundwater and sea water, relatively rare in Earth's crust	CCR fly ash and emission control wastes, particularly if bromide compounds were used to facilitate mercury capture; drinking water disinfection, flame retardants	
Copper	No	No	0.47 / 1.0 / 3.0 ug/L	Yes, pH and redox	Variable	Relatively common in Earth's crust	Manufacture of bronzes, brass, electrical conductors, and ammunition; sewage sludge wastes, municipal solid wastes, copper-containing fertilizers, cemeteries, electronics, plumbing, wood preservatives, automobiles, electroplating and metal fabricating	Solubility may be controlled by solubility of copper hydroxide. May sorb to organic matter, clay, aluminum, manganese, and iron oxides.
Iron	No	No	0.81 / 7.9 / 93 ug/L	Yes, pH and redox	Variable	Commonly has high concentration in groundwater under reduced conditions; Weathering of iron-containing minerals (dissolution of iron oxides under reducing conditions), 4th most common element in Earth's crust	Industrial emissions, pyrite oxidation/acid mine drainage from coal mining or storage, flocculants	Iron oxides my dissolve and become mobile under reducing conditions. Occurs as ferrous (+2) and ferric (+3) iron. Ferric iron can be sorbed by silica, clay, and iron and manganese oxides.

Table 2-2 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
Other Constituents								
Magnesium	No	No	4.4 / 11 / 23 mg/L	CEC	Slightly mobile	Eighth most abundant element in the Earth's crust, abundant in sea water; dissolution of magnesium carbonates and clay minerals	Aluminum fabrication and welding (alloying agent), flares and pyrotechnics, fire retardants, heat-resistant bricks, animal feed, fertilizers, drying agents	Solubility may be limited under alkaline conditions. May be removed from solution by ion exchange in soils and sediments via reversible reactions.
Manganese	No	No	0.85 / 7.0 / 84 ug/L	Yes, pH and redox	Variable	Commonly has high concentration in groundwater under reduced conditions; 13th most abundant element in the Earth's crust	Production of steel and aluminum alloys, glass production, use as an additive in gasoline	
Nickel	No	No	0.35 / 1.1 / 2.5 ug/L	No	Variable	Commonly combined with iron or sulfur	Manufacture of steels, other metal alloys, and electronic applications; automobiles, electroplating and metal fabricating, petroleum	Sorbs to iron and manganese oxides, and clay to a lesser extent.
Nitrogen	No	No	0.07 / 0.55 / 2.4 (NO_3 as N) mg/L	Nitrification/ denitrifi-cation, redox	Very mobile as NO_3	In nature, nitrogen is converted from one redox state to another by abiotic reactions and microbial catalysis in oxic conditions: $NH_4OH \rightarrow NO_2 \rightarrow NO_3$; under reducing conditions: $NO_3 \rightarrow NO_2 \rightarrow N_2$	Fertilizers, livestock wastes, wastewater treatment plants, sewage and septic effluent, rubber manufacturing; ammonia sources include CCRs from sources using SNCR or SCR technology, coke production, flame retardants	NO_2 and NO_3 are not significantly sorbed by most soils, sediments, or clays, but NH_4OH is.

Table 2-2 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25^{th} / 50^{th} / 75^{th} Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
Other Constituents								
Phosphate	No	No	<0.01 / 0.02 / 0.04 mg/L	Yes, pH	Variable	Phosphorus is the 11th most abundant element in the Earth's crust	Fertilizers, wastewater treatment plants, sewage and septic effluents, industrial effluents, soaps and detergents, flame retardants	Can be sorbed by iron, aluminum, and manganese oxides, and by clay under acidic conditions.
Potassium	Yes for some coal ash	No	0.9 / 1.7 / 3.5 mg/L	CEC	Mobile	7th most abundant element in the Earth's crust; Weathering of potassium-containing minerals	Water treatment, fertilizers, sea water intrusion, soaps and detergents, drying agents	May be removed from groundwater by reversible ion exchange with soils and sediments.
Silicon	No	No	12 / 19 / 31 mg/L	Yes	Very mobile	2nd most abundant element in the Earth's crust; usually in the form of SiO_2	Glass, ceramics, abrasives, electronic devices, metal alloying, water filtration, insulation, cement, concrete, paper, rubber, lubricants, flocculants	Can be sorbed by iron and aluminum oxides, and by clay minerals.
Silver	No	No	<1 ug/L	Yes, pH	Variable		Textile plant wastewater, photographic materials, sewage sludge, medical wastes, electronics, electroplating and metal fabricating	Can be sorbed by soils but affected by pH, clay content, particle size, organic content, and free iron and manganese oxide content.
Sodium	Yes for some coal ash	No	5.2 / 11 / 29 mg/L	CEC	Mobile	6th most abundant element in Earth's crust; brackish groundwater and surface water, sea water, weathering of sodium-containing minerals	Road salt, deicing, septic effluent, sodium hydroxide water treatment wastes, water softening, salt water intrusion (gas and oil well production), sewage and septic effluent, soaps and detergents, drying agents	Most sodium compounds are soluble but may be sorbed by reversible ion exchange in soils or sediments.

Table 2-2 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25^{th} / 50^{th} / 75^{th} Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
Other Constituents								
Strontium	No	No	100 / 270 / 680 ug/L	Yes	Slightly mobile		Glass and ceramics production, pyrotechnics, phosphate fertilizers	Reacts with sulfate ions to form $SrSO_4^0$.
Vanadium	No	No	0.30 / 1.4 / 11 ug/L	Yes, pH and redox	Variable		Crude oil, oil shale, tar sands, phosphate fertilizers, wastes from steel production, petroleum	Can be sorbed by iron, aluminum, and manganese oxides; sorption decreases as pH increases.
Zinc	No	No	1.6 / 4.8 / 18 ug/L	Yes, pH	Variable		Fertilizers, protective coatings to reduce corrosion of metal surfaces, dry-cell batteries, castings, automobiles, lubricating oils and greases, plumbing/piping, electroplating and metal fabricating	Sorption increases with increasing pH but is also affected by clay content, particle size, organic content, and iron, aluminum, and manganese oxide content.

Notes:

1. Based on EPRI (2012). "No" indicates that the constituent it is not considered an indicator due to low concentration in CCR leachate relative to typical background, low mobility, and/or potential for reactivity.

2. Concentration ranges in ug/L from USGS (2011), Table 4; concentration ranges in mg/L or SU from USGS (2008), Tables 2 and 6; radium 226+228 from Szabo et. al (2012) supplemental table S-3; NR indicates that the concentration was not reported in any of these three documents.

3. Reactivity and mobility, while separate geochemical processes, are often interrelated. Reactivity descriptions in this table refer to chemical reactions, primarily precipitation and dissolution, that can change the concentration or mobility of the element in solution under typical aquifer conditions. Yes indicates that the constituent is subject to precipitation, coprecipitation, and/or dissolution reactions. In addition, pH and redox are indicated if they have a strong influence on the environments under which reactions occur and/or mobility. CEC is listed for constituents that are subject to cation exchange.

4. The mobility classification is based on the classification system of van Loon and Duffy (2000). See Table 2-2 of EPRI (2012) for corresponding K_d values.

5. Refer to Appendix B in EPRI (2012) for brief summaries of geochemical factors affecting reactivity and sorption. Detailed information can be found for selected constituents in the following EPRI reports:

Table 2-3
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Abrasives	**Silicon, aluminum**
Acid mine drainage	**Low pH, sulfate, iron**, dissolved solids, metals (aluminum, cadmium, calcium, chromium, cobalt, copper, magnesium, manganese, nickel, zinc, and others); can travel along mine shafts and tunnels and show up in unexpected locations (sometimes across aquifers) (notes 1, 26, 51, 54)
Aerospace industry	**Boron, perchlorate, chloride, cyanide, cadmium**, beryllium, solvents (trichloroethane, methylene chloride, trichloroethylene, toluene, methylethylketone), metals, oils (notes 2, 3, 4, 5, 51)
Aging infrastructure (leaking sewage, urban runoff)	Nitrate, phosphorus, sodium, chloride, organic substances, bacteria, pesticides, miscellaneous chemicals, cadmium, copper, iron, lead, selenium, zinc, and other elements (note 6)
Agriculture - animal feed lots	**Nitrates, ammonia, other nitrogen compounds, phosphorus/phosphate, chloride**, **arsenic**, **magnesium, molybdenum, selenium** and other elements, organic substances, bacteria/viruses (notes 7, 22, 51, 52, 54)
Agriculture - fertilization	**Nitrates, ammonia, other nitrogen compounds, phosphorus/phosphate**, **boron**, **cadmium, calcium**, chloride, cobalt, **copper**, cyanide, **magnesium**, **molybdenum, potassium, selenium, strontium, vanadium, zinc**, and other elements (notes 7, 22, 51, 52, 54)
Agriculture - irrigation	**Nitrates, ammonia, other nitrogen compounds, phosphorus/phosphate,** arsenic, boron, cadmium, calcium, chloride, cobalt, copper, cyanide, magnesium, mercury, molybdenum, potassium**, selenium**, sodium, sulfate, and other elements (notes 7, 8, 9, 22, 52)
Agriculture - lime addition	**Calcium** (note 22)
Agriculture - pesticides, herbicides, and insecticides	Aldicarb, Aldrin, alachlor, atrazine, carbofuran, chlordane, dacthal, DDT, dieldrin, bibromo-chloropropane, 1,2-dichloropropane, dinoseb, endrin, endosulfan, ethylene dibromide, heptachlor, hexachlorobenzene, lindane, mirex, PCBs, prometon, simazine, toxaphene, trifluralin; **arsenic** (prior to 1960), chloride, **mercury, boron**, **sulfate** (notes 10, 51, 52, 54)
Airport runways	**Sodium, potassium**, acetate, formate, urea (note 11)
Aluminum manufacturing	**Aluminum, fluoride, sodium**, magnesium, manganese, perfluorocarbons, polycyclic aromatic hydrocarbons (notes 12, 13)
Ammunition, firearms	**Lead, antimony, copper,** other heavy metals, nitrate, perchlorate, potassium, sulfur/sulfate, chloride (notes 14, 15, 22)
Asphalt plants	Oils, greases, PAHs, other hydrocarbons (note 16)
Automobile production	**Chloride, sulfate, phosphate,** oil and grease, solvents, ethylene glycol. Potential for heavy metals: aluminum (auto bodies), **cadmium** (tires and batteries), **cobalt** (radial tires), **chromium** (brakes, coolants, engine parts), **copper** (brake linings), iron (auto bodies), **lead** (batteries, lube oil and grease, bearings, brakes), **mercury** (batteries), **nickel** (lube oil, brakes), **zinc** (tires, fuel oil, lubricants) (notes 17, 18, 22)
Automobile repair shops	Gasoline, diesel fuel, oil, degreasing solvents (toluene, xylene, chlorinated solvents, MEK), ethylene glycol, lead, sulfate (notes 19, 44)

Table 2-3 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Batteries	**Sulfate, lead, antimony**, **cadmium, cobalt, lithium, mercury, zinc, low pH** (notes 22, 51)
Bleach manufacturing	**Boron** (bleaches containing sodium perborate) (notes 20, 31)
Brick manufacturing	**Aluminum, silicon, iron**, calcium, **fluoride**, **magnesium,** chromium (notes 21, 22, 52)
Catalysts	Aluminum, chromium, **cobalt**, copper, iron, **molybdenum**, titanium, tungsten, vanadium, zinc, and other metals (depends on catalyst manufactured or used) (note 22)
CCR - ash	**Boron, sulfate**, molybdenum, lithium, bromide, potassium, sodium, fluoride, selenium; may contain ammonia (nitrogen) if SCR or SNCR technology was used at the power plant (note 22)
CCR - FGD gypsum	**Sulfate**, fluoride, calcium, boron, bromide, chloride, selenium (note 22)
CCR - FGD fixated sludge	**Boron, sulfate**, calcium, chloride, molybdenum, lithium, bromide, potassium, sodium, fluoride, selenium (note 22)
Cemeteries	**Formaldehyde**, **copper, arsenic,** mercury, pesticides, fertilizers, weed killers (note 23)
Cement and concrete manufacturing and use	**High pH, aluminum, calcium, silicon, thallium,** chromium and other elements (notes 22, 24, 51)
Ceramics production	Oxides of carbon, **silicon, boron**, and nitrogen; may include aluminum, antimony, barium, copper, fluoride, iron, **lithium**, **strontium**, and other elements (notes 21, 22, 51)
Coal mining	**Sulfate, low pH, iron**, dissolved solids, trace elements (aluminum, beryllium, cadmium, chromium, cobalt, copper, lead, magnesium, manganese, mercury, nickel, selenium, **uranium (decays into radium 226+228)**, zinc and others); Oxidation of pyrite in coal can form sulfuric acid. The low pH increases solubility of many metals. (notes 1, 26, 51, 54)
Coatings	VOCs, solvents (halogenated solvents and non-halogenated solvents such as acetone, cresols, cresylic acid, nitrobenzene, benzene, toluene, xylene, methyl ethyl ketone, methylene chloride, etc.); trace elements may include barium, cadmium, **chromium**, cobalt, lead, mercury, molybdenum, nickel, titanium, and **zinc** (note 27)
Coke production (from coal)	**Phenols, ammonia (nitrogen), polycyclic aromatic hydrocarbons, cyanide**, benzene, naphthalene, anthracene, cresols, metals (see metals in "coal piles or coal waste piles") (note 28)
Computer and telecommunications components (electronics)	Trace elements may include aluminum, arsenic, barium, **beryllium**, cadmium, chromium, cobalt, **copper**, gallium, gold, iron, lead, manganese, mercury, palladium, platinum, selenium, **silver**, and zinc; solvents may include benzene, xylene (dimethylbenzene), trichloroethane, tetrachloroethane, ethylene glycol, methyl cellosolve; **silicon** (notes 29, 30, 32)

Table 2-3 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Defense applications	**Beryllium** (note 22)
Detergent or soap manufacturing	**Sodium, potassium, sulfates and sulfonates, high pH, phosphate**, **chloride, boron**, phenol, aluminosilicate, sodium citrate, nitrilotriacetate, alcohol ethoxylates, fats, oil and grease, lead, hexane, methyl alcohol, trichloroethane, perchloroethylene, benzene, toluene (notes 22, 34, 35)
Deicing	**Sodium, chloride**, **calcium**, magnesium, urea (notes 44, 51)
Drying agents	**Aluminum, calcium, sodium, potassium, magnesium, sulfate, chloride,** cobalt, lithium, phosphorus, silicon and/or other substances (notes 22, 36, 37)
Electronic equipment manufacturing and disposal	**Copper, silver, gold, palladium**, **arsenic, beryllium, copper, mercury, nickel,** selenium, **silicon, thallium** and other trace elements, chloride, fluoride, solvents (benzene, xylene, 1,1,1-trichloroethane, tetrachloroethane, methanol), ethylene glycol, hydrogen chloride, hydrogen fluoride (notes 22, 29, 30, 33, 51)
Electroplating and metal fabricating	**Cadmium, chromium, copper, nickel, silver**, sodium, tin, **zinc**, spent solvents, paints, spent acidic and alkaline solutions, cyanide, waste oils (notes 17, 22, 44, 51, 52, 56)
Explosives manufacturing and testing	**Nitroglycerin and nitro-aromatic compounds**, nitrate, perchlorate, ammonia, lithium, sodium, potassium, sulfur/sulfate, aluminum, chloride, **lead**, antimony, **copper**, nickel, silver (notes 38, 39, 40, 51)
Fertilizers	See Agriculture - fertilization
Fiberglass manufacturing	Aluminum, silicon, calcium, magnesium, **boron**, polyester or epoxy resin, styrene, solvents, volatile organic compounds, formaldehyde, urea, phenol, vinyl acetate (notes 31, 41)
Firearms, ammunition	See Ammunition, firearms
Firing ranges	**Lead**, antimony (notes 14, 22)
Fireworks manufacturing or use	Aluminum, antimony, arsenic, barium, **boron**, chloride, copper, lead, **magnesium**, nitrate, perchlorate, potassium, sulfur/sulfate, **strontium** (notes 31, 38, 39, 40, 51)
Flame retardant manufacturing or use	**Bromine, phosphate, nitrogen/nitrate, chloride**, **antimony, boron**, **magnesium**, polybrominated diphenyl ethers (PBDEs), PCBs (notes 22, 42, 43, 51)
Flocculants	**Sulfate, chloride, aluminum, iron**, ammonium, calcium, silica, polyamines (note 45)
Fluorescent lamps/bulbs	**Mercury**, PCBs in ballasts (note 47)
Fracking	See Oil and gas wells / production

Table 2-3 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Fungicides	See Pesticides
Furniture (wood stripping and refinishing)	Methylene chloride, methanol, isopropyl alcohol, acetone, perchloroethylene, toluene, acidic and alkaline solutions, metals, other solvents, petroleum distillates, resins, halogenated hydrocarbons, glycol ether (note 44)
Gasoline stations	**Benzene, ethylbenzene, toluene, xylene, MTBE**, ethylene dichloride, naphthalene, other organic compounds, lead (prior to 1996), **manganese**; trichloroethylene, perchloroethylene, methylene chloride, carbon tetrachloride, oils, ethylene glycol, hydraulic fluid, detergents, and acids (notes 22, 49, 51, 52)
Glass manufacturing	**Silicon**, antimony, **barium, boron, lead**, iron, **lithium**, **manganese**, nickel, potassium, **strontium**, **thallium**, tin, zinc, fluoride (notes 22, 31, 50, 51)
Industrial emissions	**Chloride, sulfate, iron,** wide variety of other elements and chemical substances (notes 22, 51, 54)
Irrigation	See Agriculture – irrigation
Junk and scrap yards	Used oil, gasoline, antifreeze, lead, sulfuric acid, agricultural chemicals/pesticides/other chemicals, metals (note 44)
Lamp manufacturing and disposal	**Mercury**, bromide, chloride, fluoride, iodide, PCBs, sodium (notes 22, 47)
Landfills - industrial	Wide range of trace metals, acids, **chloride**, sulfate, organic substances and pesticides (notes 51, 53, 54)
Landfills - municipal	Salts (sodium, calcium, magnesium, **chloride**, etc.), metals (iron, copper, zinc, other heavy metals), nitrate, organic compounds, solvents, pesticides (notes 22, 51, 54)
Laundry - dry cleaning	**Perchloroethylene (tetrachloroethylene)**, camphor oil, turpentine spirits, benzene, kerosene, white gasoline, petroleum solvents (petroleum naphtha), chloroform, carbon tetrachloride, trichloroethylene, 1,1,2-trichlorotrifluoroethane, glycol ethers, 1,1,1-trichloroethane, decamethylcyclopentasiloxane, n-propyl bromide, liquid carbon dioxide, fluorocarbon-113, antimony, cadmium, copper, lead, sulfate, zinc (notes 20, 31, 44, 52)
Leather tanning	**Chromium**, **cyanide**, **tannins**, chlorinated phenols including PCB, azodyes, cadmium, cobalt, copper, antimony, barium, lead, selenium, mercury, zinc, arsenic, nickel, formaldehyde, pesticides, salts, lime, acids, sodium sulfide, hydrogen sulfide, sulfate (notes 22, 55, 56)
Lubricants and greases	**Zinc**, polyaromatic hydrocarbons, arsenic, **boron**, cadmium, lead, **lithium**, **molybdenum**, PCBs, **silicon**, and other elements (note 22)
Medical supplies or wastes	Chloride, formaldehyde, **arsenic**, cadmium, **cobalt**, lead, mercury**, silver**, other heavy metals, radioactive waste, infectious or pathological waste, dioxins and furans from incineration; Also see Pharmaceutical industry (notes 22, 51, 57, 58, 59, 62)

Table 2-3 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Metal manufacturing - smelting	**Aluminum**, **antimony**, **arsenic**, beryllium, cadmium, **chromium**, **copper**, cyanide, iron, **lead**, **magnesium** (aluminum manufacturing), **manganese** (steel and aluminum manufacturing), mercury, **molybdenum** (steel manufacturing), **nickel** (steel and other metal manufacturing), **selenium**, silver, **thallium** (iron and steel manufacturing), zinc and other elements, **fluoride** (steel and aluminum manufacturing), **silicon, vanadium** (steel manufacturing), **zinc** (notes 22, 44, 51, 52)
Metal mining	Aluminum, antimony, **arsenic**, beryllium, cadmium, **chromium**, **copper, cyanide**, iron, **lead, manganese**, **mercury, nickel, selenium**, silicon, silver, thallium, tungsten, zinc and other elements (notes 22, 51, 52, 54, 56)
Metal plating	Spent solvents, paints, spent acidic and alkaline solutions, waste oils, heavy metal sludges, metal dust, chromium, copper, nickel, selenium, **zinc** and other elements (notes 22, 44, 51, 52)
Metal recycling	Iron, copper, **mercury**, nickel, zinc, and other elements (note 22)
Mining - unspecified	Depends on contents of ore; may include aluminum, antimony, arsenic, beryllium, cadmium, chromium, copper, iron, lead, manganese, mercury, nickel, selenium, silver, **sulfate** (gypsum mines), thallium, zinc, other minerals, hydraulic oils; **radium 226+228 (uranium mines)** (notes 22, 51)
Natural gas pipelines	**Methane, PCBs** (notes 60, 61)
Nuclear power	**Tritium**, **strontium 90, radium 226+228,** boron, beryllium (notes 31, 51, 54)
Oil and gas wells / production	Produced water may contain high **TDS, chloride, sodium**, sulfate, barium, boron, bromide, iodide, lithium, potassium, radionuclides, **vanadium** and other minerals, methane, volatile organic compounds (notes 52, 60, 63)
Ore refining / smelting	Aluminum, antimony, arsenic, beryllium, cadmium, chromium, copper, cyanide, iron, lead, manganese, mercury, nickel, selenium, silver, thallium, zinc and other elements (notes 22, 44, 51)
Paint and pigment manufacturing	VOCs, solvents (halogenated solvents, non-halogenated solvents such as acetone, cresols, cresylic acid, nitrobenzene, benzene, toluene, xylene, methyl ethyl ketone, methylene chloride, etc.); metals may include **barium**, **cadmium, cobalt**, **chromium**, **lead**, mercury, **molybdenum**, titanium, and zinc (notes 22, 44, 51, 52, 64)
Paper and pulp manufacturing	Organic and inorganic compounds including lignin, cellulose, phenols, mercaptans, **chromium**, nitrates, phosphates, **silicon, sulfides/sulfates**, chlorinated compounds including chloroform and dioxin (notes 22, 65)
Petroleum facilities and refining	Benzene, ethylene, toluene, xylene, methane, other organic compounds, hydrogen sulfide, **sulfate, nickel, vanadium** and other elements; some refineries use deep-injection wells to dispose of highly contaminated wastewater that could potentially contaminate groundwater (note 51)
Pharmaceutical industry	Wide variety of organic solvents; **arsenic, cobalt**, ammonia, chloride, cobalt, **silver** and other elements; Also see Medical supplies or wastes (notes 22, 51, 57, 62)
Photographic materials/photography	**Silver,** sodium, potassium (notes 22, 51)

Table 2-3 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Pigments	See Paint and pigment manufacturing
Plastic manufacturing	Cadmium, cyanide, benzene, vinyl hydrochloride, phthalates, trichloroethane, acetone, methylene chloride, methyl ethyl ketone, styrene, toluene, trichloroethane, sulfate, methanol, ethylene oxide, volatile organic compounds, sodium, caustic, nickel, lead, cadmium, mercury (notes 51, 66)
Plumbing	**Copper, lead, zinc** (note 51)
Road salting	**Chloride, sodium**, **calcium**, other salts (notes 22, 44)
Rubber manufacturing	**Ammonia, amines**, acetic acid, **barium**, cobalt, formic acid, sodium, **silicon**, sulfite/sulfate, organics, nitrogen compounds (notes 22, 69)
Salt or brackish water intrusion (from well drilling)	**High TDS, chloride**, boron, bromide, calcium, **lithium**, magnesium, **potassium, sodium**, sulfate, and other minerals (notes 22, 51, 54)
Salvage and junk yards	Grease, oil, solvents, lead and acid from batteries, metals (notes 44, 54)
Semiconductor manufacturing	Copper, silver, gold, palladium, arsenic, beryllium, copper, mercury, nickel, selenium, silicon, thallium and other elements, chloride, fluoride, solvents (benzene, xylene, 1,1,1-trichloroethane, tetrachloroethane, methanol), ethylene glycol, hydrogen chloride, hydrogen fluoride (notes 22, 29, 30, 33, 51)
Septic effluent	**Nitrate, phosphorus, chloride, sodium**, organic substances, bacteria and viruses, detergents, oils, heavy metals including cadmium, copper, lead, **selenium**, salts, septic tank cleaners such as trichloroethane or methylene chloride, and a wide variety of other chemicals (notes 22, 51, 52, 53)
Sewage	**Nitrate, phosphorus, chloride, sodium**, organic substances, bacteria and viruses, detergents, oils, **boron**, **cadmium**, **copper**, lead, **selenium, silver**, salts, and a wide variety of other chemicals (notes 22, 51, 52)
Soap or detergent manufacturing or use	See Detergent and soap manufacturing
Soil acidity neutralization	**Calcium**
Steel (including stainless) and iron manufacturing	Iron, chromium, manganese, nickel, ammonia, cyanide, chloride, copper, fluoride, molybdenum, sulfate, tin, thallium, zinc, hydraulic oils
Textiles	Polyvinyl chloride, chlorine bleach, benzidine, toluidine, cyanide, formaldehyde, hydrocarbons, ammonia, nitrate, organic solvents, chloride, sodium, fluoride, silicon, **sulfate**, phosphate, boron, bromide, chromium, copper, aluminum, antimony, potassium, aluminum, **silver**, titanium, zinc, copper, insecticides (notes 22, 51, 56, 67, 68)
Thermometers, thermostats, switches	**Mercury** (note 51)

Table 2-3 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Underground storage tanks (USTs leaking petroleum products such as gasoline)	Benzene, toluene, xylene, other organic compounds (notes 49, 51, 53)
Urban runoff	Oils, heavy metals, salts, copper, zinc, and other chemicals (notes 6, 18, 54)
Waste incineration	**Chloride, cadmium**, chromium**, fluoride, lead, mercury**, selenium, dioxins and furans (note 22)
Water treatment - flocculants	See Flocculants (note 45)
Water treatment - industrial effluents	Wide variety of metals, aluminum, **chloride**, **phosphate**, **potassium, sulfate**, nitrate, **selenium, silicon**, **sodium**, organics depending on industry (notes 22, 46)
Water treatment - municipal supply	Bromide, **chlorine, fluoride** (notes 22, 51)
Water treatment - treated sewage effluent	May contain **nitrates and other nitrogen compounds, phosphates, sodium, chloride**, **selenium, silicon**, and a variety of other elements (notes 22, 51, 52)
Water treatment - water softening	**Sodium, chloride**, **calcium**, magnesium, iron, other salts and metals (note 22)
Water treatment - cooling water	Chromium, zinc (notes 51, 52)
Well drilling (mud or fluid)	Constituents of bentonite clay and the natural geomedia including **aluminum, barium**, calcium, potassium, sodium and other minerals (note 22)
Wood preservatives and treatments	**Pentachlorophenol (PCP), creosote**, **copper, chromium, arsenic** (chromated copper arsenic, ammoniacal copper arsenate) (notes 22, 44, 48, 51)

* Bold indicates likely key indicators; list will vary by site-specific source; list may be incomplete or may not accurately represent a particular source.

ASD EVALUATION TECHNIQUES

Primary Indicators for Coal Combustion Residual Leachate

A key line of evidence in any ASD will be whether or not there is an SSI/SSL for one or more primary CCR leachate indicator constituents. For ASD purposes, a primary indicator is:

- a constituent that typically has high concentration in leachate, relative to background, such that it is expected to have elevated concentration in the event of a release, *and*
- is not reactive, and has high mobility in groundwater such that it is expected to be at the leading edge of the plume, meaning that it will have elevated concentrations relative to background across the entire area of the plume.

Boron (B) and sulfate (SO_4) are primary indicators for coal ash leachate (EPRI 2012). The association of both boron and sulfate with CCP leachate was established during the late 1970s (EPRI 1979, Cherkauer 1980). Based on the EPRI CPInfo database, boron concentrations in fly ash leachate range between 1.1 and 109 mg/L with an average concentration of 8.3 mg/L; sulfate concentrations range from 89 to 6,070 mg/L with an average concentration of 1,370 mg/L (EPRI 2012). For FGD gypsum, sulfate is a primary indicator constituent. Sulfate concentrations for FGD leachate range from 437 to 1,549 mg/L with average concentrations around 1,300 mg/L (EPRI 2012).

There may be other primary indicators for a given CCR site depending on a variety of factors (Table 3-1). For example, molybdenum may be a primary indicator for landfilled fly ash derived from bituminous coal, and boron, bromide, and chloride may be primary indicator constituents for unwashed FGD gypsum. When determining primary indicator constituents, the optimal approach is to start with field-measured leachate concentrations. If field data are not available, published sources provide an alternative source of data. EPRI (2016) provides landfill leachate data ranges for a variety of CCRs and source coals.

Table 3-1
Potential Indicator Constituents for Coal Ash and FGD Gypsum

Potential Indicators for Coal Ash		Potential Indicators for FGD Gypsum	
Constituent	**Advantages and Caveats**	**Constituent**	**Advantages and Caveats**
Boron	Typically present in leachate, non-reactive and mobile in common hydrogeologic environments, and not a common anthropogenic contaminant.	Sulfate	High concentrations expected in both washed and unwashed FGD gypsum (EPRI, 2011). Commonly analyzed. Very mobile in all hydrogeologic environments. Less useful in strongly reducing environments where sulfate can be reduced to hydrogen sulfide gas.
Molybdenum	Most useful for dry-managed coal ash. May be less mobile than boron in some hydrogeologic environments. Concentrations may be too low in impoundment leachate to be useful if background groundwater has detectable concentrations.	Fluoride	Assure that leachate concentration is higher than background, particularly for washed gypsum. Mobile in common hydrogeologic environments, although precipitation as CaF_2 is possible.
Lithium	Useful for coal ash management sites where the power plant burned bituminous coal. Leachate concentrations are typically low in coal ash derived from subbituminous and lignite coal (EPRI, 2006).	Calcium	High concentrations expected in both washed and unwashed FGD gypsum (EPRI, 2011). Understanding of carbonate chemistry necessary to assure that precipitation or dissolution does not affect downgradient concentrations.
Sulfate	Commonly analyzed and very mobile in all hydrogeologic environments. Concentration in impoundment leachate may in some cases be too low relative to background to be useful. Less useful in strongly reducing environments where sulfate can be reduced to hydrogen sulfide gas.	Boron	Mobile indicator constituent for unwashed FGD gypsum. Concentrations for washed gypsum may be too low to be useful (EPRI, 2011).
Bromide	May have high concentration in coal ash leachate at power plants where brominated powdered activated carbon (Br-PAC) or calcium bromide is used for mercury control. Leachate concentrations for coal ash generated absent use of these technologies may be too low to be useful. Mobile and non-reactive in typical groundwater environments.	Bromide	Mobile indicator constituent for unwashed FGD gypsum, especially if Br-PAC or CaBr used for mercury controls. Concentrations for washed gypsum may be too low to be useful (EPRI, 2011).

Table 3-1 (continued)
Potential Indicator Constituents for Coal Ash and FGD Gypsum

Potential Indicators for Coal Ash		Potential Indicators for FGD Gypsum	
Constituent	**Advantages and Caveats**	**Constituent**	**Advantages and Caveats**
Potassium	Commonly analyzed, although may be less mobile than boron and sulfate. Assure that leachate concentration is higher than background and that there are no anthropogenic sources such as agricultural fields where potassium may be applied in fertilizers.	Chloride	Mobile indicator constituent for unwashed FGD gypsum. Concentrations may be very high if transport water is recirculated. Concentrations for washed gypsum may be too low to be useful (EPRI, 2011).
Sodium	Useful for coal ash management sites where the power plant injects trona or sodium bicarbonate, or burned subbituminous coal. Absent dry sorbent injection, leachate concentrations are considerably lower in coal ash derived from bituminous coal, particularly at impoundments (EPRI, 2006). Assure that leachate concentration is higher than background and that there are no anthropogenic sources such as agricultural fields, or major highways in northern climates where sodium may be applied as road salts.		
Fluoride	Mobile and non-reactive in common hydrogeologic environments. Assure that leachate concentration is higher than background.		
Source: EPRI, 2012			

Site-Specific Leachate Analysis

Collection of site-specific field leachate data is useful for ASDs because it identifies 1) whether or not particular constituents that can cause an exceedance have higher concentration in leachate than in background groundwater, and 2) the leachate signature or fingerprint.

Where possible, leachate samples from landfills and impoundments can be collected using leachate wells, lysimeters, and/or leachate collection systems. These collection methods are preferred because the samples collected are representative of interstitial porewater. Because leachate characteristics will change with coal types and sources as well as changes in emission control technology, it is important to collect leachate samples representative of the spectrum of CCR materials placed into the CCR unit. Samples of pond water, sluice water, and runoff water are less useful than porewater samples for groundwater fingerprint analysis because their chemistry is affected by the composition of the source water used for sluicing as well as the leachate. Laboratory samples do not always represent actual leaching conditions (pH, redox, and liquid-to-solid ratio) and therefore, are less representative of actual field leachate composition than field samples. They are also more likely to provide only a snapshot of leachate chemistry based on the coal type and technologies used at the time of generation.

Water Quality Analyses for an ASD

The constituents included in a groundwater monitoring plan may not provide all data needed to evaluate certain lines of evidence for an ASD. The list below will typically provide the information needed for all except specialized lines of evidence.[5] Some of these constituents may already be part of the monitoring plan, while others may represent extra or special analyses.

- The constituents listed in Table 3-1, depending on the CCR managed in the site, in order to identify primary indicators for the leachate. All of these could be analyzed in leachate samples, and those with elevated concentration could be analyzed in groundwater samples.
- Major ion concentrations (alkalinity, chloride, sulfate, calcium, magnesium, potassium, and sodium) in leachate and groundwater. These concentrations can be used to evaluate whether downgradient groundwater chemistry remains representative of background groundwater chemistry. Major ion chemistry can also be used to evaluate natural variability due to seasonal changes or other causes.
- Field turbidity in groundwater is an indicator of the presence of suspended solids that may contribute to elevated concentrations of constituents monitored in unfiltered samples under the CCR Rule.
- pH in leachate and groundwater because it provides information on chemical reactions and mobility in groundwater.
- Dissolved oxygen (DO), oxidation reduction potential (ORP), and iron and manganese in groundwater are all indicators of redox conditions. Changes in redox can affect the chemical state and solubility of sulfate in addition to trace elements including arsenic and selenium. For example, under strongly reduced conditions, sulfate can be reduced to form hydrogen sulfide or it can precipitate as iron sulfide, arsenic reduces to the more mobile arsenite species, and selenium reduces to the low-mobility selenite species.

Water Quality Signatures

Natural surface water and groundwater may contain literally thousands of other substances (USGS, 2003). In fact, water is often referred to as the universal solvent because it dissolves more substances than any other solvent. Sources of these dissolved constituents or solutes include dust and gases collected as precipitation falls to the earth, dissolution of minerals in the soil and rocks, infiltration of contaminants from anthropogenic sources, etc. Groundwater monitored at a CCR unit for compliance with the CCR Rule is a compilation of the history of all sources of water comingling at that particular monitoring well. Different sources may contribute some of the same solutes, making source identification challenging. The identification and use of water quality "signatures" can be used as a tool for deciphering the similarity between potential sources and the water quality at a specific monitoring point.

EPRI (2012) describes three tiers of investigation for evaluation of water quality signatures to determine if elevated concentrations represent a release from a CCR facility. Conversely, these

[5] Specialized lines of evidence include geochemical modeling, isotopic signatures, and tritium age dating. Refer to EPRI (2017).

tools can also be used to evaluate whether or not sources other than CCR are contributing to groundwater quality degradation. The three tiers defined by EPRI (2012) are:

- Tier I: Trend Analysis and Statistics
- Tier II: Advanced Geochemical Evaluation Methods
- Tier III: Isotopic Analyses

This section provides guidance for interpretation of results using these evaluation techniques for an ASD.

Tier I Evaluation

By requiring determination of statistically significant increases/levels, the CCR Rule essentially requires Tier I statistical analysis under detection monitoring and under assessment monitoring. Many of the indicator constituents listed in Table 3-1 are included in constituent lists for these monitoring programs, including the primary constituents boron and sulfate. As discussed next, if there is an SSI/SSL without a corresponding increase in a primary indicator constituent (boron and usually sulfate[6] for coal ash), then this is a key line of evidence for an alternative source demonstration.

As previously introduced, an ideal primary indicator is a constituent that has concentrations in leachate greater than concentrations in background/upgradient groundwater, is mobile, and is relatively non-reactive in the hydrogeologic environment. Boron and sulfate are the most common primary indicators for coal ash leachate (EPRI, 2012). This is the first line of evidence to investigate for an ASD. If a constituent other than boron and/or sulfate is identified as an SSI/SSL but boron and/or sulfate are not also identified as elevated over background, it is unlikely that leakage from the CCR unit is the source of the SSI/SSL. This relationship holds for other potential indicators identified in Table 3-1, such as fluoride and sodium, if they have elevated concentration in site leachate relative to background.

If the site-specific leachate signature has not been determined, the potential indicators identified for fly ash and FGD gypsum in Table 3-1 can be considered. All of these potential indicators are naturally occurring and may be present in background groundwater. If any of these potential indicators are elevated over background but boron and/or sulfate are not, that provides a line of evidence for an ASD. Conversely, if any of these constituents have been identified as an SSI/SSL in addition to boron and sulfate, then temporal trends can be compared to determine if the constituents are trending together in the same direction. The more this "fingerprint" matches, the more strongly the monitoring results point to a release from the CCR unit. The trends in Figure 3-1 for boron, lithium, and sulfate indicate that lithium concentrations tend to rise and fall with boron and sulfate concentrations indicating that lithium may be an additional indicator parameter for a release from this site.

[6] Sulfate concentration increases may not be evident if groundwater is strongly reduced.

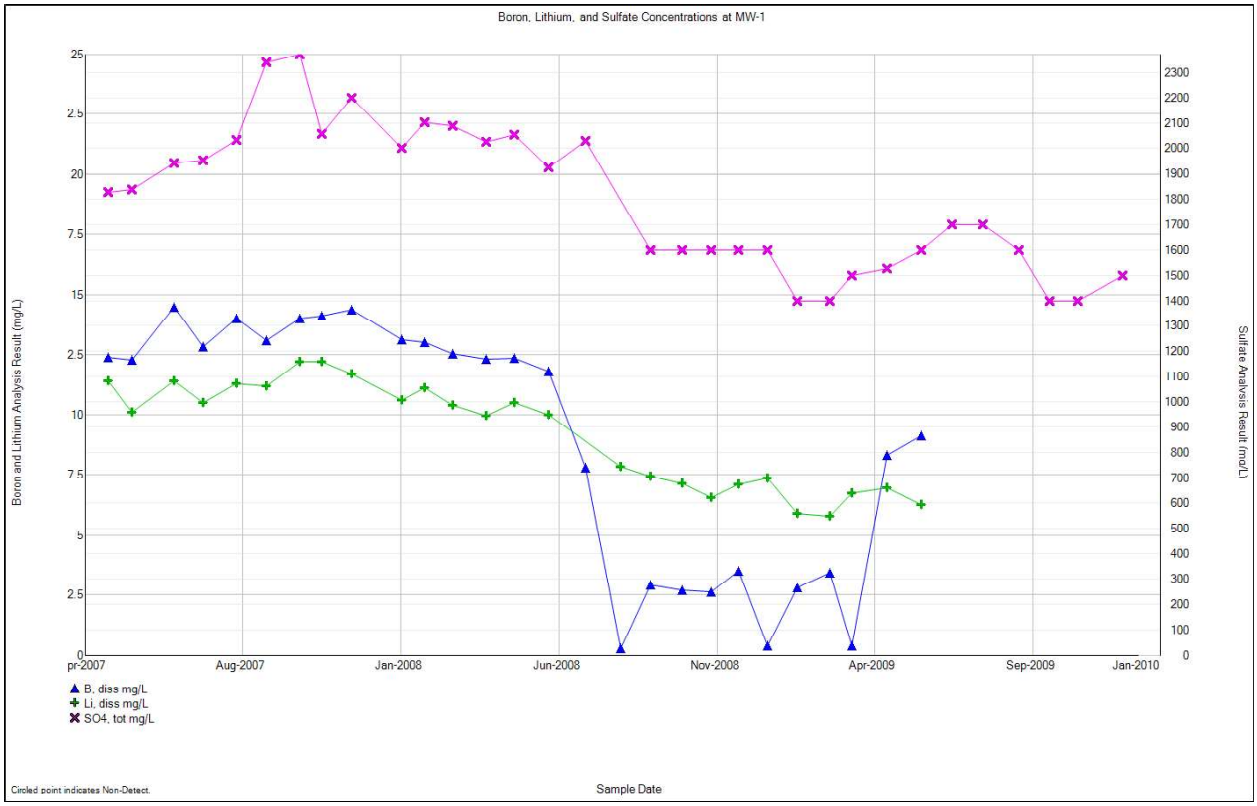

Figure 3-1
Time series plot showing potential correlation for lithium with boron and sulfate concentration changes indicating that lithium may be an indicator parameter for this site.

Scatter plots are another useful technique for identifying or refuting indicator parameters and identifying the presence of alternative sources. This technique plots one constituent on the X axis against another constituent on the Y axis. It can be used to show the relationship between two constituents. If the pattern of dots slopes from the lower left to the upper right portion of the graph, the two constituents are positively related (as one increases the other also increases). In this case, they are both likely related to the same source. If the pattern of dots slopes from the upper left to the lower right portion of the graph, the two constituents are negatively related and not from the same source. Figure 3-2 shows that arsenic and boron are not positively related. Therefore, even though the elevated boron concentrations suggest that a release has occurred, the lack of correlation suggests that the highest arsenic concentrations have a different source than the boron, which becomes a line of evidence in an ASD *specific to the arsenic*.

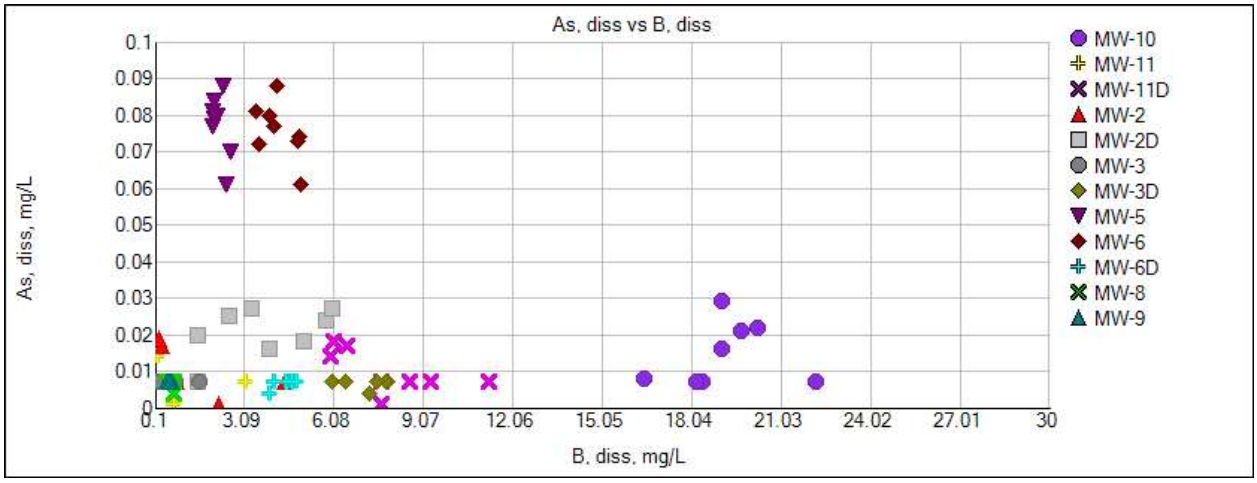

Figure 3-2
Scatter plot of arsenic versus boron, showing no correlation

Tier II Evaluation – Advanced Geochemical Evaluation Methods

Analysis of indicator constituents may not provide the lines of evidence needed for a strong ASD. More sophisticated methods may be needed at sites that have high concentrations of naturally occurring indicator constituents, multiple CCR sources, or upgradient sources of indicator constituents not related to the monitored unit, or where groundwater is brackish or saline. Furthermore, as groundwater travels through the environment, the composition may change due to geochemical interactions such as pH and ORP changes, influences from microbial activity, mixing with recharging surface water or other aquifers, or contamination from a variety of other anthropogenic or natural sources. The methods described below are useful for evaluating and visualizing the differences in water chemistry between upgradient and downgradient sampling locations.

Five Tier II methods were recommended in EPRI (2012) for multi-parameter comparison of water chemistry at multiple locations:

1. Ion ratios
2. Piper diagrams
3. Durov diagrams
4. Stiff diagrams
5. Fingerprint Analysis of Leachate Contaminants (FALCON)

This section adds a geochemical modeling and multivariate statistics to the EPRI (2012) list.

Ion Ratios and FALCON

The ion ratio method is the simplest approach from the list above and, unlike items 2 through 5, does not require analytical data for all major cations (calcium, magnesium, sodium, and potassium) and anions (chloride, sulfate, carbonate and bicarbonate or total alkalinity). Ion ratios are calculated by dividing the concentration of one constituent (usually the higher concentration constituent) by the concentration of another constituent from the same sample. Any units may be

used as long as the units are the same, because the ratio calculation is dimensionless. Ion ratios can be used to identify different source waters, or to determine that an additional source water is being added along a flow path. The method is based on the premise that if two constituents with similar mobility are released to groundwater, they will travel in groundwater at the same relative concentration or ratio unless they are mixed with water from other sources that have significantly different ratios of the same constituents. In other words, if leachate is released, then the relative concentration (ion ratio) in downgradient wells should be similar to the relative concentration in the leachate even if the concentration is diluted due to mixing with background groundwater. EPRI 2012 recommends that mobile, non-reactive constituents such as boron, chloride, lithium, molybdenum, and sulfate are the best candidates for this approach.

Table 3-2 illustrates the use of ion ratios as a line of evidence that downgradient well MW-3 is not impacted by ash leachate. In this example, MW-3 has higher sulfate concentrations than the two background wells, indicating that it may be impacted by CCR leachate. Boron concentrations at MW-3 are similar to upgradient well MW-1, whereas boron was not detected at upgradient well MW-2. Field leachate data indicate that chloride may be a CCR leachate indicator for this site in addition to boron and sulfate. Ion ratios for sulfate/chloride and boron/chloride were calculated and are provided in the chart (note that the boron/chloride ratios were multiplied by 1000 for enhanced visual representation). Since boron, sulfate, and chloride are all non-reactive in groundwater, ion ratios (boron/chloride and sulfate/chloride) representative of the leachate should remain consistent as leachate disperses and is diluted in groundwater unless there is another source of these constituents. In this case, the ion ratios at MW-3 are more representative of those at background wells MW-1 and MW-2, providing a line of evidence that CCR leachate is not the source of these constituents at MW-3.

Table 3-2
Use of Ion Ratios to Show that Groundwater Concentrations Are Not Caused by a CCR Release

		Background Wells		Downgradient Well	Field Leachate Concentration
Constituent	**Units**	**MW-1**	**MW-2**	**MW-3**	**LH-1**
B, tot	mg/L	0.02	<0.01	0.02	29
Cl, tot	mg/L	15	8	34	2,500
SO4, tot	mg/L	33	31	130	3,294
SO4/Cl Ratio		2.2	3.9	3.8	1.3
B/Cl Ratio	*1000	1.3	1.2	0.59	12

Ion ratios are also the basis of the Fingerprint Analysis of Leachate Contaminants (FALCON) method that was developed by the U.S. EPA. The FALCON method is more robust than simple ion ratios because it utilizes multiple constituents including all major cations and anions, as well as selected indicator constituents representative of the leachate signature. Regression analysis is used to mathematically represent the correlation between monitoring well, leachate, and background well signatures. EPRI (2012) provides a step-by-step procedure for the application of FALCON.

Piper, Durov, and Stiff Diagrams

Piper, Durov, and Stiff diagrams use graphical methods to group groundwater data to evaluate major ion chemistry. For an ASD, these methods are used to determine whether or not downgradient groundwater quality is a mixture of background groundwater and leachate. Interpretation of these plots can be subjective due to variation in the quality of various water groups. However, with Piper and Durov diagrams, a mixture is evident when downgradient groundwater quality plots at a point between leachate and background groundwater quality, and little or no mixing is determined if downgradient points plot with background, or at a point that is not between background and leachate. For a Stiff diagram, mixing is determined if the downgradient point evolves along a flow path to look less like background and more like leachate, where little or no mixing can be concluded if the shape of the downgradient point remains similar to background. These methods can also be used to evaluate whether or not an alternative source is affecting downgradient groundwater quality.

Common to each method is the necessity to conduct chemical analyses of the leachate and groundwater samples that include major cations and anions. Major cations present in natural water sources are calcium, magnesium, sodium, and potassium. Major anions are chloride, sulfate, bicarbonate, and carbonate. Bicarbonate and carbonate can be analyzed and reported together as total alkalinity. Prior to using graphical analysis for evaluation of major ion chemistry, it is good practice to calculate the charge balance in the sample. If the charge balance is not within an acceptable criterion (typically ±10%), it indicates that analytical results may be missing significant constituents, or there may be errors in the reported results. EPRI (2012) provides the equation and describes how to calculate and interpret the charge balance error for a water sample.

A Piper diagram is a graphical technique used to classify types of groundwater. It consists of two ternary plots (one for cations, and one for anions) linked to a diamond plot that is a combination of cations and anions. The Piper diagram below (Figure 3-3) shows an example where mixing is evident between leachate and groundwater, as denoted by the yellow-shaded area; however, the lysimeter chemistry does not indicate mixing of groundwater and leachate (primarily based on the cation triangle).

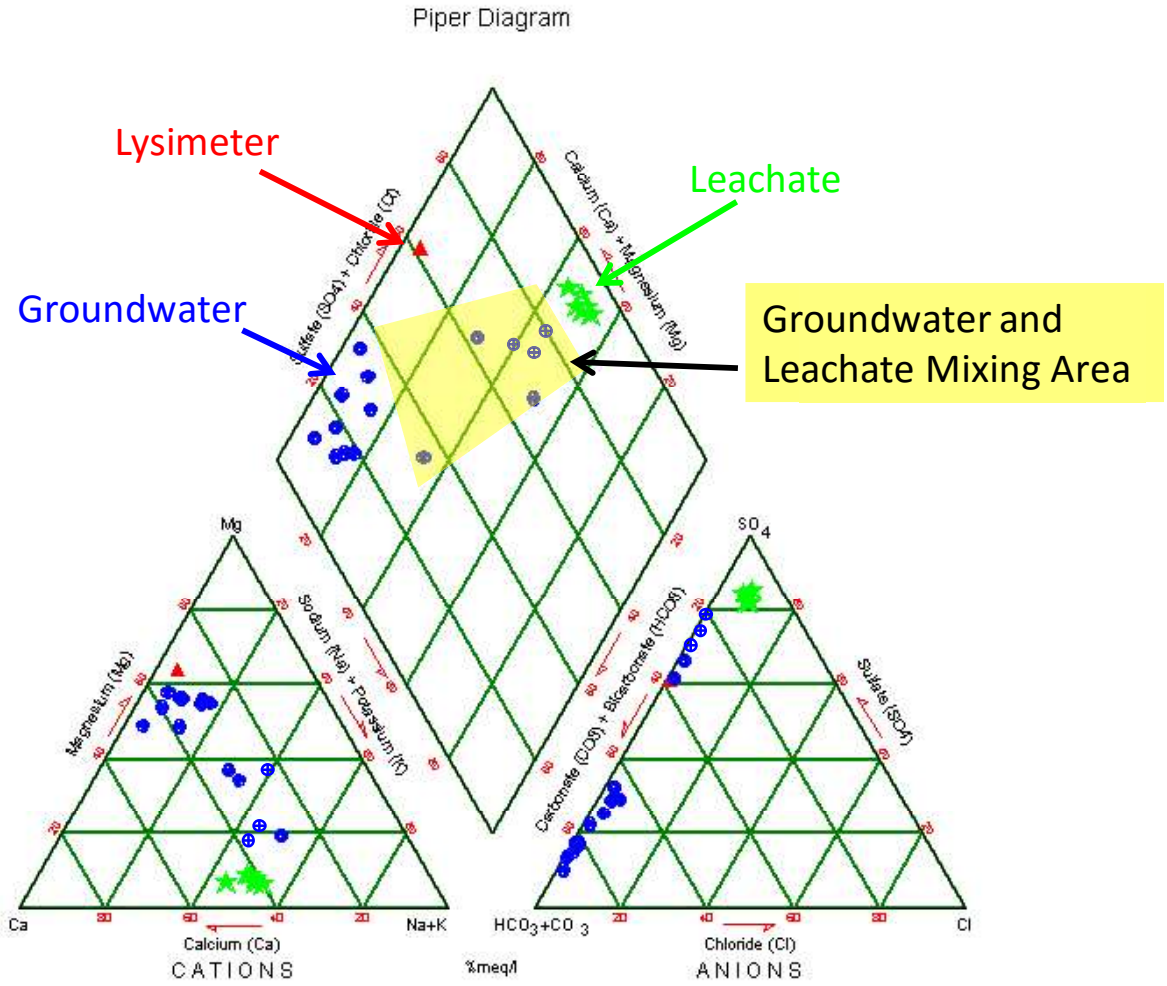

Figure 3-3
Example Piper diagram (from EPRI, 2012)

A Durov diagram is a combination of two ternary plots attached to a square-shaped plot. It displays data similar to a Piper diagram in different format. An example is provided in Figure 3-4. This diagram shows that bituminous coal ash leachate can be characterized as calcium-magnesium-sulfate water type, leachate from subbituminous coal ash can be characterized as sodium-calcium-sulfate water type, and background groundwater in this illustration can be characterized as calcium-magnesium-bicarbonate type.

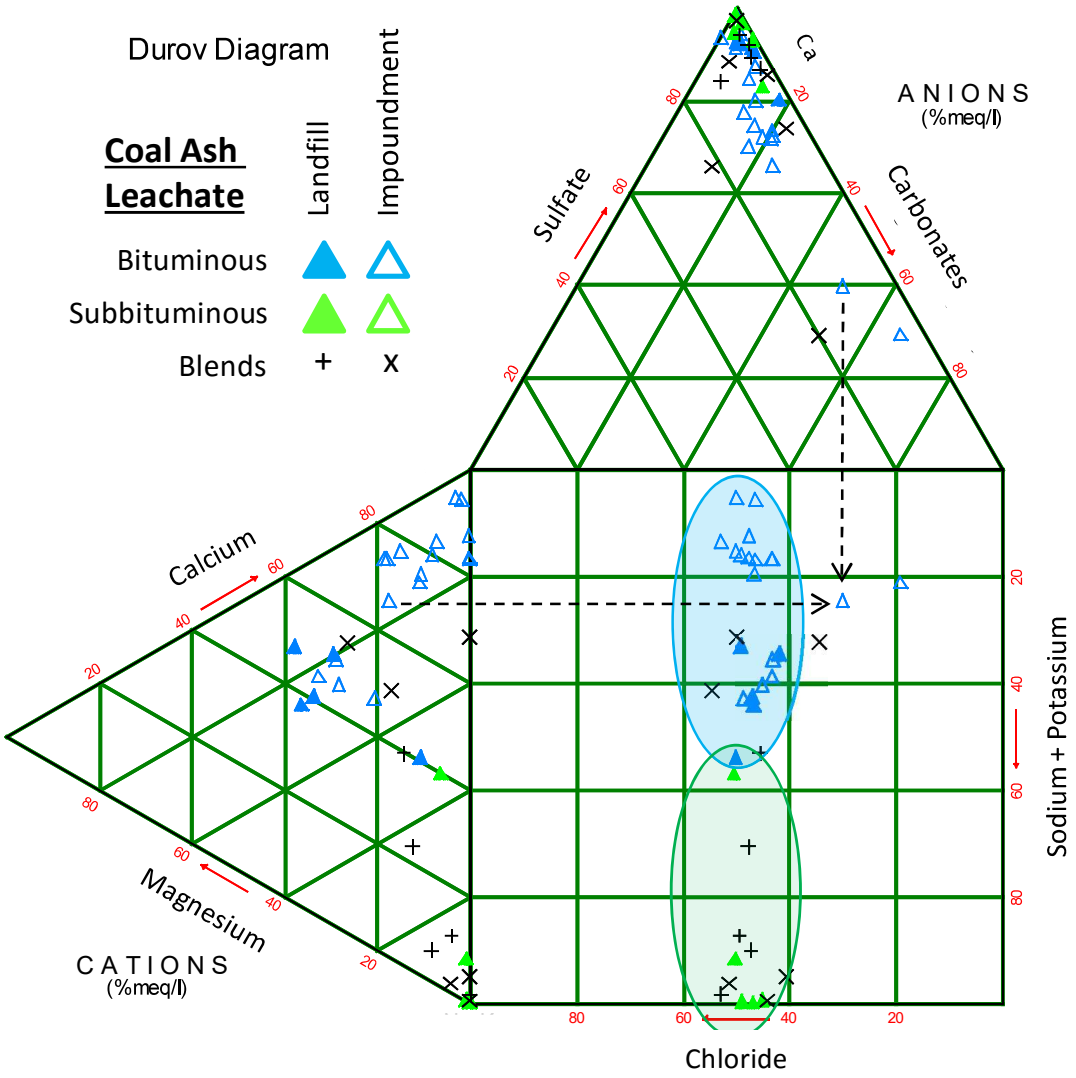

Figure 3-4
Durov diagram showing coal ash leachate derived from bituminous coal compared to subbituminous-lignite coal (From EPRI, 2012)

A Stiff diagram (Figure 3-5) is a multi-sided figure that compares the major cations in solution with the major anions. The resulting polygon can be placed in cross-sections or maps to show how the composition of the groundwater changes spatially.

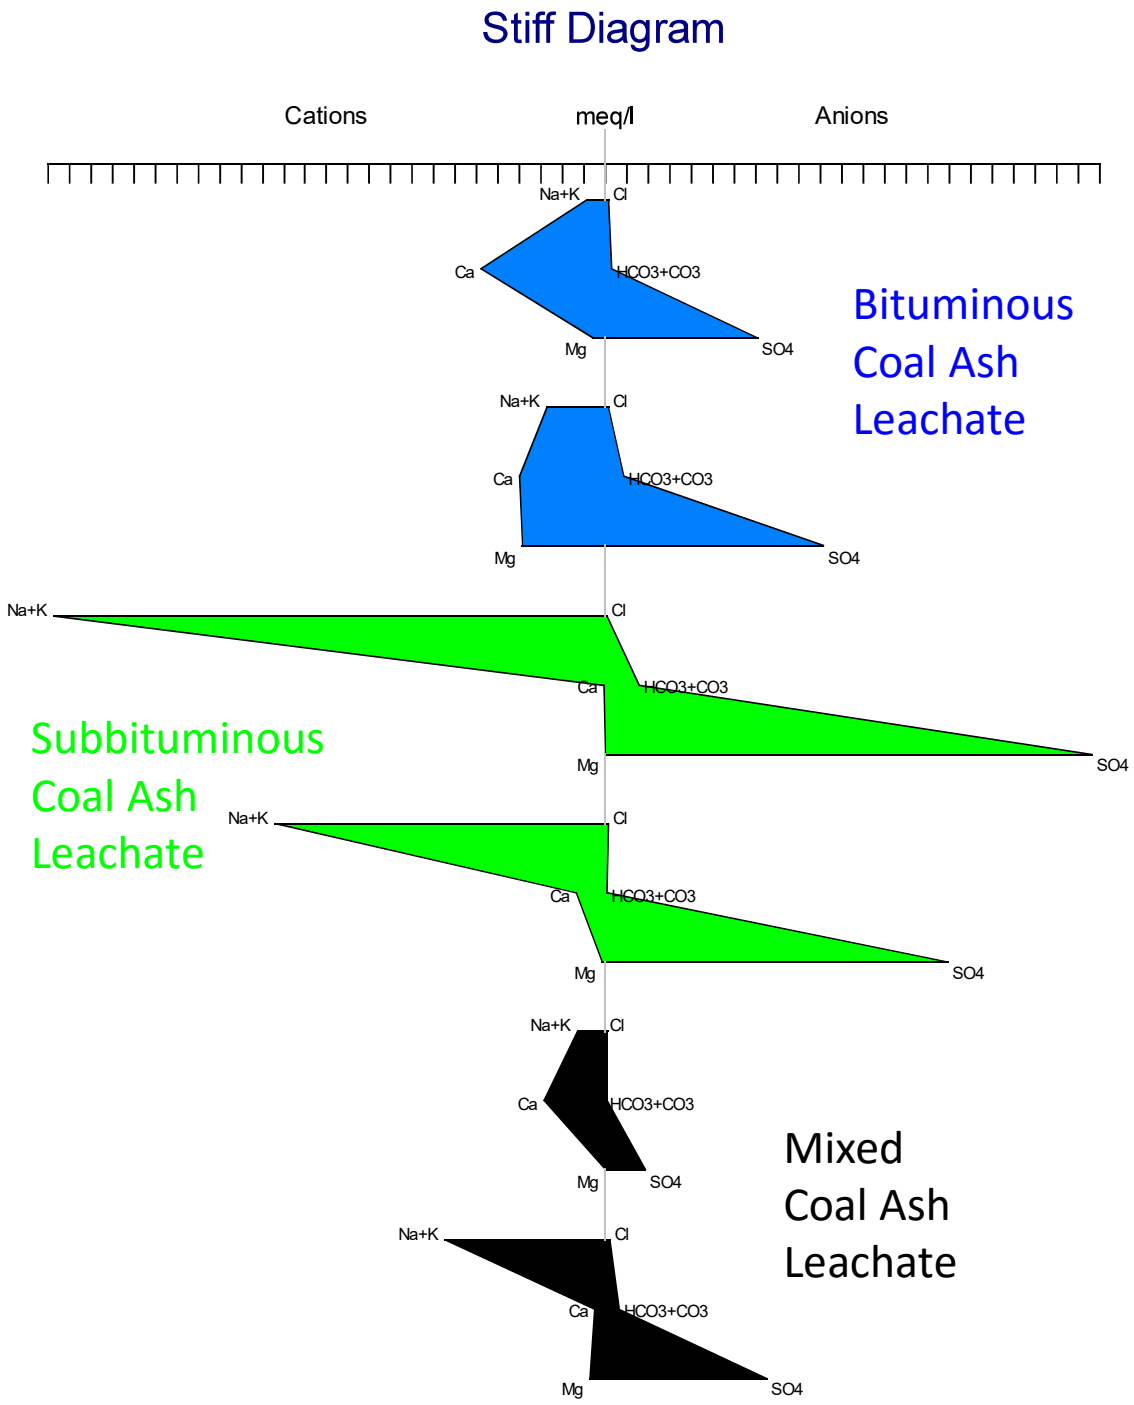

Figure 3-5
Stiff diagram showing six coal ash leachate samples (From EPRI, 2012)

Geochemical Modeling

Geochemical modeling is an additional Tier II geochemical method that can be used to evaluate the mobility of leachate or groundwater constituents based on chemical equilibrium and to potentially differentiate sources of groundwater contamination. Computer-assisted geochemical modeling has been used for many years to investigate the chemical equilibria of laboratory

extracts and field groundwater-leachate samples. EPRI (2017) discusses use of geochemical modeling to evaluate whether or not observed concentrations in a downgradient monitoring well can be a result of a groundwater flow path that includes mixing with CCR leachate.

Geochemical modeling can be used to identify the solid mineral phases that are controlling the solubility of dissolved cations and anions. Modeling can be used to identify whether dissolved constituents are thermodynamically favored to precipitate or remain in solution. Kinetic modeling attempts to identify the rate of chemical reactions. Such information is potentially useful for predicting the fate of dissolved constituents in a timeframe beyond the monitoring period. Kinetic modeling, however, may require additional information about the chemical and physical characteristics of the geomedia of the area under study.

Use of geochemical computer models requires entry of chemical characterization data for the groundwater sample(s) being evaluated. Analytical data, such as total sulfate or boron, are entered into the model, which will estimate the concentrations of several ionic forms (speciation) of each parameter. The model then calculates the degree of saturation of the liquid sample for hundreds of solid mineral phases. For example, if the liquid sample appears to be supersaturated with respect to a specific mineral, then that mineral is thermodynamically poised to precipitate from solution. Chemical precipitation may limit the movement of CCR constituents off-site.

The data required for chemical modeling are more extensive than those typically collected during a groundwater monitoring program. Most geochemical models require data for pH, ORP, alkalinity, and all the major anions and cations to ensure that the liquid sample is electrically balanced. In addition, solids data are often collected and used in the model to enhance confidence in results.

Multivariate Statistics

Multivariate statistics encompasses statistical analysis methods for evaluating more than two variables simultaneously and to determine how those variables relate to each other. Multivariate statistical techniques can be paired with geochemical modeling to determine the main sources of groundwater impacts in an aquifer, whether from a CCR leachate source, a naturally occurring source, or an anthropogenic source. Hydrogeological factors can also be co-evaluated with water quality data, including isotopic data from Tier III evaluations, using multivariate statistical methods. Although multivariate statistics is a powerful analysis tool for evaluating more complex datasets, it requires robust datasets, an experienced statistician, and a conceptual understanding of the input variables and their potential correlations. Computer software to perform multivariate statistical analysis relevant to environmental data is readily available.

Multivariate statistical methods utilized in the environmental field are typically correlation analysis, principal components analysis (PCA), and cluster analysis (CA). However, there are numerous other statistical methods available. Detailed explanations of the various multivariate methods available for statistical analysis are found in the following references:

- Anderson, T.W., 2003. An Introduction to Multivariate Statistical Analysis, Third Edition, John Wiley and Sons, Inc.
- Johnson, T.W. and D.W. Wichern, 2007. Applied Multivariate Statistical Analysis, Sixth Edition, Pearson Prentice Hall.

The scientific objectives identified by Johnson and Wichern (2007) for which multivariate statistics might be used include the following:

- **Data reduction or structural simplification**. To represent the information or conceptual model as simply as possible to aid in interpretation.
- **Sorting and grouping**. Groups of similar objects or variables are created based upon measured characteristics.
- **Investigation of dependence among variables**. Relationships between variables are evaluated to determine which variables might be independent and what two or more variables are dependent. From that information, the investigator might determine how the variables are related or what factor or feature they are related to.
- **Prediction**. Predicting the values of one or more variables based on observations of other variables. This is not a typical objective for an ASD evaluation.
- **Hypothesis construction and testing**. Testing of statistical hypotheses about multivariate populations to validate assumptions or reinforce other lines of evidence.

A brief description of a few of the more commonly used multivariate statistical methods pertinent to evaluation of groundwater and hydrogeologic data during an ASD is provided here, with the caveat that there are numerous other methods available.

Correlation Analysis can be performed on multiple variables, such as water quality constituents, to determine how much the variance of each constituent can be explained by the relationship with other constituents. Table 3-3 shows the Pearson product moment correlation matrix between pairs of variables measured in groundwater in background monitoring wells at a site. The correlation coefficients range between -1 and 1 and measure the strength of the linear relationship between the variables. The number of pairs of data values used to compute each coefficient was 60 (6 observations of each chemical parameter in groundwater per well for 10 wells). In the case of this dataset, correlations greater than 0.50 or less than -0.50 indicate statistically significant non-zero correlations at the 95 percent confidence level. Positive numbers indicate that the parameters are directly proportional, and negative numbers indicate that the parameters are inversely proportional. Bold-face numbers within highlighted boxes in the sample table indicate a high level of correlation between two parameters. Typically, correlation coefficients are rated as “high”, “medium”, and “low” (or “strong”, “moderate”, and “weak”) for values > 0.75, 0.75 to 0.50, and 0.50 to 0.30, respectively.

Table 3-3
Example Correlation Analysis Table

	Boron	Barium	Calcium	Chloride	Iron	Potassium	Lithium	Magnesium	Manganese	Sodium	Sulfate	TDS
Boron		0.13	-0.20	0.65	-0.02	0.25	0.47	-0.10	-0.04	0.63	-0.19	0.61
Barium			-0.11	0.77	**0.87**	0.38	0.28	-0.04	-0.16	0.73	-0.23	0.72
Calcium				-0.30	0.06	0.18	0.01	**0.98**	**0.81**	-0.34	**0.86**	0.00
Chloride					0.55	0.32	0.48	-0.17	-0.23	**0.94**	-0.37	**0.88**

Principal Components Analysis (PCA) is used to reduce data to a small number of significant factors (i.e., components) for analyzing relationships among variables. PCA can be performed to evaluate the spatial variations of groundwater quality data and determine possible sources of specific contaminants. An analysis of principal components may reveal relationships between variables that were not readily apparent or suspected (Johnson and Wichern, 2007), or may assist in removing variables from an analysis that have no bearing on the objectives of an investigation. PCA analysis may serve as an intermediate step to determining what factors to focus on in an investigation and to assist in developing multiple lines of evidence in an ASD.

Cluster Analysis (CA) is a descriptive statistical analysis method used to identify groupings (i.e., clusters) of samples or other variables. CA is used to reveal the latent structure within a data set and is an exploratory tool only. For example, the data from a site can be analyzed using cluster analysis to demonstrate the following:

- Groupings of samples from wells into clusters based on water quality as defined by the major cations and anions
- Groupings of samples from wells into clusters based on water quality of minor and trace elements
- Groupings of wells into clusters based on selected water quality parameters and/or hydrogeologic variables

CA analysis results can be presented in several ways. To visually interpret how the data have been categorized, a graphical depiction of the clusters can be shown with a dendrogram. The dendrogram is a linkage tree that first links those samples or parameters that have the greatest similarity. Each subsequent linkage (or cluster) is less similar than earlier linkages. The greater the distance on the y-axis between linkages, the lower the significance between the linked samples or variables. In the example dendrogram displayed below (Figure 3-6), the first clusters of trace elements in groundwater upgradient from a CCR unit are between barium and iron, and the next cluster is aluminum and lithium. The correlation coefficient {R} calculated for barium and iron is strong at R = 0.87. The R value for aluminum and lithium is moderate at 0.63. Next, barium-iron is clustered with strontium (R = 0.54 and 0.56, respectively) and aluminum-lithium

is clustered with boron (R = -0.02 and 0.47, respectively). Manganese concentrations in groundwater at the study site are very poorly correlated with all the other minor/trace elements, and there is no cluster formed with any other parameters.

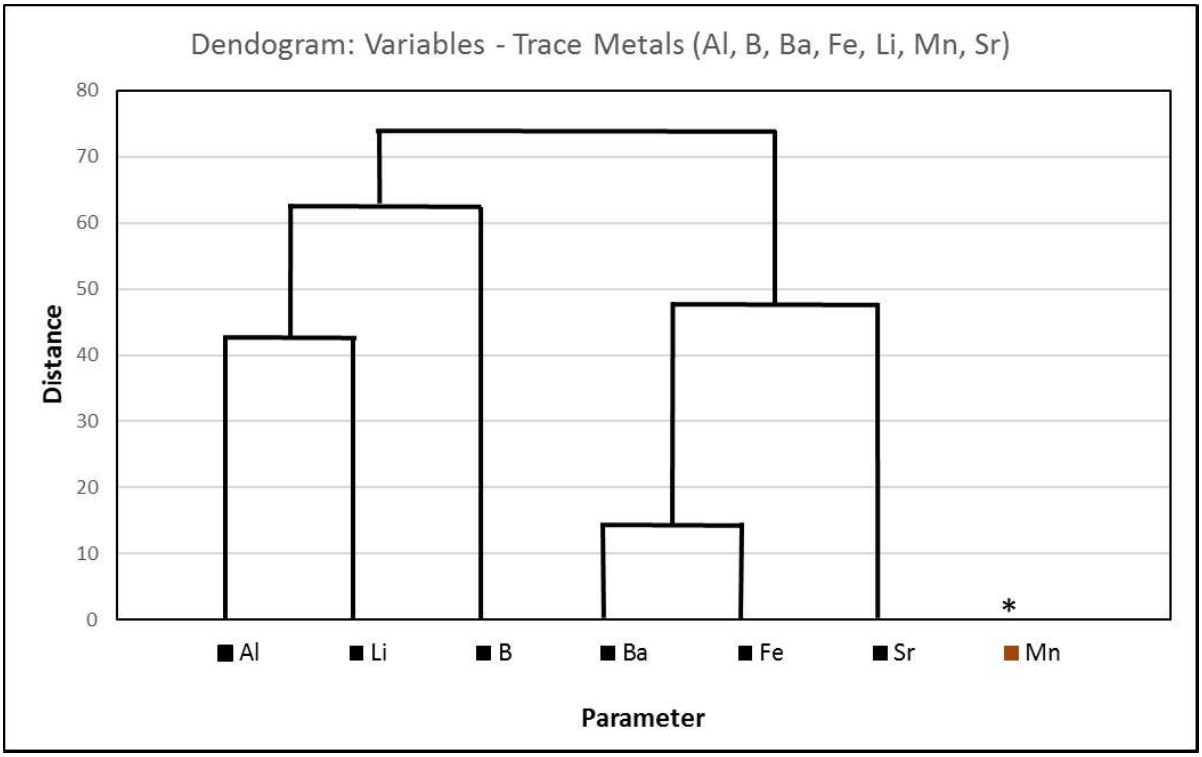

Figure 3-6
Example Cluster analysis dendrogram

Tier III Evaluation – Isotopic Analyses

Tier III uses isotopic analyses as a method to determine a groundwater signature. As described in EPRI (2017), isotopes have the same number of protons, but each form has a different number of neutrons. Because of this difference in atomic mass (neutrons plus protons), the isotopes will react differently with geomedia as they migrate in groundwater. These differences can be expressed as isotopic ratios, and can be used as diagnostic tools.

The application of isotopes as groundwater signatures is a relatively new technique, but boron isotopes are particularly relevant to CCR. Boron-11 is heavier than boron-10, and the heavier isotope is preferentially precipitated or sorbed from solution. Changes in the ratio of these two isotopes can yield information about the source of boron in the groundwater. Available data suggest that CCR leachate is often isotopically light, while groundwater may be isotopically heavy. Other isotopes that may be useful include strontium, oxygen, and hydrogen. EPRI (2012 and 2017) provides a comprehensive review on the use of boron and selected other isotopes as groundwater signatures.

Another form of isotopic analysis is tritium age dating. As discussed in EPRI (2017), tritium has a relatively short half-life of 12.3 years. Furthermore, there was an accumulation of tritium in the atmosphere in the early 1960s due to atmospheric atomic bomb testing. These two observations

enable use of tritium data to determine whether or not groundwater recharged prior to atmospheric testing of atomic bombs (i.e., prior to the 1960s) or since that time. If a CCR site was built during or after the 1960s, but the groundwater does not have detectable levels of tritium (meaning it recharged prior to the 1960s), that provides a line of evidence that an SSI/SSL is not due to a release from that site because the leachate from such a site would have detectable levels of tritium that should be evident in the downgradient groundwater.[7]

Hydrogeologic Scenario Evaluation

Hydrogeologic scenario evaluation is another line of evidence that can be used in an ASD. The premise is that if a mobile and non-reactive constituent is released to groundwater, it will travel in groundwater with a predictable concentration profile unless mixed with water from other sources that have significantly different concentrations of the same constituent. Following the ion ratio approach discussed above, the downgradient concentration of the mobile, non-reactive constituent of concern should be proportional to the mixing ratio of the relative volumes and concentrations of all sources combined and collected at the downgradient monitoring point.

Figure 3-7 presents a variety of hydrogeologic scenarios comparing leachate concentration of a mobile, non-reactive constituent to the concentrations observed in upgradient and downgradient wells. Groundwater flow directions are also considered to point out that some downgradient monitoring wells may be in a side-gradient or partial intercept path rather than in the direct path of the monitored upgradient groundwater. Each column in Figure 3-7 presents two to three hydrogeologic scenarios as follows:

- Column 1 – Scenarios providing a line of evidence that a CCR facility is the source of an SSI/SSL.
- Column 2 – Scenarios providing a line of evidence that both a CCR facility and a possible alternative source are the source of an SSI/SSL.
- Column 3 – Scenarios providing a line of evidence that an alternative source is causing an SSI/SSL.

The basis for these scenarios is fairly straightforward:[8]

- If leachate concentration is less than background, leachate cannot cause downgradient concentrations to be higher than background, and an alternative source is indicated.
- If downgradient concentrations are greater than leachate concentrations, an alternative source (natural or anthropogenic) must be present.

These scenarios, particularly those shown in columns 2 and 3 of Figure 3-7, demonstrate the benefit of multiple upgradient monitoring wells. This benefit is also realized for intrawell statistical programs if there is any potential for naturally occurring or anthropogenic changes in groundwater quality upgradient of the monitored unit.

[7] This line of evidence may not be valid in the case of a pond where "old" groundwater, for example from a deep aquifer, was used for sluice water.

[8] Assuming that leachate and background concentrations are well-characterized.

	Line of Evidence for:		
	CCR Leachate Release	**Possible CCR Leachate Release + Possible Alternative Source**	**Alternative Source Release**
	Column 1	**Column 2**	**Column 3**
Row a			Row b			Row c			
	1. Leachate concentration is higher than upgradient/background. 2. One or more downgradient concentrations are higher than upgradient/background but lower or equal to leachate concentration.	1. Leachate concentration is higher than upgradient/background. 2. One or more downgradient concentrations are higher than the leachate concentration.	1. Leachate concentration is less than upgradient/background.

Figure 3-7
Example hydrogeologic lines of evidence

Time-of-Travel Evaluation

Time-of-travel for a mobile and non-reactive source constituent to a downgradient monitoring well can also be considered as a potential line of evidence for connecting a source to an elevated result at a downgradient monitoring location. It takes time for a source constituent to travel downward to reach the aquifer and then travel within the aquifer to the downgradient monitoring location. For example, if groundwater velocity is 50 ft/year, assuming minimal dispersion, it would take about two years for a release to reach a monitoring well 100 feet from the waste boundary *if* the release occurred at the waste boundary, and *assuming* a relatively thin unsaturated zone. It would take more than two years if the release occurred toward the center of the facility as opposed to the waste boundary of a lined facility, or if there was a thick unsaturated zone. Since the permeability of different geological media such as sand, gravel, clay, silt, and fractured bedrock can vary considerably, time-of-travel evaluation requires knowledge of site and regional hydrogeology. If this information is available, it can be used to identify or discredit potential sources. Horizontal groundwater flow velocity through a uniform (homogeneous) water-bearing unit with no preferential flow direction (i.e., anisotropic), is calculated as follows:

$$V = K i / n_e$$

V = Groundwater Velocity
K = Hydraulic Conductivity
i = Hydraulic Gradient (unitless value)
n_e = Effective Porosity

Simple analytical models such as MYGRT (EPRI, 2005), or more advanced fate and transport models, can also be used for this evaluation. Models can account for dispersivity, which is not accounted for in the equation above.

4
NATURAL VARIATION

Natural variation encompasses natural variation in background levels and variability due to geologic influences such as dissolution of geomedia and natural ion exchange, changes in groundwater quality and/or flow related to precipitation such as changing water levels in monitoring wells, groundwater recharge and discharge fluctuations near surface water bodies, and time-of-travel for monitoring wells to detect upgradient changes, as well as influences related to changes in pH, oxidation reduction potential, and biological activity. These interactions, and how they may affect groundwater quality, are discussed below.

Changes in Mineralogy Along a Groundwater Flow Path

The mineralogy of soils and rocks near the monitored CCR unit can affect the natural chemistry of groundwater. For example:

- Geomedia such as limestones and certain sand units that are rich in carbonates can add calcium to the groundwater.
- Geomedia with little carbonates lack buffering capability that can enable changes in chemistry if low-pH recharge from precipitation reduces the overall pH of the aquifer along the flow path.
- Geomedia that contain reactive clay minerals can alter the chemical composition of groundwater by dissolution-precipitation reactions, and by either removing (by sorption) or adding (by desorption) solutes along the flow path.

The extent of the reactions can be pH-dependent, which may depend on changes in mineralogy. These examples underscore the importance of placing background monitoring wells in the same geomedia as compliance monitoring wells. If background and compliance wells are in different geomedia,[9] then SSIs/SSLs due to this natural variation and unrelated to a release from the facility are possible, and even likely. An ASD in this case would highlight the mineralogical differences between the geomedia and constituents expected to be affected.

Changes in pH Along a Flow Path or over Time

If pH is different between background and compliance wells, and/or changes over time, it can cause chemical changes capable of triggering an SSI/SSL. Examples of concentration changes that can occur due to a change in pH are illustrated in Figure 4-1 and the text that follows. For the purposes of an ASD, if there is an SSI/SSL at a monitoring well where pH is different from

[9] It is not always possible to screen background wells in the same geomedia as compliance wells. In these cases, intrawell statistical analysis can avoid this form of natural variation; however, intrawell analysis may not be an option in certain detection monitoring plans if monitoring wells have already been affected by a release.

or has changed from background (SSI) or baseline (SSL), and the constituent with the SSI/SSL is sensitive to changes in pH, then the pH difference can be a line of evidence in an ASD.

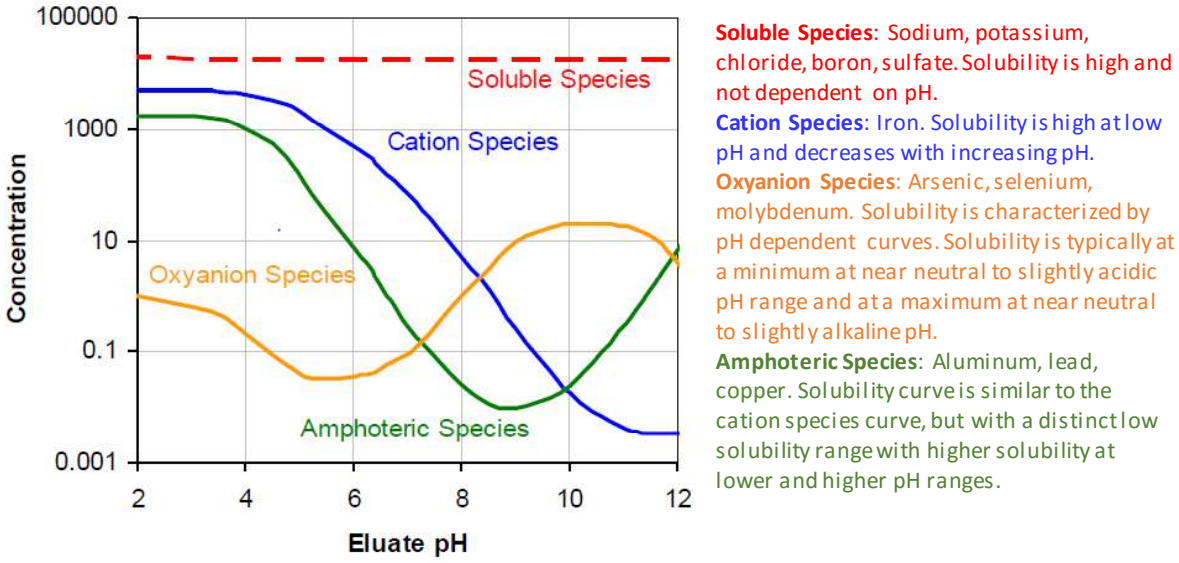

Figure 4-1
Typical solubility behavior of various constituents as pH changes (EPRI, 2007)

Soluble species such as sodium, potassium, chloride, boron, and sulfate tend to have relatively high solubility that is not affected by changes in pH. Cation species such as iron usually have higher solubility at low pH and minimum solubility at high pH.

Oxyanion species include elements such as arsenic, selenium, and molybdenum that react with oxygen or hydroxide to form anions. The solubility of oxyanion species varies with pH and often ORP because their chemical form changes as these two variables change. For example, the specific form of arsenic in solution depends on both pH and ORP. Under highly alkaline conditions (pH > 11), the dominant form of arsenic is AsO_4^{3-}. In relatively acidic groundwater (pH < 7), the dominant form is $H_2AsO_4^-$ under oxidized conditions, and $As(OH)_3$ under reduced conditions. The solubility curves of oxyanions characteristically have minimum solubility at near neutral to slightly acidic pH and maximum solubility at slightly alkaline pH.

Amphoteric species such as aluminum, lead, and copper have solubility curves similar to the cation species; however, they typically exhibit a range of minimum solubility, with higher solubility at lower and higher pH ranges.

Changes in Redox

Similar to a change in pH, a change in the redox state of the groundwater can have a significant impact on the concentration of some constituents in groundwater. If there is an SSI/SSL at a monitoring well where there is indication that redox is different from or has changed from background (SSI) or baseline (SSL), and the constituent with the SSI/SSL is sensitive to changes in redox, then the redox change can be a line of evidence in an ASD (Figure 4-2).

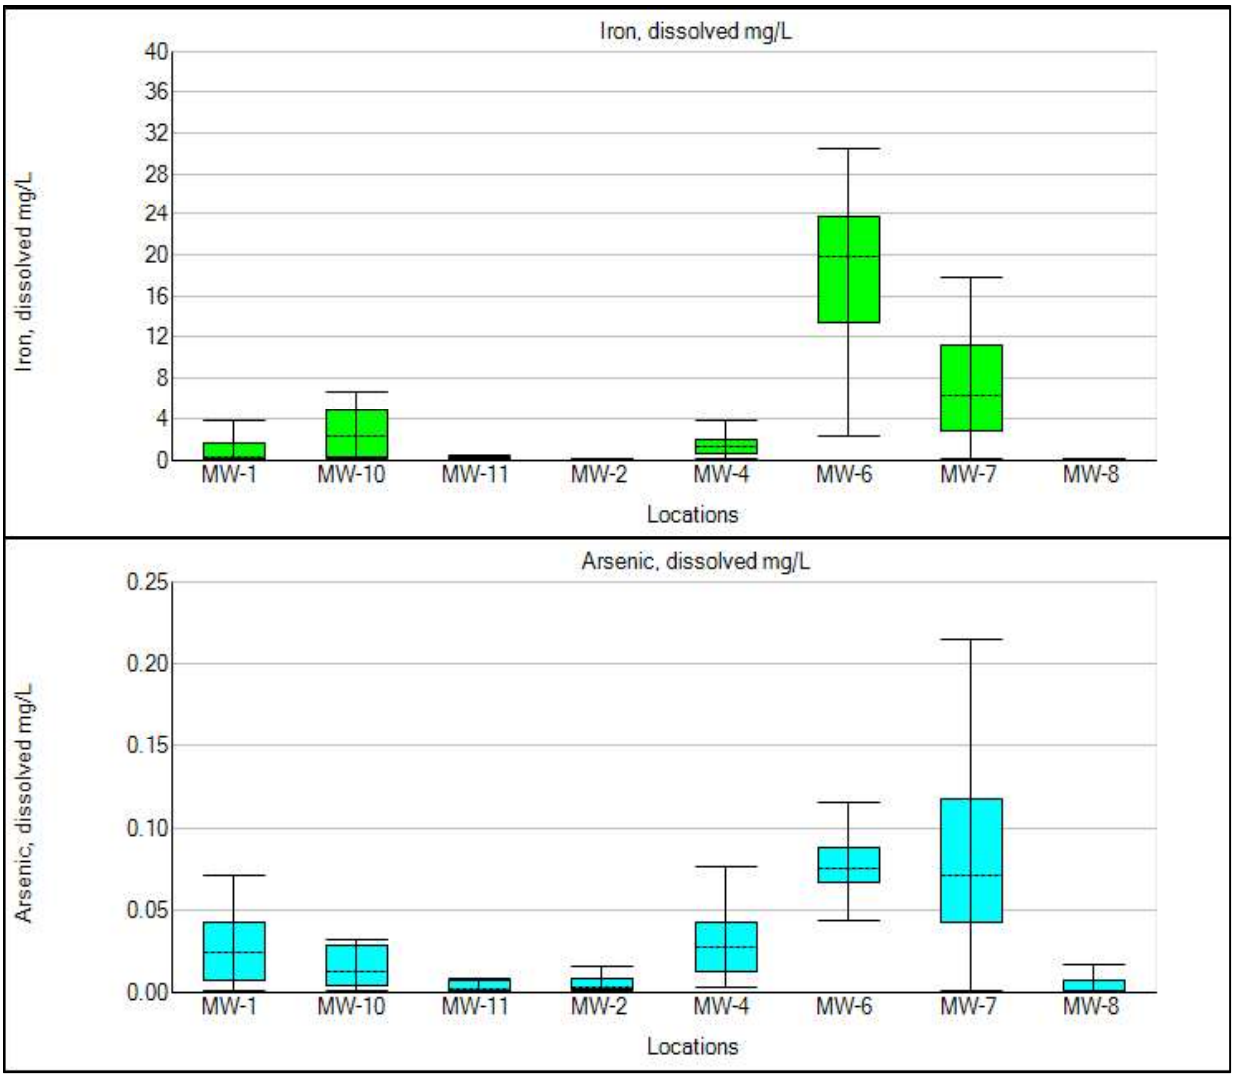

Figure 4-2
Example ASD line of evidence where elevated arsenic concentrations occur in monitoring wells with elevated iron, indicative of reduced conditions

The term redox refers to reduction-oxidation. Oxidation is the loss of electrons or an increase in the oxidation state of an ion or molecule. Reduction is the gain of electrons or a decrease in the oxidation state of an ion or molecule. In a more practical sense, the redox potential of groundwater reflects the dissolved oxygen content. Oxic water has higher levels of oxygen—if an element has multiple oxidation states in groundwater, then the species with a higher electrical charge will be prevalent in an oxic environment. Reduced groundwater typically has low dissolved oxygen content—the species with a lower electrical charge will be prevalent in a reduced environment. Redox potential, Eh, ORP, and pE are all measures of redox state. In addition, concentrations of iron and manganese can be used as indicators of redox state in groundwater because these constituents tend to have low concentration in oxic groundwater and high concentration in reduced groundwater.

Examples of redox-sensitive constituents include, but are not limited to the following:

- Naturally occurring sulfide minerals in reduced soils may form soluble sulfate if exposed to oxygen—which can occur when a monitoring well is installed, resulting in a naturally occurring increase in sulfate concentration in that monitoring well. Conversely, under strongly reducing conditions, sulfur in groundwater can convert from sulfate to hydrogen sulfide gas, with a corresponding reduction in sulfate concentration.
- Under oxidized conditions, arsenic in groundwater occurs in the 5+ oxidation state as arsenate (AsO_4^{3-}), but under reducing conditions it occurs in the 3+ oxidation state as arsenite (AsO_3^{3-}) and is more soluble and mobile. It is not uncommon to see naturally occurring arsenic in reduced groundwater. Conversely, if arsenic-containing sulfide minerals are present in an aquifer under reduced conditions, introduction of oxygen, for example by installing a monitoring well, can result in release of arsenic to groundwater in the vicinity of the monitoring well.
- The solubility and speciation of selenium in groundwater is dependent on the pH and ORP of the solution. In highly oxidized solutions, selenium exists as highly mobile selenate. Over a relatively large range in pH and ORP, selenium occurs in the selenite forms as $HSeO_3^-$ and SeO_3^{2-}. Under oxygen-poor conditions, the concentration of selenium in groundwater (as HSe^-) may be controlled by the solubility of ferroselite ($FeSe_2$). Because anionic selenium is the dominant form of the element in groundwater, sorption may not be significant by many types of geologic media.
- Boron, molybdenum, lithium, and cobalt concentrations are not significantly impacted by the range of redox commonly observed in groundwater.

Influence of Biological Activity

The potential for biologically mediated chemical reactions should not be overlooked. Some of the redox reactions described above, particularly release of naturally occurring arsenic, can be biologically mediated. For example, when pyrite (ferrous sulfide) deposits (commonly present in coal) are exposed to air by mining operations, oxidation and release of ferric iron, sulfate, and sulfuric acid can be accelerated by bacteria that thrive in a low-pH sulfuric acid environment, accelerating the reaction and increasing the release of sulfuric acid and other minerals present in the geomedia that are more soluble in low pH and/or oxidizing environments, such as arsenic. Another example of natural microbial redox activity in geomedia is oxidation of ammonia nitrogen to nitrate and/or nitrite compounds. As discussed in Section 5, the presence of ammonia, nitrate, or nitrite in CCR monitoring wells is typically related to agricultural activities; however, it may also be due to leaching of ammonia compounds deposited on fly ash or FGD solids due to the use of ammonia in selective catalytic reduction (SCR) and selective non-catalytic reduction (SNCR) emission control technology for reduction of nitrogen oxide emissions.

Changes in Groundwater Elevation at Compliance Wells

In some cases, groundwater can be naturally stratified, for example if shallow groundwater is oxic and deeper groundwater is reduced. Stratification may also occur near groundwater discharge points where upwelling of deep groundwater, which may have higher dissolved solids content than shallow groundwater, may be occurring. Stratification is also common near oceans

where saltwater wedges form beneath fresh water due to the higher density of seawater. When there is a natural stratification of groundwater quality, changes in groundwater elevation can trigger a naturally occurring SSI/SSL if the deeper water rises and intersects the monitoring well screen.

Such changes in groundwater elevation can be due to precipitation/recharge events, or changes in elevation at nearby groundwater discharge points such as rivers (which can also affect flow direction as described next). Changing groundwater elevation can be a line of evidence for an ASD if there is evidence that the groundwater is naturally stratified. A hydrograph showing a change in groundwater elevation (up or down) that corresponds with the SSI/SSL may be useful in supporting this cause.

Changes in Groundwater Flow Direction at Compliance Wells

Groundwater flow direction naturally exhibits variability. For many sites, this variability may not be significant; however for some sites, flow direction can vary by as much as 180 degrees. Inland locations may have relatively narrow ranges of variability, such that groundwater flow is usually in one broad direction. Sites along rivers can exhibit very large ranges of variability, including complete flow reversals, that are dependent on river stage. Much of this variability will be accounted for during the background monitoring period. However, if the background monitoring was performed during a period of little variation, or if there is an extreme hydrologic event such as a 100-year (or larger) flood, then groundwater flow can change in a way that was not accounted for during the background monitoring period, and if there is aerial variability in groundwater chemistry, then this change in flow direction can trigger an SSI/SSL due to natural variation in groundwater flow direction.

If groundwater flow direction at the time of, or prior to, sampling for an SSI/SSL is different than flow directions that occurred during the background monitoring period, then that is a line of evidence for a naturally occurring ASD. Groundwater flow direction is not typically monitored between sampling events, so a change in flow direction prior to a sampling event may need to be demonstrated based on indirect evidence such as river hydrographs showing that a particular river stage was not representative of the background monitoring period.

Another ASD consideration with changes in groundwater flow direction is detection of an alternative anthropogenic source that had not previously been detected. While the cause of the SSI/SSL in this case is not natural variation, the detection of the alternative source is due to natural variation.

Time-of-Travel Consideration for Natural Variation

As noted in Section 3, there will be a time lag between the time that a change in concentration affects background groundwater and when that same change is detected in downgradient groundwater. Just as it takes time for somebody to walk from point A to point B, it takes time for water to travel through geomedia. Methods for calculating that time lag are presented at the end of Section 3.

If a change in concentration is noted at an upgradient monitoring location, and a similar change at a downgradient well triggers an SSI/SSL at a later date, then a line of evidence for an ASD can be developed if it can be demonstrated that the detected constituents are the same as detected in

the upgradient well, and the time lag is consistent with groundwater velocity between the upgradient and downgradient locations.

This line of evidence applies to both natural variability and upgradient anthropogenic sources. A natural variability example would be a case where pH changes in groundwater chemistry affect upgradient locations before downgradient locations.

5
ANTHROPOGENIC IMPACTS TO GROUNDWATER

When considering alternative sources that may be contributing to an SSI/SSL, it is important to investigate the site and surrounding area for current and historical land uses. Mapping descriptions and locations of current and historical land uses near the CCR unit, along with groundwater flow direction and locations of surface water bodies, can narrow the list of likely alternative anthropogenic sources and identify constituents to look for that may point to an alternative source (Figure 5-1).

If the CCR unit is on or near a power plant, note the past and current locations of coal piles, impoundments, landfills, underground and aboveground oil storage tanks, known oil and chemical spill areas, CCR transport routes (i.e., haul roads and sluice lines) and processing areas, and areas where ash or other fill material has been used as structural fill. This information may help identify on-site activities that may be contributing to an SSI/SSL.

Understanding the area surrounding the CCR unit can guide the ASD investigation, because the groundwater signature often reflects the combined local land uses. Land uses and/or features that may be near coal-fired power plants are discussed below. Tables A-3 and A-4 in Appendix A list activities that can affect the groundwater concentrations of constituents monitored at CCR management facilities by constituent and by activity, respectively.[10]

[10] Tables A-3 and A-4 are also presented in Section 2 as Tables 2-2 and 2-3.

Figure 5-1
Examples of anthropogenic activities near a CCR unit with potential to affect groundwater quality in one or more monitoring wells, depending on the direction and variability of groundwater flow.

Power Plant Land Use and Operations

Power plant operations including other CCR impoundments and landfills, as well as historical land uses, can be reviewed as potential alternative sources, depending on their location relative to groundwater flow at the CCR unit with the SSI/SSL and the water quality signature. Areas to evaluate during the ASD include areas of coal or coal ash spillage, coal piles and coal pile runoff conveyance structures, underground storage tanks, underground piping, locations of past chemical spills, and other CCR management facilities.

Preparation of subgrades to achieve favorable power plant building conditions may have required low areas to be filled with structural fill. Historical requirements for fill material were not as strict as current standards for leachability and therefore, materials such as fly ash, bottom ash, construction debris, demolition debris, dredge spoils, and/or incinerator residue may have been used as fill material, particularly at older power plant sites. If these types of materials are present, they may contribute leachate to groundwater from random, non-point source locations. If historical fill practices are a potential concern, consider researching fill locations and material types and quality by reviewing historical fill maps and aerial photographs, reviewing historical fill records with sampling data and/or fill material descriptions, reviewing information available on neighboring properties, and interviewing knowledgeable persons and neighbors.

Historical ash management practices may have included on-site use of fly ash and/or bottom ash for fill, road base, berm construction, and other structural applications. Ash may also have been piled in various areas for dewatering or temporary storage or transfer to trucks. Former ash ponds and/or landfills may have been covered and closed on-site, or may have a residual contribution to groundwater contamination.

Current or past ash handling practices may also have allowed for dispersion of ash and subsequent accumulation in plant sumps, storm water swales and ponds, and other low-lying areas. In particular, wind-blown ash may accumulate in ditches, or leachate sprayed for dust control on an active landfill face may be blown off the lined area where it can infiltrate. Such conditions can contribute to localized, elevated groundwater concentrations with ash leachate signatures. It is important to be aware of these activities and their locations because their presence can result in SSIs/SSLs, but from sources other than a release from the liner/base of the monitored CCR unit.

Contaminants from underground storage tank (UST) leaks, aboveground tank and transformer leaks, underground oil piping leaks, or oil and/or chemical spills may also cause groundwater impacts, the extent of which depends on the severity and duration of the leak or spill. Oil-based contamination primarily involves organic constituents; however, trace elements may also be of concern. For example, biological activity associated with a petroleum plume may result in biologically mediated arsenic release from minerals in the aquifer. Therefore, it is important to be aware of site history as it relates to major oil and chemical spills, and UST and underground piping leaks in case these issues may potentially be impacting CCR monitoring.

If an on-site anthropogenic source is suspected, consider testing for additional analytes such as organics (to diagnose oil-related contamination), and/or all major ions to enable use of Tier II geochemical analysis to help determine similarity and source of groundwater collected at the monitoring wells. Other constituents such as aluminum, iron, and manganese may also be helpful in fingerprinting potential alternative power-plant-related groundwater impacts. Perhaps most

importantly, knowledge of site history can be very helpful in determining whether or not alternative plant-related sources are positioned upgradient of wells where an SSI/SSL was determined.

Agricultural Activities

If the CCR unit is located in an area with upgradient farmlands or livestock, then groundwater impacts associated with these agricultural activities can be evaluated for an ASD. Agricultural impacts to groundwater are possible due to its prevalence and the use of irrigation water, fertilizers, and pesticides to support optimal plant growth. The most common constituents of concern include nitrogen compounds (nitrate, nitrite, and ammonium) and phosphorus compounds associated with fertilizers, runoff from animal feedlots, and the use of manure for crop fertilization; however, other inorganic constituents may also come from agricultural sources (refer to Table A-4).

Relatively high levels of nitrate, nitrite, and/or ammonium ions in groundwater are indicators of agricultural impacts. Consider analyzing for these constituents, particularly in upgradient wells, if groundwater degradation from surrounding agriculture is possible.

If the power plant that produced the CCR utilizes SCR or SNCR technology, ammonia compounds may have adsorbed onto the ash (usually as ammonium bisulfate or ammonium sulfate) and may subsequently be released to groundwater as ammonium ions. Biological activity may convert the ammonium ions into nitrate and/or nitrite. Nitrogen compounds also may occur naturally in soil due to fixation by bacteria in the root nodules of legume plants, such as soybeans and alfalfa. Therefore, when considering a potential alternative source demonstration related to nitrogen compounds, consider agricultural activities surrounding the CCR management unit, the potential for natural occurrence associated with legumes, and the processes used to produce the CCR. It may be difficult to distinguish between naturally occurring nitrates/nitrites and those present due to leaching from fertilizers, animal wastes, or ammoniated CCR. However, phosphorus is not a common constituent of CCR, so the presence of elevated concentrations of phosphorus in groundwater typically points towards agricultural sources.

In addition to nitrogen and phosphorus, agricultural activities may also contribute trace elements, salts, herbicides, pesticides, and pathogens to the groundwater. Because herbicides, pesticides, and pathogens are not monitored under the CCR Rule, they are not discussed in more detail here, but if they are known to be present, their presence indicates a source other than CCR.

Salts and trace elements may leach into groundwater as a result of agriculture, particularly in arid western regions of the United States that rely heavily on irrigation to support agricultural activity (Carter, 1980). This is particularly a concern if the native soils originated from marine mud and sediments that may contain elevated concentrations of arsenic, boron, calcium, chloride, magnesium, mercury, molybdenum, nitrate, potassium, selenium, sodium, and sulfate, and/or if the irrigation water is salty.[11] Selenium is a common constituent of concern in these environments (Fio et al., 1991). Use of salty irrigation water can result in salt deposition and the

[11] http://www.waterboards.ca.gov/waterrights/water_issues/programs/bay_delta/docs/cmnt081712/cwin/cwinappendix_a.pdf

need for increased irrigation to flush salts from the root zone of the crops, resulting in increased leaching of these salts and trace elements to the receiving groundwater. Distinguishing between agricultural sources and CCR sources may be challenging in this situation. Evaluation of nitrogen and phosphorus compounds and/or use of Tier 2 geochemical methods can be used to try to distinguish between sources. Another evaluation option in this case is analysis for boron isotopes.

Road Salting

Use of salt or salt spray for road deicing can affect groundwater quality near roads in northern climates (Kelly et al., 2009). Common types of salt used for road deicing include sodium chloride, calcium chloride, magnesium chloride, and potassium chloride. High chloride concentrations in groundwater observed during detection monitoring may be due to road salting rather than a release from the monitored facility.

Leaking Underground Pipes

In large urban areas, liquid waste including household and commercial sewage, storm water runoff, and industrial wastewater, is transported to treatment facilities in underground pipes. Under certain conditions (i.e., leaks and outward flow) this underground infrastructure may serve as conduits to transport contaminants from their original source to other areas that may be difficult to connect with the source. If the groundwater quality signature indicates an anthropogenic source, but does not resemble CCR, and no other anthropogenic source is apparent, then it may be worthwhile to investigate whether or not leakage from underground pipes is a potential alternative source.

Gasoline (Gas) Stations

Leaking underground storage tanks (LUSTs) at gas stations containing gasoline, diesel, kerosene or oil are a common source of groundwater contamination. As of March 2012, over 504,000 leaks had been recorded from federally regulated LUSTs in the United States.[12] The associated groundwater contaminants include benzene, toluene, ethylbenzene, xylene, lead, MTBE (a gasoline additive), ethylene dichloride, and naphthalene. If the gas station included a service shop, other compounds that may be released include trichloroethylene, perchloroethylene, methylene chloride, carbon tetrachloride, oils, ethylene glycol, motor oil, hydraulic fluid, detergents, and acidic solutions. These compounds are not present in CCR leachate, so their presence in groundwater indicates a source other than CCR leachate.

Septic Systems

Septic systems are potential sources of nitrate, phosphorus, chloride, organic substances, bacteria and viruses, detergents, oils, salts, septic tank cleaners such as trichloroethane or methylene chloride, and a wide variety of other chemicals.[13] These systems rely on the capacity of the native soils to attenuate, and naturally occurring microbes to digest, elements and compounds

[12] http://earthrepair.ca/resources/scenarios/gas-stations/

[13] http://infohouse.p2ric.org/ref/01/00065.htm

contained in the sewage. If improperly located, designed, constructed, or maintained these systems may fail or inadequately treat the effluent. If spaced too closely due to residential population density, these systems may exceed the capacity of the local soil to assimilate the chemical loads. High concentrations of chloride, nitrate, phosphorus, and/or sodium provide a line of evidence for an ASD for monitoring wells downgradient of areas where septic systems are used.

Mineral and Oil Extraction

Mining (Non-Coal)

Leaching from slag piles and other mining-related activities can result in groundwater quality impacts. If the background monitoring does not fully characterize these impacts, then SSIs/SSLs are possible. The water quality signatures from mining sources are highly variable depending on the substance being mined and the composition of the local soils, but common constituents include phosphates, sulfates, fluorides, and trace elements. Furthermore, if pyrite (FeS_2) was exposed to oxygen and water from the mining process, the drainage may be acidic (low pH) and have high iron and sulfate concentrations, as discussed next.

Major ion chemistry may provide a line of evidence for an ASD in this case if groundwater at the monitoring well(s) with an SSI/SSL plots in a region of the Piper diagram that is not between leachate and background groundwater. Isotopic analysis may be also considered, although unless an isotopic signature is available for the suspected mining source, it would only demonstrate that the CCR is or is not the source of an SSI/SSL. As with all potential upgradient sources, a stronger line of evidence would be installation of an intermediate monitoring well if it is possible to install such a well downgradient of the suspected mining-related source *and* upgradient or side gradient of the CCR units.

Coal Mining

The coal mining process exposes underground coal, as well as stock piles of coal and coal refuse, to oxygen and moisture, which results in oxidation of the pyrite (iron and other sulfides). The resultant leachate has high concentrations of iron and is acidic due to high concentrations of sulfuric acid. As the acidic leachate moves through the natural environment, it breaks down clay, and silicate and carbonate minerals releasing silica, aluminum, calcium, magnesium, and manganese. Concentrations of trace elements including chromium, cobalt, copper, nickel, and zinc may also increase above background levels (USEPA, 1980). The solubility of most of these elements is higher under acidic conditions. If limestone is present near the mining site, the acidic water may be neutralized by the calcium carbonate alkalinity of the limestone, and the concentrations of these elements may decrease. If the soil does not have this inherent alkalinity, the acidic water, known as acid mine drainage, may migrate from the mine site as contaminated groundwater or surface water. Mine-impacted groundwater may travel to deeper or more distant aquifers along fractures, seams, mining tunnels, and other subsurface conduits, sometimes making it difficult to trace the source.

Building an ASD where coal mining impacts are the suspected source of an SSI/SSL may require multiple lines of evidence because the water quality signatures may be only slightly different from that of groundwater mixed with CCR leachate. An obvious line of evidence for an ASD

would be the presence of a coal mine in an upgradient position. Other lines of evidence may include pH differences if the CCR leachate is alkaline, since the coal mining leachate would be expected to be acidic; absolute concentrations if it can be demonstrated that groundwater has higher concentrations for some constituents than CCR leachate; and Tier II data comparison techniques such as geochemical modeling, multivariate statistics, and/or FALCON. Isotopic analysis would need to look at more than boron and strontium, since the coal may have similar isotopic ratios, and could also include hydrogen and oxygen isotopes to build an isotopic signature.

Oil and Gas Production

Hundreds of thousands of wells have been drilled in the United States for oil and gas exploration, production, and brine disposal. Brines with high concentrations of dissolved solids are extracted with oil and gas and separated from the oil and gas at the land surface. The brines, called produced water, are stored in tanks or surface impoundments until they are disposed, often by reinjecting back into the subsurface oil and gas formation. Mechanisms for brine release include leaks from tanks, impoundments (which are usually lined but were not always lined in the past) and piping. Oil field brines may also be released to groundwater if there is a leak in the casing of an injection well. In addition, abandoned oil and gas wells can act as direct conduits for vertical oil field brine migration if the seal is incomplete or has failed. Vertical migration via abandoned oil and gas wells can occur either up or down, depending on a variety of factors. Pressure-induced upwelling of brine from depth to shallow aquifers is most relevant for ASD purposes.

Multiple lines of evidence may be available for an ASD where impacts from oil field brines are suspected. Oil field brines can have elevated boron, chloride, and other constituent concentrations. The first line of evidence would be confirmation that oil and gas production occurred in the area of the CCR unit—such areas are commonly mapped by state geological surveys. Another line of evidence is major ion chemistry, because brines have high chloride concentrations while coal ash leachate has high sulfate concentration. Brines can have much higher total dissolved solids (TDS) than CCR leachate, and depending on the level of dilution in groundwater, absolute concentrations of constituents such as barium may be higher in the monitoring well than in the CCR leachate. Ion ratios may also yield a considerably different signature than CCR leachate (Figure 5-2).

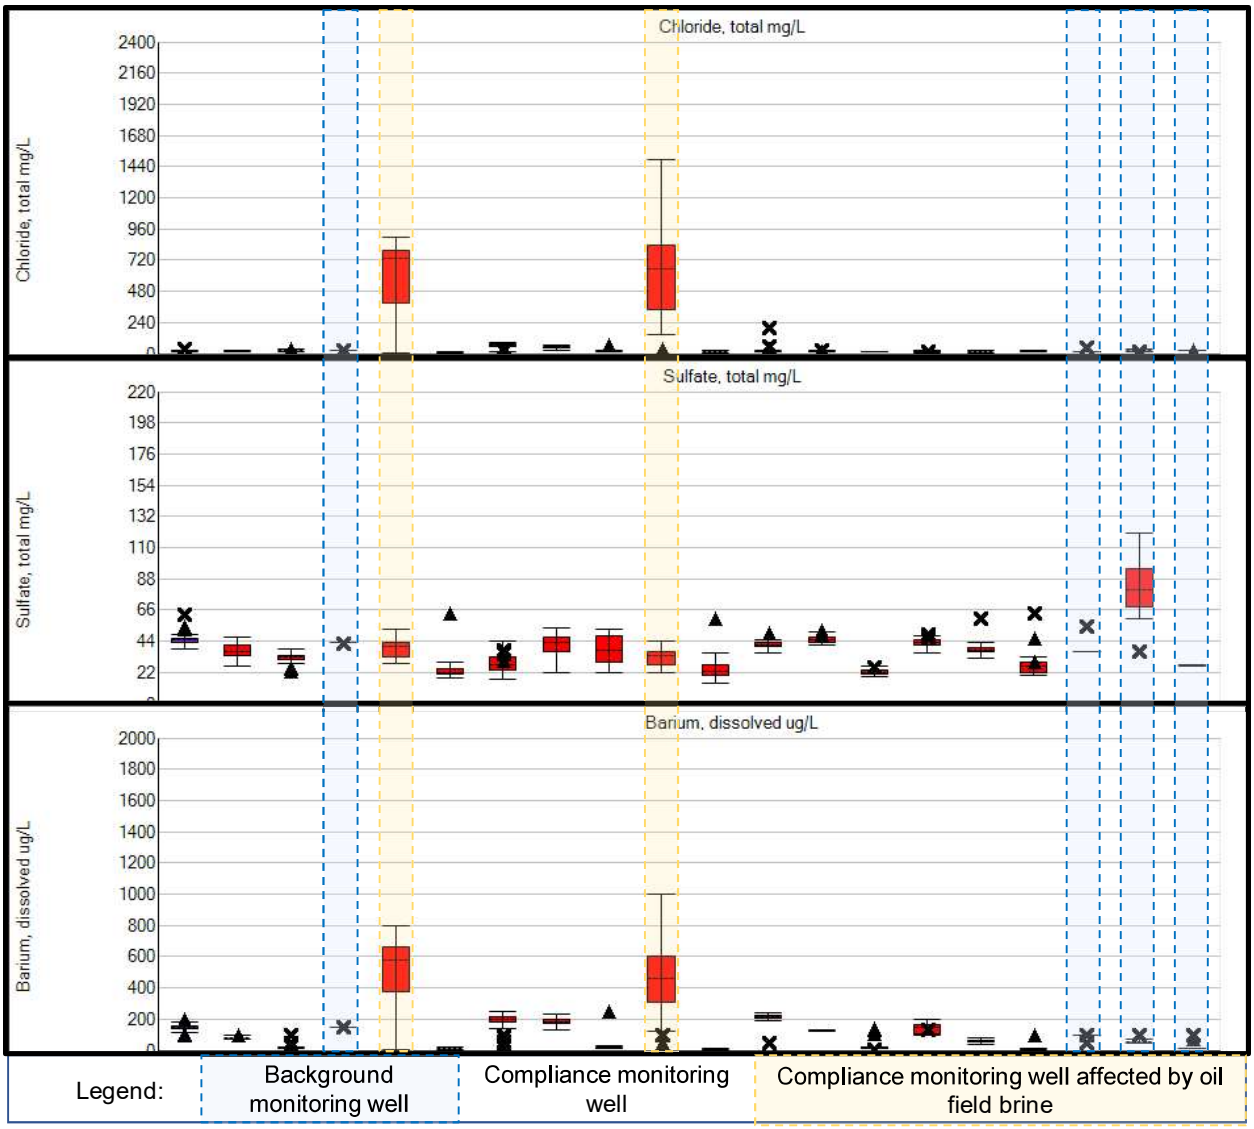

Figure 5-2
Box-whisker plots showing relatively high chloride and barium, and low sulfate concentrations, in brine-impacted groundwater monitored at a CCR management facility

Induced Salt Water Intrusion into Freshwater Aquifers

The water quality in shallow freshwater aquifers can be degraded by upwelling of deeper, naturally salty groundwater caused by heavy pumpage for anthropogenic activities such as mine dewatering, irrigation, or drinking water supplies if there is an underlying source of salt water. Salt water sources include seawater wedges and brackish groundwater that occurs naturally at depth in many areas of the United States.

Lines of evidence for an ASD based on induced pumping are similar to the lines of evidence when oil and gas brines are suspected as the cause of an SSI/SSL. First, there must be evidence for seawater or brackish water underlying the area where an SSI/SSL is observed. Additional lines of evidence can include major ion chemistry, because brackish groundwater and seawater have high chloride concentrations, while coal ash leachate has high sulfate concentration.

Brackish groundwater and seawater can also have higher TDS than CCR leachate, and depending on the level of dilution in groundwater, absolute concentrations of constituents such as barium may be higher in the monitoring well than in the CCR leachate. Ion ratios may also yield a considerably different signature than CCR leachate. Isotopic analysis could also be considered if other lines of evidence do not build a strong ASD, because boron in seawater and brines tends to be isotopically heavy ($\delta^{11}B > 0$), and boron in CCR leachate tends to be isotopically light ($\delta^{11}B < 0$) (Figure 5-3).

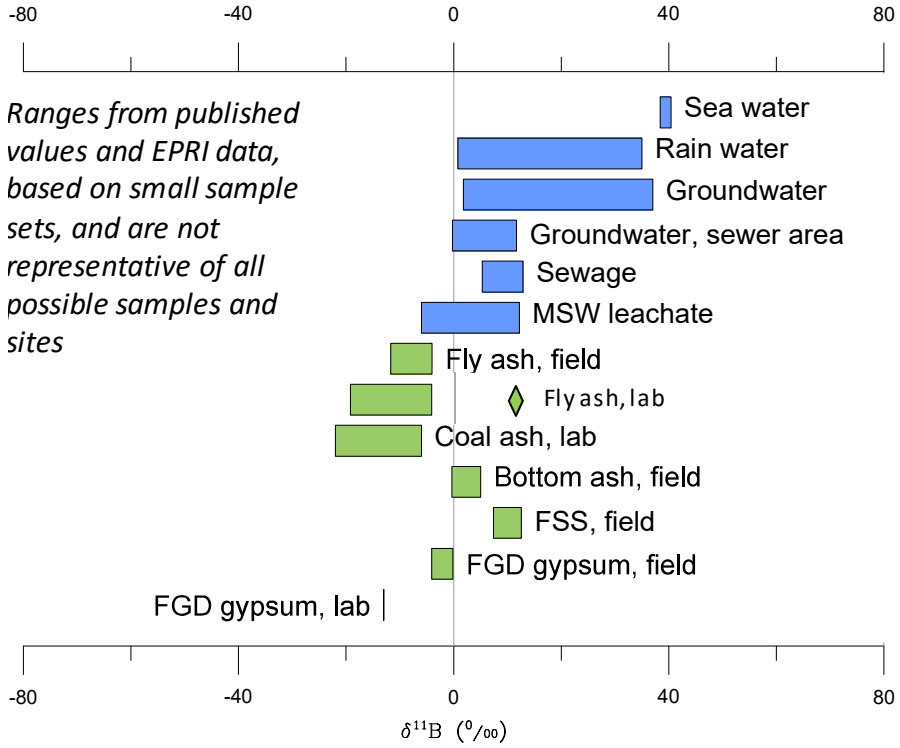

Figure 5-3
Boron isotope ranges, expressed as $\delta^{11}B$, based on EPRI (2012)

Industrial Land Use and Activities

Industrial activities produce liquid and solid waste containing a variety of inorganic constituents, organic compounds, acids, and chemicals that is too variable to cover in detail in this report. Environmental regulations now require treatment and proper disposal to prevent or minimize the risk of contamination to land and water resources, but this has not always been the case. Historical dumping, land application, seepage from unlined or poorly lined impoundments and landfills, and discharge of untreated or poorly treated waste may have contaminated the environment near areas with present or historical industrial activity.

If industrial impacts other than CCP leachate are suspected, the first line of evidence is to identify current and historical industrial activities and land use in the vicinity and upgradient of the monitored CCR unit. Identification of the types of industrial uses can help identify likely contaminants associated with these industrial activities. If these "industrial signatures" can be identified in the CCR program wells, they can be used as lines of evidence supporting an ASD.

Waste Disposal – Municipal and Industrial Landfills

State and federal regulations mandate liners and leachate collections for current landfills. However, prior to enactment and promulgation of implementing rules, waste disposal was often managed in open pits with minimal or no barriers to migration of leachate into groundwater. In the event of a release from a current or legacy solid waste landfill, potential constituents in the leachate include sodium and chloride, nitrate, organic compounds, and trace elements.

If a solid waste landfill is a suspected cause of an SSI/SSL, it may be possible to obtain leachate data from the agency that regulates the facility for use in a water quality signature evaluation. Groundwater monitoring data may also be available from the same agency, which could be used to document whether or not the solid waste landfill monitoring wells had elevated concentrations of the constituent(s) with an SSI/SSL. This assumes that the constituent is monitored at the solid waste landfill, because CCR indicators such as boron, lithium, and molybdenum are not always monitored at non-CCR sites. Otherwise, lines of evidence for an ASD can include major ion chemistry, ion ratio analysis, and perhaps isotopic analysis.

6
PREPARATION OF AN ALTERNATIVE SOURCE DEMONSTRATON

Overview

A combination of tables and checklists have been developed to guide development of an ASD. The following assumptions are inherent with this process:

- There has been an SSI, an SSL, or an exceedance of a groundwater quality standard or benchmark.[14]
- The SSI/SSL is not due to a release from the CCR unit. Note that in some situations, ASDs may apply to all SSI/SSLs at a site, for example at a lined landfill where background groundwater monitoring does not fully characterize the variability possible in groundwater quality. In other situations, ASDs may apply to some, but not all, SSIs/SSLs at a CCR unit, as may be the case for an unlined impoundment where boron and sulfate concentrations in downgradient groundwater may be elevated due to a release, while other constituents in groundwater may be due to naturally occurring or anthropogenic sources.
- ASDs based on sampling (ASD I), laboratory (ASD II), or statistical (ASD III) causes do not require a weight of evidence approach, provided that the cause is documented, or otherwise verified and defensible.
- For natural variation (ASD IV) or alternative sources (ASD V), it is assumed that there are sufficient data to build a weight of evidence case that the SSI/SSL is not due to a release from the CCR unit. If such data are not available, then the ASD process may identify additional data collection that could be used to build a stronger ASD.

The first step in an ASD is to determine if ASD Types I, II, or III explain the SSI/SSL. If not, then a weight of evidence approach is used for ASD Types IV and V. The weight of evidence approach outlined here is dependent on two types of lines of evidence (Figure 6-1):

- Key lines of evidence are based on relationships that must be observed in order for an SSI/SSL to be due to a release from a CCR unit. If these relationships are not observed, then they are critical to establishing an ASD. It is difficult to build a strong ASD without any key lines of evidence. It may be possible to build an ASD with a single key line of evidence, but the ASD will be stronger with additional key or supporting lines of evidence.
- Supporting lines of evidence provide additional information that supports the ASD. Supporting lines of evidence are generally not sufficient to build an ASD unless there is at least one key line of evidence, although it may be possible if there are many supporting lines of evidence.

[14] Throughout this document, and continuing into this chapter, this is referred to as an SSI/SSL.

		Supporting Lines of Evidence		
		None	**Few**	**Many**
Key Lines of Evidence	**None**	No ASD	Weak ASD	ASD possible
	One	Weak ASD	ASD possible	**Strong ASD**
	Multiple	ASD possible	**Strong ASD**	**Strong ASD**

Figure 6-1
Use of key and supporting lines of evidence for ASD Types IV and V

Reference tables for the ASD process are included in the text of this report, and are also provided in Appendix A for simplified reference. The ASD checklists are provided in Appendix B. Table 6-1 summarizes potential causes to consider under each of the ASD types.

Table 6-1
Potential Causes for an SSI/SSL

Sampling Causes (ASD Type I)	Laboratory Causes (ASD Type II)	Statistical Evaluation Causes (ASD Type III)	Natural Variation (ASD Type IV)	Alternative Sources (ASD Type V - Natural and Anthropogenic)
• Sample mislabeling • Contamination • Change in technique • Excessive suspended solids or turbidity • Other sampling anomalies	• Analytical method • Calibration • Analytical technique • Contamination • Interference • Recording • Dilution errors • Digestion methods	• Lack of statistical independence • Outliers • Trends • Non-detect Processing • False positives • New background data	• Geology • Precipitation • Seasonality • Water level • Changes in pH and/or ORP • Biological activity • Time of travel	• See Appendix A, Tables A-3 and A-4

ASD Evaluation Checklists

Checklist 1: ASD Types I, II, and III

The evaluation process starts with ASD Checklist 1 (Appendix B). This checklist is based on the discussion in Section 2 and lists potential sampling, laboratory, and statistical causes for an SSI/SSL. In some cases, the data record may contain sufficient information to document an ASD, but in some cases resampling may be required. If there is documentation, or a resample to demonstrate one of these types of ASD, or if there is irrefutable evidence that one of these ASDs

caused the SSI/SSL, then a weight of evidence approach is not needed. Examples of documentation and evidence include, but are not limited to:

- Laboratory reports showing qualifier flags, uncorrected dilution calculations, contamination in blanks, poor spike recovery, or other anomalies
- Field sampling notes describing difficulties or anomalies encountered while sampling
- High turbidity values in the unfiltered sample, accompanied by filtered sample showing low concentration
- Resample results showing low concentrations
- Graphs clearly showing reversed results (see Figure 2-1), or concentration spikes by a factor of 10 or more (see Figure 2-2)
- Graphs and calculations showing that new background data have triggered a change in background normality, while downgradient concentrations have not increased

If the ASD is not documented, and other evidence is not irrefutable, or if there is insufficient time for resampling, then ASD Checklist 2 could be used to build a weight of evidence approach that the SSI/SSL is not due to a release from the site.

Checklist 2: ASD Types IV and V Lines of Evidence Associated with the CCR Unit

Checklist 2 can be used to guide the evaluation of lines of evidence associated with the CCR unit. The checklist provides a template for recording answers to questions related to primary indicator constituents, secondary indicator constituents, other chemical evaluation techniques, and hydrogeological evaluation. The answers to each question can be recorded in columns that organize the evidence pointing to a release from the CCR Unit (Column A), evidence pointing to a natural or anthropogenic alternative source (Column B), or unknown or indeterminate evidence (Column C). Note that all key lines of evidence are contained in Checklist 2.

If most answers fall into Column B, and particularly if the line of evidence is identified as "key," then weight of evidence is developed that an alternative cause explains the SSI/SSL. Checklist 3 can then be used to guide further evaluation of alternative causes.

Checklist 3: ASD Types IV and V Lines of Evidence Associated with Alternative Natural and Anthropogenic Sources

Checklist 3 is designed to develop lines of evidence to identify alternative source(s) for an SSI/SSL. There are no key lines of evidence on Checklist 3. Rather, it provides for a methodical approach to documenting alternative sources if evaluation using Checklist 2 indicates that an ASD is likely.

ASD Reporting

An ASD requires both defensible lines of evidence and a well-organized presentation of the lines of evidence that clearly lead to the conclusion that the SSI/SSL is not due to a release from the monitored CCR facility. The following format, modified from one developed by Southern Company (2016), provides a viable approach for ASD documentation. Other formats may be equally effective.

Introduction and summary of the SSI/SSL

An example of language that could be used for introducing the SSI/SSL is: "Review of the statistical analysis indicates that the concentrations of the parameters were within the [specify statistical test used] limits for each constituent at each monitoring well except for the following statistically significant increases/levels (SSIs/SSLs): [List each well with SSI/SSL constituents and identify all constituents at each well location that were identified to have SSI or SSL trends.]

Cite the ASD language included in the CCR Rule (or state rule is applicable) using explicit language

For example: "40 CFR 257.94(e)(2) allows the owner or operator 90 days from the date of determination to demonstrate that a source other than the CCR unit caused the SSI or that the apparent SSI was from a source other than the CCR unit or resulted from errors in sampling, analysis, statistical evaluation, or natural variation in groundwater quality. Pursuant to 40 CFR 257.94(e)(2), the following text is provided as a demonstration that the listed SSIs are due to [identify the cause(s) applicable to the site-specific case]."

Present the ASD checklists

Identify all lines of evidence, and supporting data as needed, that the release is not from the CCR unit and is explained by alternative causes. Identify whether each line of evidence is key or supporting, and why. Also group and explain the evidence by well if multiple constituents have SSI trends at the same well(s). If the same constituent has SSI trends at multiple wells, explain how this is relevant to the ASD being presented. Include supporting data such as the checklists, maps, trend charts, geological factors, hydrogeological factors, and any geochemical data analysis tools used that support the conclusions.

Clearly state the conclusion and provide a closing statement

Example language for the closing statement if the ASD is for SSIs during detection monitoring: "The preceding information serves as the ASD prepared in accordance with 40 CFR 257.94(e)(2) and supports the position that the SSIs during [the monitoring period] are not due to a release from the CCR unit. Therefore, no further action (i.e., assessment monitoring) is warranted and [name the CCR unit] will remain in detection monitoring."

Certification by a PE (for ASDs developed under the CCR Rule)

An ASD developed under the CCR Rule requires certification by a Professional Engineer (PE). Including the PE early in the evaluation process can improve this individual's confidence in supporting the conclusions. Keep in mind that the PE may request time to review the data and the ASD report, and factor this time into schedules so that ASD compliance dates can be achieved (the demonstration must be completed and posted to the owner's CCR website within 90 days from the determination that an SSI or SSL has occurred under the CCR Rule). If the PE requires approval by a Professional Geologist (PG), ensure that a PG is also involved early in the evaluation. It may also be beneficial to develop a certification statement that passes management and legal approval.

ASD REFERENCE TABLES

Table A-1
Potential Indicator Constituents for Coal Ash and FGD Gypsum

Potential Indicators for Coal Ash		Potential Indicators for FGD Gypsum	
Constituent	**Advantages and Caveats**	**Constituent**	**Advantages and Caveats**
Boron	Typically present in leachate, non-reactive and mobile in common hydrogeologic environments, and not a common anthropogenic contaminant.	Sulfate	High concentrations expected in both washed and unwashed FGD gypsum (EPRI, 2011). Commonly analyzed. Very mobile in all hydrogeologic environments. Less useful in strongly reducing environments where sulfate can be reduced to hydrogen sulfide gas.
Molybdenum	Most useful for dry-managed coal ash. May be less mobile than boron in some hydrogeologic environments. Concentrations may be too low in impoundment leachate to be useful if background groundwater has detectable concentrations.	Fluoride	Assure that leachate concentration is higher than background, particularly for washed gypsum. Mobile in common hydrogeologic environments, although precipitation as CaF_2 is possible.
Lithium	Useful for coal ash management sites where the power plant burned bituminous coal. Leachate concentrations are typically low in coal ash derived from subbituminous and lignite coal (EPRI, 2006).	Calcium	High concentrations expected in both washed and unwashed FGD gypsum (EPRI, 2011). Understanding of carbonate chemistry necessary to assure that precipitation or dissolution does not affect downgradient concentrations.
Sulfate	Commonly analyzed and very mobile in all hydrogeologic environments. Concentration in impoundment leachate may in some cases be too low relative to background to be useful. Less useful in strongly reducing environments where sulfate can be reduced to hydrogen sulfide gas.	Boron	Mobile indicator constituent for unwashed FGD gypsum. Concentrations for washed gypsum may be too low to be useful (EPRI, 2011).

Table A-1 (continued)
Potential Indicator Constituents for Coal Ash and FGD Gypsum

Potential Indicators for Coal Ash		Potential Indicators for FGD Gypsum	
Constituent	**Advantages and Caveats**	**Constituent**	**Advantages and Caveats**
Bromide	May have high concentration in coal ash leachate at power plants where brominated powdered activated carbon (Br-PAC) or calcium bromide is used for mercury control. Leachate concentrations for coal ash generated absent use of these technologies may be too low to be useful. Mobile and non-reactive in typical groundwater environments.	Bromide	Mobile indicator constituent for unwashed FGD gypsum, especially if Br-PAC or CaBr used for mercury controls. Concentrations for washed gypsum may be too low to be useful (EPRI, 2011).
Potassium	Commonly analyzed, although may be less mobile than boron and sulfate. Assure that leachate concentration is higher than background and that there are no anthropogenic sources such as agricultural fields where potassium may be applied in fertilizers.	Chloride	Mobile indicator constituent for unwashed FGD gypsum. Concentrations may be very high if transport water is recirculated. Concentrations for washed gypsum may be too low to be useful (EPRI, 2011).
Sodium	Useful for coal ash management sites where the power plant injects trona or sodium bicarbonate, or burned subbituminous coal. Absent dry sorbent injection, leachate concentrations are considerably lower in coal ash derived from bituminous coal, particularly at impoundments (EPRI, 2006). Assure that leachate concentration is higher than background and that there are no anthropogenic sources such as agricultural fields, or major highways in northern climates where sodium may be applied as road salts.		
Fluoride	Mobile and non-reactive in common hydrogeologic environments. Assure that leachate concentration is higher than background.

Note: This table is also presented in the body of the report as Table 3-1.

Table A-2
Hydrogeologic Scenarios

	Line of Evidence for:		
	CCR Leachate Release	**Possible CCR Leachate Release + Possible Alternative Source**	**Alternative Source Release**
	Column 1	**Column 2**	**Column 3**
Row a			Row b			Row c			
	1. Leachate concentration is higher than upgradient/background. 2. One or more downgradient concentrations are higher than upgradient/background but lower or equal to leachate concentration.	1. Leachate concentration is higher than upgradient/background. 2. One or more downgradient concentrations are higher than the leachate concentration.	1. Leachate concentration is less than upgradient/background.

This table is also presented in the body of the report as Figure 3-7.

Table A-3
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix III Detection Monitoring Constituents								
Boron	Key Indicator	Yes if unwashed	17 / 35 / 82 ug/L	No	Very mobile	Boron-containing rocks (especially marine shales and clays), seawater, volcanic and geothermal activities, mined in arid regions of the United States (and other countries)	Fly ash leachate, may also be present in FGD leachate; sewage sludge, boron-containing fertilizers or herbicides, manufacture of glass, fiberglass, ceramics, soaps, detergents, bleach, fire retardants, and lubricants; used in control rods of nuclear reactors, and to produce a green color in pyrotechnics and flames; also used in the aerospace industry	Micronutrient for plants but may be toxic to some plant species in high concentrations. Boron deficiencies are more common than toxicities. Mobile in most hydrogeological environments, particularly sandy materials. Sorption to clay reaches a maximum in the pH range of 8-10.
Calcium	No	Yes	21 / 43 / 70 mg/L	CEC	Slightly mobile	Calcium carbonate rocks, limestone, calcium clay; fifth most common element in Earth's crust	Water softening wastes, soil acidity neutralization (lime additions to soil), calcium road salt, deicing, agriculture, cement and concrete, drying agents	Calcium carbonate is one of the most common calcium minerals. The concentration in groundwater may be limited by the solubility of calcium carbonate or calcium sulfate (gypsum). May be sorbed by ion exchange in soil and sediments but tends to be a reversible reaction.

Table A-3 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix III Detection Monitoring Constituents								
Chloride	No	Yes if unwashed	3.1 / 8.6 / 23 mg/L	No	Very mobile	Salt water and brackish water sources; chloride anion is the most abundant element (other than hydrogen and oxygen) in Earth's oceans	Road salt, deicing, water softening wastes, sewage, septic effluent, livestock waste, oil-field brines, salt water intrusion (oil and gas well production), industrial emissions, incinerator ash, landfill leachate, aerospace industry, automobile industry, soaps and detergents, drying agents, flame retardants, flocculants, pharmaceutical and medical waste	
Fluoride	Yes for some coal ash	Yes for some FGD gypsum	<0.1 / 0.2 / 0.4 mg/L	No	Mobile	Natural weathering of fluoride-containing minerals	Steel, brick, and aluminum manufacturing; waste incineration, municipal water treatment	Occurs as fluoride anion at pH > 3, hydrofluoric acid at pH < 3. Can be sorbed by amorphous aluminum and iron oxides under strongly acidic conditions.
pH	No	No	6.9 / 7.3 / 7.6 SU	- -	- -	Oxidation/weathering of naturally occurring pyritic soils due to well installation or other excavation may cause low pH	Low pH: Oxidation/weathering of pyrite in coal or coal ash, leaking batteries High pH: Certain coal ash leachates may have high pH; cement and concrete manufacturing and use, soaps and detergents	Fly ash leachate pH may be acidic or basic depending on coal type. Bituminous coals tend to produce more acidic leachate, especially if comanaged with pyritic mill rejects, and subbituminous coals tend to produce more basic leachate. Important due to impact of pH on leachability of many trace elements.

(note 1)	Typical U.S. Groundwater Concentration at 25^{th} / 50^{th} / 75^{th} Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix III Detection Monitoring Constituents								
Sulfate	Yes for most coal ash	Key Indicator	4.7 / 14 / 36 mg/L	No	Very mobile	Sulfur is the 14th most abundant element in the Earth's crust; oxidation/weathering of naturally occurring pyritic soils (such as iron sulfide)	Fly ash and FGD leachate, lead acid batteries, algaecides, gypsum mines, wood pulp production (paper mills), textile mills, tanneries, coal pyrite oxidation/weathering from mining or storage, industrial emissions and effluents, soaps and detergents, drying agents, flocculants, petroleum refining	Sulfate may precipitate with calcium, barium, and strontium. Not usually sorbed due to negative charge, but can be sorbed under acidic conditions by soils and sediments containing iron, aluminum, and manganese oxides with positive charges. May precipitate from solution as sulfides under strongly reducing conditions.
Total Dissolved Solids (TDS)	No	No	146 / 254 / 381 mg/L	- -	- -	TDS is largely based on concentration of major ions in groundwater (Ca, Mg, Na, K, carbonates, Cl, SO_4)		Refer to primary components.

Table A-3 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25^{th} / 50^{th} / 75^{th} Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix IV Assessment Monitoring Constituents								
Antimony	No	No	<1 ug/L	No	Very mobile		Flameproof retardants, batteries, lead shot; metal and glass manufacturing	Usually soluble but may be sorbed by iron, aluminum and manganese oxides under acidic conditions (EPRI, 1987).
Arsenic	No	No	0.23 / 0.79 / 3.0 ug/L	Yes, pH and redox	Variable	May be present in sulfide minerals and in organic forms; concentrations can be naturally higher than typical under reduced conditions or if sulfide minerals are oxidized	Wood preservatives (chromated copper arsenate), feed additives, pharmaceuticals, electronic devices, metallurgical applications, metal mining and smelting, cemeteries; pesticides/herbicides/ insecticides (prior to 1960)	Arsenic occurs in the 5+ oxidation state as arsenate (AsO_4^{3-}) under relatively neutral pH and oxidized conditions, and as 3+ arsenite (AsO_3^{3-}) under reduced conditions. Arsenic fate and transport is complex due to sensitivity to pH and redox. Sorption usually increases with decreasing pH.
Barium	No	No	24 / 54 / 120 ug/L	Yes	Mobile	Weathering of sedimentary rocks	Well drilling mud or fluid, mining; manufacture of glass, paint, and rubber	Usually present as relatively insoluble barium sulfate in fly ash. Most barium compounds have limited solubility. Sorbed by clay, soils, and sediment.
Beryllium	No	No	<1 ug/L	Yes, pH	Immobile	Relatively scarce in Earth's crust	Electronic and electrical components, telecommunications and computer components, defense applications	Strong tendency to sorb at neutral to alkaline pH. Sorption may be reduced in the presence of humic acids.

Table A-3 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix IV Assessment Monitoring Constituents								
Cadmium	No	No	<1 ug/L	Yes, pH	Slightly mobile	Minor component in Earth's crust, occurs in zinc minerals	Batteries, waste incineration, sewage sludge disposal, paint pigments, phosphate fertilizers, automobiles, electroplating and metal fabricating	Can be sorbed by clay, soil, and sediment at pH less than 8, but sorption decreases at low pH.
Chromium	No	No	0.68 / 1.2 / 3.0 ug/L	Yes, pH and redox	Variable	Primarily occurs as Cr(III) in soils and rocks	Electroplating, leather tanning, wood pulp production (paper mills), metal ore refining, wood preservatives, steel manufacturing, automobiles, electroplating and metal fabricating, paint and coatings	The solubility of Cr(III) generally increases at pH levels <6.5 and >11. Cr(III) is the predominant dissolved species under reducing to mildly oxidizing conditions. Cr(IV) is more soluble than Cr(III) at neutral to alkaline pH. Cr(VI) is soluble at alkaline pH and mildly to strongly oxidizing conditions.
Cobalt	No	No	0.063 / 0.17 / 0.48 ug/L	Yes	Variable	Relatively scarce in Earth's crust; usually occurs in combination with arsenic and sulfur in nature	Rechargeable battery electrodes, radial tires, drying agents, catalysts, paint pigments, medical wastes, automobiles	May be sorbed by mineral oxides (e.g., Fe and Mn), crystalline materials such as aluminosilicate, and natural organic substances in soil.
Lead	No	No	0.018 / 0.070 / 0.27 ug/L	Yes pH	Variable	Rare in Earth's crust	Smelting and mining, batteries, waste incineration, leaded gasoline (before 1996), lead-containing paint, glass manufacturing, ammunition, firing ranges, plumbing, automobiles	Sorption usually increases with pH.

Table A-3 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix IV Assessment Monitoring Constituents								
Lithium	Yes for some coal ash	No	2.0 / 6.0 / 18 ug/L	No	Mobile	Rare in Earth's crust, dissolution of lithium-containing minerals	Glass and ceramics production, lubricants, greases, batteries, salt water intrusion	Reacts with sulfate ions to form lithium sulfate anion.
Mercury	No	No	NR	No	Slightly mobile	Occurs as HgS in nature; can be converted to methylated forms by anaerobic microbes	Waste incineration, mercury mining, metal recycling, fungicides, fluorescent lamps, batteries, thermometers/ thermostats/switches (electronic equipment), automobiles	Can be sorbed by iron, magnesium, silicon oxides, and organic matter.
Molybdenum	Yes for some coal ash	No	0.32 / 1.0 / 3.3 ug/L	No	Very mobile	Usually combined with sulfur or oxygen in natural minerals	Steel production, catalysts, lubricants, pigments, fertilizers, animal feed	Micronutrient for plants and animals; may be in fertilizers or animal feed. Peak sorption at pH <5 and limited sorption above pH 8. Phosphate and other oxyanions will depress sorption.

Table A-3 continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25^{th} / 50^{th} / 75^{th} Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
CCR Rule Appendix IV Assessment Monitoring Constituents								
Radium 226 + 228	No	No	NR / 0.28 / 1.2 pCi/L	Yes, CEC	No data	Natural decay product of uranium and thorium ores	Uranium mines, nuclear power, nuclear fuel and weapons manufacturing, uranium in coal	Radium decays to radon gas, so it is prevalent in locations where radon gas is a concern.
Selenium	No	No	0.12 / 0.34 / 1.0 ug/L	Yes, pH and redox	Variable	Usually occurs with silver, copper, lead, and nickel sulfide minerals; may exist in a variety of organic compounds	Metal mining and milling, industrial waste water, sewage effluent, waste incineration, saline agricultural waste waters	May exist as selenate (SeO_4^{2-}), selenite (SeO_3^{2-}), elemental selenium (Se^0), and selenide (Se^{2-}) in groundwater (shown in order from most to least oxic species). Since anionic selenium is the dominant form in groundwater, sorption typically is not significant. However, selenite can be sorbed by iron and aluminum oxides.
Thallium	No	No	<1 ug/L	Yes, redox	Mobile	Occurs in combinations with oxygen, sulfur, and halogens	Glass and electronic industries, iron and steel production, cement factories	May be immobilized under reducing conditions.

Table A-3 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
Other Constituents								
Aluminum	No	No	0.98 / 3.0 / 4.9 ug/L	Yes, pH	Slightly mobile	Most abundant metal in Earth's crust; weathering of aluminosilicate minerals	Mining and industrial emissions and effluents; most abundant metal in coal ash, cement and concrete, drying agents, well drilling, flocculants, abrasives, aluminum manufacturing	Most soluble in water under acidic and alkaline solutions, essentially insoluble in near neutral water. May be sorbed by soils, sediments, and organic matter.
Bromide	Possible for certain coal ash	Yes if unwashed	0.02 / 0.04 / 0.09 mg/L	No	Mobile	Brackish groundwater and sea water, relatively rare in Earth's crust	CCR fly ash and emission control wastes, particularly if bromide compounds were used to facilitate mercury capture; drinking water disinfection, flame retardants	
Copper	No	No	0.47 / 1.0 / 3.0 ug/L	Yes, pH and redox	Variable	Relatively common in Earth's crust	Manufacture of bronzes, brass, electrical conductors, and ammunition; sewage sludge wastes, municipal solid wastes, copper-containing fertilizers, cemeteries, electronics, plumbing, wood preservatives, automobiles, electroplating and metal fabricating	Solubility may be controlled by solubility of copper hydroxide. May sorb to organic matter, clay, aluminum, manganese, and iron oxides.
Iron	No	No	0.81 / 7.9 / 93 ug/L	Yes, pH and redox	Variable	Commonly has high concentration in groundwater under reduced conditions; Weathering of iron-containing minerals (dissolution of iron oxides under reducing conditions), 4th most common element in Earth's crust	Industrial emissions, pyrite oxidation/acid mine drainage from coal mining or storage, flocculants	Iron oxides my dissolve and become mobile under reducing conditions. Occurs as ferrous (+2) and ferric (+3) iron. Ferric iron can be sorbed by silica, clay, and iron and manganese oxides.

Table A-3 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25^{th} / 50^{th} / 75^{th} Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
Other Constituents								
Magnesium	No	No	4.4 / 11 / 23 mg/L	CEC	Slightly mobile	Eighth most abundant element in the Earth's crust, abundant in sea water; dissolution of magnesium carbonates and clay minerals	Aluminum fabrication and welding (alloying agent), flares and pyrotechnics, fire retardants, heat-resistant bricks, animal feed, fertilizers, drying agents	Solubility may be limited under alkaline conditions. May be removed from solution by ion exchange in soils and sediments via reversible reactions.
Manganese	No	No	0.85 / 7.0 / 84 ug/L	Yes, pH and redox	Variable	Commonly has high concentration in groundwater under reduced conditions; 13th most abundant element in the Earth's crust	Production of steel and aluminum alloys, glass production, use as an additive in gasoline	
Nickel	No	No	0.35 / 1.1 / 2.5 ug/L	No	Variable	Commonly combined with iron or sulfur	Manufacture of steels, other metal alloys, and electronic applications; automobiles, electroplating and metal fabricating, petroleum	Sorbs to iron and manganese oxides, and clay to a lesser extent.
Nitrogen	No	No	0.07 / 0.55 / 2.4 (NO_3 as N) mg/L	Nitrification/ denitrifi-cation, redox	Very mobile as NO_3	In nature, nitrogen is converted from one redox state to another by abiotic reactions and microbial catalysis in oxic conditions: $NH_4OH \rightarrow NO_2 \rightarrow NO_3$; under reducing conditions: $NO_3 \rightarrow NO_2 \rightarrow N_2$	Fertilizers, livestock wastes, wastewater treatment plants, sewage and septic effluent, rubber manufacturing; ammonia sources include CCRs from sources using SNCR or SCR technology, coke production, flame retardants	NO_2 and NO_3 are not significantly sorbed by most soils, sediments, or clays, but NH_4OH is.

Table A-3 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25^{th} / 50^{th} / 75^{th} Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
Other Constituents								
Phosphate	No	No	<0.01 / 0.02 / 0.04 mg/L	Yes, pH	Variable	Phosphorus is the 11th most abundant element in the Earth's crust	Fertilizers, wastewater treatment plants, sewage and septic effluents, industrial effluents, soaps and detergents, flame retardants	Can be sorbed by iron, aluminum, and manganese oxides, and by clay under acidic conditions.
Potassium	Yes for some coal ash	No	0.9 / 1.7 / 3.5 mg/L	CEC	Mobile	7th most abundant element in the Earth's crust; Weathering of potassium-containing minerals	Water treatment, fertilizers, sea water intrusion, soaps and detergents, drying agents	May be removed from groundwater by reversible ion exchange with soils and sediments.
Silicon	No	No	12 / 19 / 31 mg/L	Yes	Very mobile	2nd most abundant element in the Earth's crust; usually in the form of SiO_2	Glass, ceramics, abrasives, electronic devices, metal alloying, water filtration, insulation, cement, concrete, paper, rubber, lubricants, flocculants	Can be sorbed by iron and aluminum oxides, and by clay minerals.
Silver	No	No	<1 ug/L	Yes, pH	Variable		Textile plant wastewater, photographic materials, sewage sludge, medical wastes, electronics, electroplating and metal fabricating	Can be sorbed by soils but affected by pH, clay content, particle size, organic content, and free iron and manganese oxide content.
Sodium	Yes for some coal ash	No	5.2 / 11 / 29 mg/L	CEC	Mobile	6th most abundant element in Earth's crust; brackish groundwater and surface water, sea water, weathering of sodium-containing minerals	Road salt, deicing, septic effluent, sodium hydroxide water treatment wastes, water softening, salt water intrusion (gas and oil well production), sewage and septic effluent, soaps and detergents, drying agents	Most sodium compounds are soluble but may be sorbed by reversible ion exchange in soils or sediments.

Table A-3 (continued)
Potential Alternative Sources by Constituent

Constituent Name	Coal Ash Indicator? (note 1)	FGD Gypsum Indicator? (note 1)	Typical U.S. Groundwater Concentration at 25th / 50th / 75th Percentile (note 2)	Reactivity (note 3)	Mobility (note 4)	Natural Prevalence and Naturally Occurring Causes for Presence in Groundwater	Potential Anthropogenic Sources	Comments (note 5)
Other Constituents								
Strontium	No	No	100 / 270 / 680 ug/L	Yes	Slightly mobile		Glass and ceramics production, pyrotechnics, phosphate fertilizers	Reacts with sulfate ions to form $SrSO_4^0$.
Vanadium	No	No	0.30 / 1.4 / 11 ug/L	Yes, pH and redox	Variable		Crude oil, oil shale, tar sands, phosphate fertilizers, wastes from steel production, petroleum	Can be sorbed by iron, aluminum, and manganese oxides; sorption decreases as pH increases.
Zinc	No	No	1.6 / 4.8 / 18 ug/L	Yes, pH	Variable		Fertilizers, protective coatings to reduce corrosion of metal surfaces, dry-cell batteries, castings, automobiles, lubricating oils and greases, plumbing/piping, electroplating and metal fabricating	Sorption increases with increasing pH but is also affected by clay content, particle size, organic content, and iron, aluminum, and manganese oxide content.

Notes:

1. Based on EPRI (2012). "No" indicates that the constituent it is not considered an indicator due to low concentration in CCR leachate relative to typical background, low mobility, and/or potential for reactivity.

2. Concentration ranges in ug/L from USGS (2011), Table 4; concentration ranges in mg/L or SU from USGS (2008), Tables 2 and 6; radium 226+228 from Szabo et. al (2012) supplemental table S-3; NR indicates that the concentration was not reported in any of these three documents.

3. Reactivity and mobility, while separate geochemical processes, are often interrelated. Reactivity descriptions in this table refer to chemical reactions, primarily precipitation and dissolution, that can change the concentration or mobility of the element in solution under typical aquifer conditions. Yes indicates that the constituent is subject to precipitation, coprecipitation, and/or dissolution reactions. In addition, pH and redox are indicated if they have a strong influence on the environments under which reactions occur and/or mobility. CEC is listed for constituents that are subject to cation exchange.

4. The mobility classification is based on the classification system of van Loon and Duffy (2000). See Table 2-2 of EPRI (2012) for corresponding K_d values.

5. Refer to Appendix B in EPRI (2012) for brief summaries of geochemical factors affecting reactivity and sorption. Detailed information can be found for selected constituents in the following EPRI reports:

Table A-4
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Abrasives	**Silicon, aluminum**
Acid mine drainage	**Low pH, sulfate, iron**, dissolved solids, metals (aluminum, cadmium, calcium, chromium, cobalt, copper, magnesium, manganese, nickel, zinc, and others); can travel along mine shafts and tunnels and show up in unexpected locations (sometimes across aquifers) (notes 1, 26, 51, 54)
Aerospace industry	**Boron, perchlorate, chloride, cyanide, cadmium**, beryllium, solvents (trichloroethane, methylene chloride, trichloroethylene, toluene, methylethylketone), metals, oils (notes 2, 3, 4, 5, 51)
Aging infrastructure (leaking sewage, urban runoff)	Nitrate, phosphorus, sodium, chloride, organic substances, bacteria, pesticides, miscellaneous chemicals, cadmium, copper, iron, lead, selenium, zinc, and other elements (note 6)
Agriculture - animal feed lots	**Nitrates, ammonia, other nitrogen compounds, phosphorus/phosphate, chloride**, **arsenic**, **magnesium, molybdenum, selenium** and other elements, organic substances, bacteria/viruses (notes 7, 22, 51, 52, 54)
Agriculture - fertilization	**Nitrates, ammonia, other nitrogen compounds, phosphorus/phosphate**, **boron**, **cadmium, calcium**, chloride, cobalt, **copper**, cyanide, **magnesium**, **molybdenum, potassium, selenium, strontium, vanadium, zinc**, and other elements (notes 7, 22, 51, 52, 54)
Agriculture - irrigation	**Nitrates, ammonia, other nitrogen compounds, phosphorus/phosphate,** arsenic, boron, cadmium, calcium, chloride, cobalt, copper, cyanide, magnesium, mercury, molybdenum, potassium**, selenium**, sodium, sulfate, and other elements (notes 7, 8, 9, 22, 52)
Agriculture - lime addition	**Calcium** (note 22)
Agriculture - pesticides, herbicides, and insecticides	Aldicarb, Aldrin, alachlor, atrazine, carbofuran, chlordane, dacthal, DDT, dieldrin, bibromo-chloropropane, 1,2-dichloropropane, dinoseb, endrin, endosulfan, ethylene dibromide, heptachlor, hexachlorobenzene, lindane, mirex, PCBs, prometon, simazine, toxaphene, trifluralin; **arsenic** (prior to 1960), chloride, **mercury, boron**, **sulfate** (notes 10, 51, 52, 54)
Airport runways	**Sodium, potassium**, acetate, formate, urea (note 11)
Aluminum manufacturing	**Aluminum, fluoride, sodium**, magnesium, manganese, perfluorocarbons, polycyclic aromatic hydrocarbons (notes 12, 13)
Ammunition, firearms	**Lead, antimony, copper,** other heavy metals, nitrate, perchlorate, potassium, sulfur/sulfate, chloride (notes 14, 15, 22)
Asphalt plants	Oils, greases, PAHs, other hydrocarbons (note 16)
Automobile production	**Chloride, sulfate, phosphate,** oil and grease, solvents, ethylene glycol. Potential for heavy metals: aluminum (auto bodies), **cadmium** (tires and batteries), **cobalt** (radial tires), **chromium** (brakes, coolants, engine parts), **copper** (brake linings), iron (auto bodies), **lead** (batteries, lube oil and grease, bearings, brakes), **mercury** (batteries), **nickel** (lube oil, brakes), **zinc** (tires, fuel oil, lubricants) (notes 17, 18, 22)
Automobile repair shops	Gasoline, diesel fuel, oil, degreasing solvents (toluene, xylene, chlorinated solvents, MEK), ethylene glycol, lead, sulfate (notes 19, 44)

Table A-4 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Batteries	**Sulfate, lead, antimony**, **cadmium, cobalt, lithium, mercury, zinc, low pH** (notes 22, 51)
Bleach manufacturing	**Boron** (bleaches containing sodium perborate) (notes 20, 31)
Brick manufacturing	**Aluminum, silicon, iron**, calcium, **fluoride**, **magnesium,** chromium (notes 21, 22, 52)
Catalysts	Aluminum, chromium, **cobalt**, copper, iron, **molybdenum**, titanium, tungsten, vanadium, zinc, and other metals (depends on catalyst manufactured or used) (note 22)
CCR - ash	**Boron, sulfate**, molybdenum, lithium, bromide, potassium, sodium, fluoride, selenium; may contain ammonia (nitrogen) if SCR or SNCR technology was used at the power plant (note 22)
CCR - FGD gypsum	**Sulfate**, fluoride, calcium, boron, bromide, chloride, selenium (note 22)
CCR - FGD fixated sludge	**Boron, sulfate**, calcium, chloride, molybdenum, lithium, bromide, potassium, sodium, fluoride, selenium (note 22)
Cemeteries	**Formaldehyde**, **copper, arsenic,** mercury, pesticides, fertilizers, weed killers (note 23)
Cement and concrete manufacturing and use	**High pH, aluminum, calcium, silicon, thallium,** chromium and other elements (notes 22, 24, 51)
Ceramics production	Oxides of carbon, **silicon, boron**, and nitrogen; may include aluminum, antimony, barium, copper, fluoride, iron, **lithium**, **strontium**, and other elements (notes 21, 22, 51)
Coal mining	**Sulfate, low pH, iron**, dissolved solids, trace elements (aluminum, beryllium, cadmium, chromium, cobalt, copper, lead, magnesium, manganese, mercury, nickel, selenium, **uranium (decays into radium 226+228)**, zinc and others); Oxidation of pyrite in coal can form sulfuric acid. The low pH increases solubility of many metals. (notes 1, 26, 51, 54)
Coatings	VOCs, solvents (halogenated solvents and non-halogenated solvents such as acetone, cresols, cresylic acid, nitrobenzene, benzene, toluene, xylene, methyl ethyl ketone, methylene chloride, etc.); trace elements may include barium, cadmium, **chromium**, cobalt, lead, mercury, molybdenum, nickel, titanium, and **zinc** (note 27)
Coke production (from coal)	**Phenols, ammonia (nitrogen), polycyclic aromatic hydrocarbons, cyanide**, benzene, naphthalene, anthracene, cresols, metals (see metals in "coal piles or coal waste piles") (note 28)
Computer and telecommunications components (electronics)	Trace elements may include aluminum, arsenic, barium, **beryllium**, cadmium, chromium, cobalt, **copper**, gallium, gold, iron, lead, manganese, mercury, palladium, platinum, selenium, **silver**, and zinc; solvents may include benzene, xylene (dimethylbenzene), trichloroethane, tetrachloroethane, ethylene glycol, methyl cellosolve; **silicon** (notes 29, 30, 32)

Table A-4 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Defense applications	**Beryllium** (note 22)
Detergent or soap manufacturing	**Sodium, potassium, sulfates and sulfonates, high pH, phosphate**, **chloride, boron**, phenol, aluminosilicate, sodium citrate, nitrilotriacetate, alcohol ethoxylates, fats, oil and grease, lead, hexane, methyl alcohol, trichloroethane, perchloroethylene, benzene, toluene (notes 22, 34, 35)
Deicing	**Sodium, chloride**, **calcium**, magnesium, urea (notes 44, 51)
Drying agents	**Aluminum, calcium, sodium, potassium, magnesium, sulfate, chloride,** cobalt, lithium, phosphorus, silicon and/or other substances (notes 22, 36, 37)
Electronic equipment manufacturing and disposal	**Copper, silver, gold, palladium**, **arsenic, beryllium, copper, mercury, nickel,** selenium, **silicon, thallium** and other trace elements, chloride, fluoride, solvents (benzene, xylene, 1,1,1-trichloroethane, tetrachloroethane, methanol), ethylene glycol, hydrogen chloride, hydrogen fluoride (notes 22, 29, 30, 33, 51)
Electroplating and metal fabricating	**Cadmium, chromium, copper, nickel, silver**, sodium, tin, **zinc**, spent solvents, paints, spent acidic and alkaline solutions, cyanide, waste oils (notes 17, 22, 44, 51, 52, 56)
Explosives manufacturing and testing	**Nitroglycerin and nitro-aromatic compounds**, nitrate, perchlorate, ammonia, lithium, sodium, potassium, sulfur/sulfate, aluminum, chloride, **lead**, antimony, **copper**, nickel, silver (notes 38, 39, 40, 51)
Fertilizers	See Agriculture - fertilization
Fiberglass manufacturing	Aluminum, silicon, calcium, magnesium, **boron**, polyester or epoxy resin, styrene, solvents, volatile organic compounds, formaldehyde, urea, phenol, vinyl acetate (notes 31, 41)
Firearms, ammunition	See Ammunition, firearms
Firing ranges	**Lead**, antimony (notes 14, 22)
Fireworks manufacturing or use	Aluminum, antimony, arsenic, barium, **boron**, chloride, copper, lead, **magnesium**, nitrate, perchlorate, potassium, sulfur/sulfate, **strontium** (notes 31, 38, 39, 40, 51)
Flame retardant manufacturing or use	**Bromine, phosphate, nitrogen/nitrate, chloride**, **antimony, boron**, **magnesium**, polybrominated diphenyl ethers (PBDEs), PCBs (notes 22, 42, 43, 51)
Flocculants	**Sulfate, chloride, aluminum, iron**, ammonium, calcium, silica, polyamines (note 45)
Fluorescent lamps/bulbs	**Mercury**, PCBs in ballasts (note 47)
Fracking	See Oil and gas wells / production

Table A-4 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Fungicides	See Pesticides
Furniture (wood stripping and refinishing)	Methylene chloride, methanol, isopropyl alcohol, acetone, perchloroethylene, toluene, acidic and alkaline solutions, metals, other solvents, petroleum distillates, resins, halogenated hydrocarbons, glycol ether (note 44)
Gasoline stations	**Benzene, ethylbenzene, toluene, xylene, MTBE**, ethylene dichloride, naphthalene, other organic compounds, lead (prior to 1996), **manganese**; trichloroethylene, perchloroethylene, methylene chloride, carbon tetrachloride, oils, ethylene glycol, hydraulic fluid, detergents, and acids (notes 22, 49, 51, 52)
Glass manufacturing	**Silicon**, antimony, **barium, boron, lead**, iron, **lithium**, **manganese**, nickel, potassium, **strontium**, **thallium**, tin, zinc, fluoride (notes 22, 31, 50, 51)
Industrial emissions	**Chloride, sulfate, iron,** wide variety of other elements and chemical substances (notes 22, 51, 54)
Irrigation	See Agriculture – irrigation
Junk and scrap yards	Used oil, gasoline, antifreeze, lead, sulfuric acid, agricultural chemicals/pesticides/other chemicals, metals (note 44)
Lamp manufacturing and disposal	**Mercury**, bromide, chloride, fluoride, iodide, PCBs, sodium (notes 22, 47)
Landfills - industrial	Wide range of trace metals, acids, **chloride**, sulfate, organic substances and pesticides (notes 51, 53, 54)
Landfills - municipal	Salts (sodium, calcium, magnesium, **chloride**, etc.), metals (iron, copper, zinc, other heavy metals), nitrate, organic compounds, solvents, pesticides (notes 22, 51, 54)
Laundry - dry cleaning	**Perchloroethylene (tetrachloroethylene)**, camphor oil, turpentine spirits, benzene, kerosene, white gasoline, petroleum solvents (petroleum naphtha), chloroform, carbon tetrachloride, trichloroethylene, 1,1,2-trichlorotrifluoroethane, glycol ethers, 1,1,1-trichloroethane, decamethylcyclopentasiloxane, n-propyl bromide, liquid carbon dioxide, fluorocarbon-113, antimony, cadmium, copper, lead, sulfate, zinc (notes 20, 31, 44, 52)
Leather tanning	**Chromium**, **cyanide**, **tannins**, chlorinated phenols including PCB, azodyes, cadmium, cobalt, copper, antimony, barium, lead, selenium, mercury, zinc, arsenic, nickel, formaldehyde, pesticides, salts, lime, acids, sodium sulfide, hydrogen sulfide, sulfate (notes 22, 55, 56)
Lubricants and greases	**Zinc**, polyaromatic hydrocarbons, arsenic, **boron**, cadmium, lead, **lithium**, **molybdenum**, PCBs, **silicon**, and other elements (note 22)
Medical supplies or wastes	Chloride, formaldehyde, **arsenic**, cadmium, **cobalt**, lead, mercury**, silver**, other heavy metals, radioactive waste, infectious or pathological waste, dioxins and furans from incineration; Also see Pharmaceutical industry (notes 22, 51, 57, 58, 59, 62)

Table A-4 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Metal manufacturing - smelting	**Aluminum**, **antimony**, **arsenic**, beryllium, cadmium, **chromium**, **copper**, cyanide, iron, **lead**, **magnesium** (aluminum manufacturing), **manganese** (steel and aluminum manufacturing), mercury, **molybdenum** (steel manufacturing), **nickel** (steel and other metal manufacturing), **selenium**, silver, **thallium** (iron and steel manufacturing), zinc and other elements, **fluoride** (steel and aluminum manufacturing), **silicon, vanadium** (steel manufacturing), **zinc** (notes 22, 44, 51, 52)
Metal mining	Aluminum, antimony, **arsenic**, beryllium, cadmium, **chromium**, **copper, cyanide**, iron, **lead, manganese**, **mercury, nickel, selenium**, silicon, silver, thallium, tungsten, zinc and other elements (notes 22, 51, 52, 54, 56)
Metal plating	Spent solvents, paints, spent acidic and alkaline solutions, waste oils, heavy metal sludges, metal dust, chromium, copper, nickel, selenium, **zinc** and other elements (notes 22, 44, 51, 52)
Metal recycling	Iron, copper, **mercury**, nickel, zinc, and other elements (note 22)
Mining - unspecified	Depends on contents of ore; may include aluminum, antimony, arsenic, beryllium, cadmium, chromium, copper, iron, lead, manganese, mercury, nickel, selenium, silver, **sulfate** (gypsum mines), thallium, zinc, other minerals, hydraulic oils; **radium 226+228 (uranium mines)** (notes 22, 51)
Natural gas pipelines	**Methane, PCBs** (notes 60, 61)
Nuclear power	**Tritium**, **strontium 90, radium 226+228,** boron, beryllium (notes 31, 51, 54)
Oil and gas wells / production	Produced water may contain high **TDS, chloride, sodium**, sulfate, barium, boron, bromide, iodide, lithium, potassium, radionuclides, **vanadium** and other minerals, methane, volatile organic compounds (notes 52, 60, 63)
Ore refining / smelting	Aluminum, antimony, arsenic, beryllium, cadmium, chromium, copper, cyanide, iron, lead, manganese, mercury, nickel, selenium, silver, thallium, zinc and other elements (notes 22, 44, 51)
Paint and pigment manufacturing	VOCs, solvents (halogenated solvents, non-halogenated solvents such as acetone, cresols, cresylic acid, nitrobenzene, benzene, toluene, xylene, methyl ethyl ketone, methylene chloride, etc.); metals may include **barium**, **cadmium, cobalt**, **chromium**, **lead**, mercury, **molybdenum**, titanium, and zinc (notes 22, 44, 51, 52, 64)
Paper and pulp manufacturing	Organic and inorganic compounds including lignin, cellulose, phenols, mercaptans, **chromium**, nitrates, phosphates, **silicon, sulfides/sulfates**, chlorinated compounds including chloroform and dioxin (notes 22, 65)
Petroleum facilities and refining	Benzene, ethylene, toluene, xylene, methane, other organic compounds, hydrogen sulfide, **sulfate, nickel, vanadium** and other elements; some refineries use deep-injection wells to dispose of highly contaminated wastewater that could potentially contaminate groundwater (note 51)
Pharmaceutical industry	Wide variety of organic solvents; **arsenic, cobalt**, ammonia, chloride, cobalt, **silver** and other elements; Also see Medical supplies or wastes (notes 22, 51, 57, 62)
Photographic materials/photography	**Silver,** sodium, potassium (notes 22, 51)

Table A-4 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Pigments	See Paint and pigment manufacturing
Plastic manufacturing	Cadmium, cyanide, benzene, vinyl hydrochloride, phthalates, trichloroethane, acetone, methylene chloride, methyl ethyl ketone, styrene, toluene, trichloroethane, sulfate, methanol, ethylene oxide, volatile organic compounds, sodium, caustic, nickel, lead, cadmium, mercury (notes 51, 66)
Plumbing	**Copper, lead, zinc** (note 51)
Road salting	**Chloride, sodium**, **calcium**, other salts (notes 22, 44)
Rubber manufacturing	**Ammonia, amines**, acetic acid, **barium**, cobalt, formic acid, sodium, **silicon**, sulfite/sulfate, organics, nitrogen compounds (notes 22, 69)
Salt or brackish water intrusion (from well drilling)	**High TDS, chloride**, boron, bromide, calcium, **lithium**, magnesium, **potassium, sodium**, sulfate, and other minerals (notes 22, 51, 54)
Salvage and junk yards	Grease, oil, solvents, lead and acid from batteries, metals (notes 44, 54)
Semiconductor manufacturing	Copper, silver, gold, palladium, arsenic, beryllium, copper, mercury, nickel, selenium, silicon, thallium and other elements, chloride, fluoride, solvents (benzene, xylene, 1,1,1-trichloroethane, tetrachloroethane, methanol), ethylene glycol, hydrogen chloride, hydrogen fluoride (notes 22, 29, 30, 33, 51)
Septic effluent	**Nitrate, phosphorus, chloride, sodium**, organic substances, bacteria and viruses, detergents, oils, heavy metals including cadmium, copper, lead, **selenium**, salts, septic tank cleaners such as trichloroethane or methylene chloride, and a wide variety of other chemicals (notes 22, 51, 52, 53)
Sewage	**Nitrate, phosphorus, chloride, sodium**, organic substances, bacteria and viruses, detergents, oils, **boron**, **cadmium**, **copper**, lead, **selenium, silver**, salts, and a wide variety of other chemicals (notes 22, 51, 52)
Soap or detergent manufacturing or use	See Detergent and soap manufacturing
Soil acidity neutralization	**Calcium**
Steel (including stainless) and iron manufacturing	Iron, chromium, manganese, nickel, ammonia, cyanide, chloride, copper, fluoride, molybdenum, sulfate, tin, thallium, zinc, hydraulic oils
Textiles	Polyvinyl chloride, chlorine bleach, benzidine, toluidine, cyanide, formaldehyde, hydrocarbons, ammonia, nitrate, organic solvents, chloride, sodium, fluoride, silicon, **sulfate**, phosphate, boron, bromide, chromium, copper, aluminum, antimony, potassium, aluminum, **silver**, titanium, zinc, copper, insecticides (notes 22, 51, 56, 67, 68)
Thermometers, thermostats, switches	**Mercury** (note 51)

Table A-4 (continued)
Constituents Potentially Associated with Alternative Anthropogenic Sources

Potential Source	Constituents That May Be released to Groundwater*
Underground storage tanks (USTs leaking petroleum products such as gasoline)	Benzene, toluene, xylene, other organic compounds (notes 49, 51, 53)
Urban runoff	Oils, heavy metals, salts, copper, zinc, and other chemicals (notes 6, 18, 54)
Waste incineration	**Chloride, cadmium**, chromium**, fluoride, lead, mercury**, selenium, dioxins and furans (note 22)
Water treatment - flocculants	See Flocculants (note 45)
Water treatment - industrial effluents	Wide variety of metals, aluminum, **chloride**, **phosphate**, **potassium, sulfate**, nitrate, **selenium, silicon**, **sodium**, organics depending on industry (notes 22, 46)
Water treatment - municipal supply	Bromide, **chlorine, fluoride** (notes 22, 51)
Water treatment - treated sewage effluent	May contain **nitrates and other nitrogen compounds, phosphates, sodium, chloride**, **selenium, silicon**, and a variety of other elements (notes 22, 51, 52)
Water treatment - water softening	**Sodium, chloride**, **calcium**, magnesium, iron, other salts and metals (note 22)
Water treatment - cooling water	Chromium, zinc (notes 51, 52)
Well drilling (mud or fluid)	Constituents of bentonite clay and the natural geomedia including **aluminum, barium**, calcium, potassium, sodium and other minerals (note 22)
Wood preservatives and treatments	**Pentachlorophenol (PCP), creosote**, **copper, chromium, arsenic** (chromated copper arsenic, ammoniacal copper arsenate) (notes 22, 44, 48, 51)

* Bold indicates likely key indicators; list will vary by site-specific source; list may be incomplete or may not accurately represent a particular source.

B
ASD CHECKLISTS

		Supporting Lines of Evidence		
		None	**Few**	**Many**
Key Lines of Evidence	**None**	No ASD	Weak ASD	ASD possible
	One	Weak ASD	ASD possible	**Strong ASD**
	Multiple	ASD possible	**Strong ASD**	**Strong ASD**

Figure B-1
Use of key and supporting lines of evidence for ASD Types IV and V

ASD Checklist 1: Sampling, Laboratory, or Statistical Causes

ASD Type	Potential Cause	Identify and Comment on Applicability of Potential Cause
Sampling Causes (ASD Type I)	Sample mislabeling	
	Contamination	
	Sampling technique	
	Turbidity	
	Sampling anomalies	
Laboratory Causes (ASD Type II)	Calibration	
	Contamination	
	Digestion methods	
	Dilution corrections	
	Interference	
	Analytical methods	
	Laboratory technique / qualifier flags	
	Transcription error(s)	
Statistical Evaluation Causes (ASD Type III)	Lack of statistical independence	
	Outliers	
	False positives	
	Non-detect processing	
	Background data / change in normality	

ASD Types I, II, and III do not require a weight of evidence approach. Refer to Section 2 for descriptions of potential causes.

ASD Checklist 2: Lines of Evidence Associated with the CCR Unit

		Column A	Column B	Column C				
	Line of Evidence (LOE)	**Points to release from the CCR unit if:**	**Points to alternative source if:**	**LOE is not applicable if:[1]**	**LOE Type[2]**	**Applies to[3]**	**Weight of Evidence Determination / Basis**	**Alternative Source Demonstration Approach**
	Primary CCR Indicators							
1a	If the CCR unit contains fly ash, is there an SSI/SSL for boron and sulfate?	Yes	No	ND	Key	Monitoring Point	The primary indicators for CCR leachate typically have high concentration in the leachate, are mobile, and are not reactive in groundwater, such that any groundwater affected by a leachate release will have elevated concentration for the indicator constituent. Boron and sulfate are primary indicators for coal ash leachate. Sulfate is a primary indicator for FGD gypsum leachate. Other potential indicators are identified in Table A-1. Leachate analysis can confirm site-specific primary indicators by identifying constituents present in leachate in concentrations higher than background. An SSI/SSL is unlikely to be due to release from the facility if the leachate concentration is not higher than background.	Demonstrate using graphical and statistical analysis. Special leachate sampling may be needed if not already routinely sampled.
1b	If the CCR unit contains FGD gypsum (only) is there an SSI/SSL for sulfate?	Yes	No	ND	Key	Monitoring Point		
1c	Are there other constituents in the groundwater that represent primary indicators? List the applicable constituents.	Yes	No	ND	Supporting	Monitoring Point		
1d	Is there an SSI/SSL for any of the other primary indicators?	Yes	No	ND	Key if No	Monitoring Point		
1e	Is the *leachate* concentration for any of the primary indicators (including boron and sulfate) with an SSI/SSL statistically higher than background? List the applicable constituents.	Yes	No	ND	Key if No	Constituent		
1f	Are concentrations for the primary indicators increasing?	Yes	No	ND	Supporting	Monitoring Point		
	Secondary Indicators							
2a	Are there other SSI(s) or SSL(s) of Appendix III or IV parameters? (These are potential secondary indicators. List the applicable constituents.)	Yes	No	ND	Supporting	Monitoring Point	Secondary CCR indicators are defined by high concentration in the CCR leachate, but they may be less mobile or more reactive in the environment, or they may be relatively common in groundwater due to natural or anthropogenic causes. Leachate analysis is used to determine site-specific secondary indicators. An SSI/SSL is not likely to be due to release from the facility if the leachate concentration is not higher than background. This line of evidence is secondary to LOE 1. If LOE 1 points to an alternative source, then the alternative sources may also explain SSI/SSLs for secondary indicators.	Demonstrate using graphical and statistical analysis. Special leachate sampling may be needed if not already routinely sampled.
2b	Are the constituents identified in 2a present *in leachate* in concentrations statistically higher than background?	Yes	No	ND	Key if No	Constituent		
2c	Are concentrations for any of the secondary indicators increasing? List the applicable constituents.	Yes	No	ND	Supporting	Monitoring Point		

		Column A	Column B	Column C				
	Line of Evidence (LOE)	**Points to release from the CCR unit if:**	**Points to alternative source if:**	**LOE is not applicable if:[1]**	**LOE Type[2]**	**Applies to[3]**	**Weight of Evidence Determination / Basis**	**Alternative Source Demonstration Approach**
	Other Chemistry							
3a	Are organic constituents present in concentrations statistically higher than background? If "yes," mark column B. (May not be relevant if the CCR unit is not a monofill.)	Not applicable	Yes	No	Supporting	Monitoring Point	Organic compounds are combusted in the power plant boiler. EPRI data [1987, 2016] has shown that organic compounds typically have non-detectable concentrations in CCR leachate. The presence of organic constituents in groundwater indicates that an alternative source has affected groundwater quality at that monitoring point, although it does not rule out the CCR unit as a source for inorganic constituents. Biologically mediated reactions within organic plumes can result in natural release from soil of redox-sensitive constituents such as arsenic.	Special analyses for organic compounds may be needed if there is reason to suspect that organic compounds are present in the groundwater. Demonstrate using graphical and statistical analysis.
3b	Is major ion chemistry similar to leachate?	Yes	No	ND	Key	Monitoring Point	If the SSI/SSL is due to a release from the facility, then the major ion chemistry of the groundwater sample should be a mixture of leachate and background groundwater.	Special sampling for all eight major ions may be necessary if not routinely analyzed as part of the groundwater monitoring program. This demonstration can be performed using Piper diagrams, Stiff charts, and ion ratios (see Section 3; Tier II analysis is also described in EPRI 2012).
3c	Does major ion chemistry suggest a mixture of leachate and background groundwater?	Yes	No	ND				
3d	Does tritium age dating indicate that the groundwater was recharged after the facility was first used?	Not applicable	No	Yes	Key if No	Monitoring Point	Tritium can be used to determine if groundwater recharged prior to atomic testing in the 1950s. The CCR unit is unlikely to be the cause of an SSI/SSL if groundwater is older than the unit.	Special analysis for tritium is required, refer to EPRI (2017) for more on this method.
3e	Does isotopic analysis show evidence of mixing with CCR leachate?	Yes	No	ND	Key	Monitoring Point	The CCR unit is unlikely to be the cause of an SSI/SSL if isotope ratios show no evidence of mixing between leachate and background groundwater.	Special analyses required for isotope testing, refer to EPRI (2017).

		Column A	Column B	Column C				
	Line of Evidence (LOE)	**Points to release from the CCR unit if:**	**Points to alternative source if:**	**LOE is not applicable if:[1]**	**LOE Type[2]**	**Applies to[3]**	**Weight of Evidence Determination / Basis**	**Alternative Source Demonstration Approach**
	Hydrogeology							
4a	Is the monitoring well with an SSI/SSL downgradient from CCR unit at any point during year?	Yes	No	ND	Key if No	Monitoring Point	The monitoring well must be downgradient for the SSI/SSL to be attributed to the CCR unit.	Demonstrate using maps or calculated vectors for groundwater flow direction.
4b	Review the Hydrogeological vs Leachate Scenario Table (Table A-2) and identify the most representative scenario for each SSI or SSL case. List cases and scenario numbers.	(Check here for cases indicating a possible CCR release.) (Scenario types from Table A-2, column 1 or 2)	(Check here for cases indicating a possible alternative source.) (Scenario types from Table A-2, column 2 or 3)	ND	Key	Monitoring Point	CCR Leachate Release (Table A-2, column 1 scenarios) - If the CCR unit is the only source and the leachate concentration is higher than background, the downgradient well concentration should be equal to or less than the leachate concentration due to mixing with groundwater. CCR Leachate Release and/or Alternative Source (Table A-2, column 2 scenarios) - If the leachate concentration is higher than background and a downgradient concentration is higher than the leachate concentration, both leachate and an alternative source may be contributing to downgradient concentrations. Alternative Source Release (Table A-2, column 3 scenarios) - If the leachate concentration is less than background, the leachate cannot cause downgradient concentrations to be higher than background, and an alternative source is indicated.	This LOE requires site-specific knowledge of leachate concentrations. Demonstrate by comparing site-specific flow and concentration maps to Table A-2.
4c	Is the CCR unit immediately underlain by clay, shale, or other geologic media with low hydraulic conductivity?	No	Yes	ND	Supporting	Unit	Clay and shale can provide a physical barrier to migration from a CCR unit; however, CCR indicator concentrations, particularly boron, can be naturally elevated in these formations.	Cross-sections developed from boring logs
4d	Is the monitoring point distant from the facility AND does the constituent with an SSI/SSL have low mobility in groundwater given the hydrogeologic environment at the monitoring location (see Table A-3)?	No	Yes	ND	Supporting	Case	The CCR unit is less likely to be the source of the SSI/SSL if the constituent has low mobility and is monitored at a distant point.	Groundwater modeling, accounting for sorption, can be used to determine whether or not migration to the monitoring location is possible.
4e	Are the background monitoring wells screened in the same hydrostratigraphic unit, and along the same groundwater flow path, as the monitoring location with the SSI?	Yes	No	ND	Supporting	Monitoring Point	If the background and downgradient wells are not along the same flow path and/or are not screened in the same hydrostratigraphic unit, the SSI/SSL may indicate a natural difference between formations or flow paths, rather than an anthropogenic release.	The site conceptual model, based on groundwater flow and hydrogeology, provides data that can be used for this determination. Geochemical modeling can be used to evaluate the naturally occurring geochemistry expected for different hydrostratigraphic units, and whether or not the observed evolution in groundwater quality is consistent with what is known about the geochemistry of each hydrostratigraphic unit.

		Column A	Column B	Column C				
	Line of Evidence (LOE)	**Points to release from the CCR unit if:**	**Points to alternative source if:**	**LOE is not applicable if:[1]**	**LOE Type[2]**	**Applies to[3]**	**Weight of Evidence Determination / Basis**	**Alternative Source Demonstration Approach**
	CCR Unit Design							
5a	Does the entire footprint of the monitored CCR unit have a liner?	No	Yes	ND	Supporting	Unit	The presence of a liner reduces the potential (relative to an unlined unit) for a release from the CCR unit, particularly if it is not underlain by a natural barrier material.	Review design documentation. The response to this question would be no if any portion of the monitored CCR unit is unlined.
5b	If the facility is lined, is it a composite liner?	No	Yes	ND	Supporting	Unit	A composite liner, consisting of a geosynthetic barrier material over clay, further reduces the potential for a release (relative to a clay liner) from a CCR unit.	Review design documentation. The response to this question would be no if any portion of the monitored CCR unit does not have a composite liner.
5c	Does the entire footprint of the CCR unit have a leachate collection system?	No	Yes	ND	Supporting	Unit	A leachate collection system further reduces the potential (relative to a unit with liner and no leachate collection) of a release from a CCR unit.	Review design documentation. The response to this question would be no if any portion of the monitored CCR unit does not have leachate collection.
5d	If the CCR unit is unlined, is it known to have or is it likely to have groundwater intersecting the CCR?	Yes	No	ND	Supporting	Unit	This LOE is indeterminate for active impoundments. This LOE is indeterminate for CCR units with engineered or natural liners. For cases that are not indeterminate, an intersecting water table increases the potential for a release to groundwater, relative to a facility where groundwater is below the CCR.	Water table elevation contours and engineering drawings can be compared to project whether or not the water table intersects the CCR. If engineering drawings are not available, and the facility is unlined, then borings can be performed to gauge CCR depth. Spring seepage into a CCR unit would be counted as intersecting groundwater.

Table Notes:

1. ND (not determined) indicates that this line of evidence was not tested or there are insufficient data to make a determination.
2. Line of Evidence (LOE) Types:
   Key lines of evidence are based on relationships that must be observed in order for an SSI/SSL to be due to a release from a CCR unit. If these relationships are not observed, then they are critical to establishing an ASD. It is difficult to build a strong ASD without any key lines of evidence. It may be possible to build an ASD with a single key line of evidence, but the ASD will be stronger with additional key or supporting lines of evidence.
   Supporting lines of evidence provide additional information that supports the ASD. Supporting lines of evidence are generally not sufficient to build an ASD unless there is at least one key line of evidence, although it may be possible if there are many supporting lines of evidence.
3. This LOE applies to:
   Constituent: An SSI/SSL for that constituent at any monitoring point
   Monitoring Point: All SSIs/SSLs at a specific monitoring point
   Case: An SSI/SSL for a specific constituent at a specific monitoring point
   Unit: All SSIs/SSLs at the monitored unit

ASD Checklist 3: Lines of Evidence Associated with Alternative Natural and Anthropogenic Sources

		Column A	Column B	Column C				
	Line of Evidence (LOE)	***Does not* point to alternative source if:**	**Points to alternative source if:**	**LOE is not applicable if:[1]**	**LOE Type[2]**	**Applies to[3]**	**Weight of Evidence Determination / Basis**	**Alternative Source Demonstration Approach**
General								
6a	Are there any known alternative sources for any of the constituents of concern on-site or off-site?	No	Yes	ND	Supporting	Unit	Identification of an alternative source for one or more constituents with an SSI/SSL, in an upgradient location, establishes potential for an ASD.	Consider answering the questions below first to help identify possibilities, and then come back to this set of questions. Refer to Tables A-3 and A-4 for common anthropogenic sources for various constituents in groundwater. List and draw locations with reference to the CCR unit on a map.
6b	Are any current or former potential alternative sources upgradient of the monitoring location?	No	Yes	ND	Supporting	Monitoring Point		
6c	Do monitoring locations between a potential upgradient source and CCR unit have concentrations at SSI/SSL levels?	No	Yes	ND	Supporting	Constituent	If a constituent has high concentration in groundwater, relative to background, both upgradient and downgradient from a CCR unit, then an alternative source is possible, regardless of whether or not the responses to 6a and 6b are yes. If the upgradient concentration is similar to or higher than the downgradient concentration, then an alternative source is likely.	Demonstrate using statistical and graphical methods.
On-Site Alternative Source								
7a	Is the monitoring point downgradient of or near a coal pile, or coal pile runoff, or coal pile leachate management area?	No	Yes	ND	Supporting	Monitoring Point	If yes, the coal pile may be a potential alternative source if it is unlined.	Use Tier II analysis to test for differences in leachate and groundwater signatures. May require special sample from coal pile runoff ditch or collection pond.
7b	Are there former coal mines, mine spoil, or conveyers near the CCR unit or upgradient from the facility?	No	Yes	ND	Supporting	Unit	If yes, these may be alternative sources.	pH may be lower, and concentrations of iron, manganese, and trace elements may be higher in groundwater impacted by a coal mine relative to CCR leachate.
7c	Does the site have other CCR units that are upgradient or side gradient of the affected monitoring location?	No	Yes	ND	Supporting	Monitoring Point	If yes, the other CCR units may be alternative sources, particularly if they are unlined impoundments or landfills.	For this case CCR indicator constituents should have an SSI/SSL or increasing trend at the monitoring location. If water quality signatures are not different, then intermediate monitoring points may be needed.
7d	Is the CCR unit built on top of a former CCR disposal area (i.e., has a lined impoundment been built on top of a former unlined impoundment, or has a lined landfill been built on top of a portion of an unlined impoundment)?	No	Yes	ND	Supporting	Unit	If yes, groundwater quality may be affected by leachate from the underlying CCR.	For this case CCR indicator constituents should have an SSI/SSL or increasing trend at the monitoring location. If the overfill CCR unit is lined and concentrations of CCR leachate indicators are decreasing, an ASD may be possible showing that the groundwater impacts are due to the former CCR disposal activities. The water quality signature and isotope ratios for a legacy site may be different than those for the overfill unit if there has been a coal switch.

		Column A	Column B	Column C				
	Line of Evidence (LOE)	***Does not* point to alternative source if:**	**Points to alternative source if:**	**LOE is not applicable if:[1]**	**LOE Type[2]**	**Applies to[3]**	**Weight of Evidence Determination / Basis**	**Alternative Source Demonstration Approach**
On-Site Alternative Source (continued)								
7e	Do the CCR unit or adjacent units have an active underdrain piping system or groundwater pumping system, or are there any groundwater pumping activities nearby, that could have localized influence on groundwater flow and quality?	No	Yes	ND	Supporting	Unit	If yes, consider potential effects on localized groundwater flow directions and quality.	Groundwater with CCR constituents can be pulled toward another CCR unit with an underdrain system or if CCR units are within the radius of influence of on-site production wells. For example, elevated CCR constituents from an unlined fly ash pond (e.g., boron) can occur in adjacent gypsum pond downgradient wells due to localized groundwater flow.
7f	Is there evidence that water used for dust suppression on uncovered CCR or coal piles flowed off the footprint of the liner or runoff containment system near the monitoring point?	No	Yes	ND	Supporting	Monitoring Point	Runoff water from dust control can contain many of the same constituents as CCR leachate. If wind or other issues cause a spray irrigation system to deposit leachate beyond the landfill boundary, then an SSI/SSL with a CCR leachate signature can result. These are examples of an ASD where management of the unit is responsible for the SSI/SSL, but the SSI/SSL is not due to a direct release of leachate to groundwater from the unit. A change in management can mitigate this SSI/SSL source.	Identify the source of dust suppression water (coal pile runoff water, leachate, reused water from other sources). Document, using photos or other evidence, potential pathways off the liner or beyond the runoff containment system. For these cases, CCR indicator constituents should have an SSI/SSL or increasing trend at the monitoring location. Concentrations should decrease after management improvements are implemented.
7g	Is leachate or sluice water used for dust control close to the monitoring location?	No	Yes	ND	Supporting	Monitoring Point		
7h	Is the monitoring point downgradient of or near a CCR handling area (silo, storage area, dewatering bin, sump, truck loading/unloading or washing area, etc.) or haul road?	No	Yes	ND	Supporting	Monitoring Point	These are examples of an ASD where CCR handling associated with the unit is responsible for the SSI/SSL, but the SSI/SSL is not due to a direct release of leachate to groundwater from the unit. Revisions to handling practices, or repairs to handling structures, can mitigate this SSI/SSL source.	Engineering investigation of CCR and leachate handling structures may be required to demonstrate these alternative sources. Documentation of spillage or leaks (by material type, source, and location) will support this ASD. For these cases, CCR indicator constituents should have an SSI/SSL or increasing trend at the monitoring location. This ASD is particularly effective if concentrations begin to decrease after the alternative source is mitigated (allowing for lag time due to slow-moving groundwater).
7i	Is the monitoring point downgradient of or near sluice water lines, handling equipment, or storage areas?	No	Yes	ND	Supporting	Monitoring Point		
7j	Is the monitoring point downgradient of or close to a leachate collection pipeline or leachate storage structure?	No	Yes	ND	Supporting	Monitoring Point		
7k	Have there been any documented spills of CCR or leachate or sluice water in upgradient or nearby locations?	No	Yes	ND	Supporting	Monitoring Point		
7l	Were CCRs ever drained or stockpiled in unlined areas and/or without run-off/leachate control in upgradient or nearby areas?	No	Yes	ND	Supporting	Monitoring Point		

	Line of Evidence (LOE)	Column A ***Does not* point to alternative source if:**	Column B **Points to alternative source if:**	Column C **LOE is not applicable if:[1]**	**LOE Type[2]**	**Applies to[3]**	**Weight of Evidence Determination / Basis**	**Alternative Source Demonstration Approach**
On-Site Alternative Source (continued)								
7m	Is there any history of on-site or upgradient oil or chemical spills or leaking underground storage tanks?	No	Yes	ND	Supporting	Monitoring Point	If yes, groundwater may be impacted by oil or chemical spills.	Documentation of spillage or leaks (by material type, source, and location) will support this ASD. For this case, look for constituents that are higher than background that are not primary indicators of the site-specific CCR leachate signature.
7n	Does a significant amount of road salting occur on-site? (also see 9b)	No	Yes	ND	Supporting	Monitoring Point	If yes, concentrations for chloride and other major ions (depending on the type of salt; see Table A-4) may have an SSI/SSL.	If yes, look for notably elevated concentrations of the cations and anions comprising the salts used. If these are elevated, then an ASD related to road salting may be possible.
7o	Are fertilizers being used on-site for cap vegetation or other uses?	No	Yes	ND	Supporting	Monitoring Point	Consider if groundwater impacts include nitrates or phosphates, or if the fertilizers include calcium, sulfate, or other minerals that are monitored under the CCR program.	Documentation of on-site use of fertilizers will help support this ASD.
7p	Is there any history of on-site or upgradient ash utilization (structural fill, landfill, road base, berm construction, soil stabilization, etc.)?	No	Yes	ND	Supporting	Monitoring Point	If yes, these may be on-site alternative sources.	Documentation of historical site structural fill activities, source information, and analytical data will help support this ASD.
7q	Was the power plant site subgrade prepared with CCR, dredge spoils, incinerator residue, construction debris, industrial waste, or non-native soils?	No	Yes	ND	Supporting	Monitoring Point		
Natural Variation								
8a	Are background wells screened in the same geomedia as the monitoring point?	Yes	No	ND	Supporting	Monitoring Point	If no, then one or more SSI/SSL may be a result of naturally occurring differences in groundwater quality.	Geochemical modeling can be used to evaluate whether or not observed concentrations are consistent with the geomedia.
8b	Is the aquifer comprised of poorly buffered media such as sand and gravel?	No	Yes	ND	Supporting	Unit	If yes, then pH may be evolving if the pH or precipitation water is different than the groundwater, which can cause desorption or dissolution of pH-sensitive constituents.	Investigate long-term data records for evidence of pH changes. Refer to Table A-3 to determine if this case applies to the constituent with an SSI/SSL. Geochemical modeling may be considered to fully document this effect.
8c	Is the pH at the monitoring point similar to the background pH?	Yes	No	ND	Supporting	Monitoring Point	If no, then background is not fully representative of downgradient groundwater. Concentrations may evolve over the groundwater flow path.	Refer to Table A-3 to determine if this case applies to the constituent with an SSI/SSL. Geochemical modeling may be considered to fully document this effect.

		Column A	Column B	Column C				
	Line of Evidence (LOE)	***Does not* point to alternative source if:**	**Points to alternative source if:**	**LOE is not applicable if:[1]**	**LOE Type[2]**	**Applies to[3]**	**Weight of Evidence Determination / Basis**	**Alternative Source Demonstration Approach**
Natural Variation (continued)								
8d	Is the monitoring point near a river?	No	Yes	ND	Supporting	Monitoring Point	If yes, then there may be changes in flow direction and/or groundwater elevations in response to changes in river stage that could result in monitoring different groundwater than during the background monitoring period. A yes response here also signifies potential for a redox change from oxic in upgradient areas where groundwater recharges, to reduced near the river where groundwater discharges.	Time-series plots can be used to see if there are correlations between river stage and concentration. Concentration distribution maps can be used to investigate effects of changes in flow direction. Check redox indicators to look for changes in redox.
8e	Is the constituent chemically reactive in groundwater, such that dissolution or desorption is possible (see Table A-3)?	No	Yes	ND	Supporting	Constituent	Reactive constituents can exhibit naturally occurring concentration changes if pH or redox conditions change along the flow path.	Refer to Table A-3 to determine if this case applies to the constituent with an SSI/SSL. Geochemical modeling can be used to test whether or not a change in geochemical conditions is causing a naturally occurring evolution of the groundwater.
8f	Is there a difference in redox indicators between background and compliance monitoring data?	No	Yes	ND	Supporting	Monitoring Point	This can affect redox-sensitive constituents, and can cause an SSI/SSL if the different redox environment only occurs at downgradient monitoring locations.	Compare background and compliance redox indicators to determine if this case applies. Refer to Table A-3 to determine if this case applies to the constituent with an SSI/SSL. Geochemical modeling may be considered to fully document this effect.
8g	Has there been a recent flood, recharge event, or dry period that caused groundwater elevation to rise or fall to elevations higher or lower than observed during the background monitoring period?	No	Yes	ND	Supporting	Unit	If yes, then there may be changes in groundwater elevation that could result in monitoring different groundwater than during the background monitoring period.	Time-series plots can be used to see if there are correlations between river stage and concentration.
8h	Does the aquifer contain saline water at depth?	No	Yes	ND	Supporting	Unit	If yes, monitoring wells close to the ocean, or that are deeper than background, may have higher concentrations of indicators for brine than background groundwater. Implementation of, or an increase in, groundwater withdrawals near the monitoring point could cause upwelling that would be a change over time.	The water quality signature for seawater and brines should be different than leachate, as described in Section 4.
8i	Was the direction of groundwater flow prior to or during the sample event different than observed during the background prior?	No	Yes	ND	Supporting	Monitoring Point	If yes, then the changes in flow direction could result in monitoring different groundwater than during the background monitoring period.	Concentration distribution maps can be used to investigate effects of changes in flow direction.

		Column A	Column B	Column C				
	Line of Evidence (LOE)	***Does not* point to alternative source if:**	**Points to alternative source if:**	**LOE is not applicable if:[1]**	**LOE Type[2]**	**Applies to[3]**	**Weight of Evidence Determination / Basis**	**Alternative Source Demonstration Approach**
Off-Site Anthropogenic								
9a	Are there former coal mines, mine spoil, or conveyers near the CCR unit or upgradient from the facility (also consider under "On-site")?	No	Yes	ND	Supporting	Unit	If yes, these may be alternative sources.	pH may be lower, and concentrations of iron, manganese, and trace elements may be higher, in groundwater impacted by a coal mine relative to CCR leachate.
9b	Does a significant amount of road salting occur off-site?	No	Yes	ND	Supporting	Unit	If yes, concentrations for chloride and other major ions (depending on the type of salt; see Table A-4) may have an SSI/SSL.	If yes, look for notably elevated concentrations of the cations and anions comprising the salts used. If these are elevated, then an ASD related to road salting may be possible.
9c	Does the surrounding land use include agriculture (crops)?	No	Yes	ND	Supporting	Unit	If yes, then concentrations of nitrates and other agricultural constituents (see Table A-4) may be elevated.	Use graphical or statistical analysis to demonstrate presence of agricultural indicators. This ASD is most effective if agricultural indicators are present in upgradient or intermediate monitoring points.
9d	Does the surrounding land use include agriculture (animal)?	No	Yes	ND	Supporting	Unit		
9e	Are there current or former underground or aboveground storage tanks that have had a release? (Consider gas stations and surrounding industrial activities.)	No	Yes	ND	Supporting	Unit	If yes, these may be alternative sources.	Identification of locations of underground and aboveground storage tanks, along with documented leak history (if known), will help support this ASD. Include locations of gas stations.
9f	Are there, or were there, oil and gas production wells in the vicinity of the site?	No	Yes	ND	Supporting	Unit	If yes, look for evidence of salt water intrusion, seepage of drilling fluid or additive chemicals, and organics.	Document locations of oil and gas wells.
9g	Are there existing or historical commercial and/or industrial sources of impacts, such as metal manufacturing, mining, landfills, Superfund or brownfield sites, wood treatment, etc.?	No	Yes	ND	Supporting	Unit	First determine if surrounding land use includes current or former industrial or commercial activity and identify types and locations. Then look for evidence of potential impacts to groundwater. Tables A-3 and A-4 provide information on potential impacts to groundwater related to common anthropogenic activities.	Review historical aerial photos, Sanborn maps, and available GIS data showing changing landscape and property use since the late 19th century. USGS topographic maps can be used to evaluate drainage patterns and topographic changes as well as locations of mines, quarries, and landfills. Review local, state, and federal information available through online databases or Freedom of Information Act requests related to brownfield sites and NPL listings. The local fire department and county health department may be good sources of information.
9h	Could any potential anthropogenic sources be causing changes to groundwater chemistry that would result in release of the constituent of concern through changes to pH, redox, etc.?	No	Yes	ND	Supporting	Unit	As noted, a change in pH or redox along a flow path or over time can cause concentrations for pH or redox-sensitive constituents to change.	Review field data to determine if a pH or redox change has occurred. Document the source of the pH or redox change. Refer to Table A-3 to verify that the SSI/SSL is for a constituent that is pH or redox-sensitive.
	Time-of-Travel Analysis							
10	Has groundwater flowing beneath potential sources had enough time to migrate to the affected monitoring well location?	No	Yes	ND	Supporting	Monitoring Point	Constituents must have time to travel downward to the aquifer and travel with the aquifer to the monitoring point. Sources must also be in upgradient or side gradient locations.	Use groundwater velocity calculation or simple analytical model to determine if there has been sufficient time for transport to the monitoring point.

Table Notes:

1. ND (not determined) indicates that this line of evidence was not tested or there are insufficient data to make a determination.
2. Line of Evidence (LOE) Types:
   Key lines of evidence are based on relationships that must be observed in order for an SSI/SSL to be due to a release from a CCR unit. If these relationships are not observed, then they are critical to establishing an ASD. It is difficult to build a strong ASD without any key lines of evidence. It may be possible to build an ASD with a single key line of evidence, but the ASD will be stronger with additional key or supporting lines of evidence.

Supporting lines of evidence provide additional information that supports the ASD. Supporting lines of evidence are generally not sufficient to build an ASD unless there is at least one key line of evidence, although it may be possible if there are many supporting lines of evidence.

3. This LOE applies to:
   Constituent: An SSI/SSL for that constituent at any monitoring point
   Monitoring Point: All SSIs/SSLs at a specific monitoring point
   Case: An SSI/SSL for a specific constituent at a specific monitoring point
   Unit: All SSIs/SSLs at the monitored unit

Export Control Restrictions

Access to and use of EPRI Intellectual Property is granted with the specific understanding and requirement that responsibility for ensuring full compliance with all applicable U.S. and foreign export laws and regulations is being undertaken by you and your company. This includes an obligation to ensure that any individual receiving access hereunder who is not a U.S. citizen or permanent U.S. resident is permitted access under applicable U.S. and foreign export laws and regulations. In the event you are uncertain whether you or your company may lawfully obtain access to this EPRI Intellectual Property, you acknowledge that it is your obligation to consult with your company's legal counsel to determine whether this access is lawful. Although EPRI may make available on a case-by-case basis an informal assessment of the applicable U.S. export classification for specific EPRI Intellectual Property, you and your company acknowledge that this assessment is solely for informational purposes and not for reliance purposes. You and your company acknowledge that it is still the obligation of you and your company to make your own assessment of the applicable U.S. export classification and ensure compliance accordingly. You and your company understand and acknowledge your obligations to make a prompt report to EPRI and the appropriate authorities regarding any access to or use of EPRI Intellectual Property hereunder that may be in violation of applicable U.S. or foreign export laws or regulations.

The Electric Power Research Institute, Inc. (EPRI, www.epri.com) conducts research and development relating to the generation, delivery and use of electricity for the benefit of the public. An independent, nonprofit organization, EPRI brings together its scientists and engineers as well as experts from academia and industry to help address challenges in electricity, including reliability, efficiency, affordability, health, safety and the environment. EPRI members represent 90% of the electric utility revenue in the United States with international participation in 35 countries. EPRI's principal offices and laboratories are located in Palo Alto, Calif.; Charlotte, N.C.; Knoxville, Tenn.; and Lenox, Mass.

Leaching, Geotechnical, and Hydrologic Characterization of Coal Combustion Products from a Closed Coal Ash Impoundment: Capped Unit. EPRI, Palo Alto, CA: 2020. 3002017363.

ABSTRACT

The appropriate use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field.

This report presents the results of geotechnical, hydrologic, and leaching characterization of samples collected from a closed and capped coal ash impoundment. The hydraulic conductivity of intact cores from the pond was measured in context of the distribution of particles in the coal ash samples and the overburden pressure associated with disposal at depth within the pond. The leaching test results for LEAF tests (i.e., EPA Methods 1313 and 1314) were compared to those for traditional tests (i.e., ASTM, TCLP, SPLP). In addition, concentrations derived from leaching tests were compared to porewater concentrations determined from field samples, and field-sampled porewater concentrations were compared to groundwater concentrations, to evaluate similarities and dissimilarities between these results.

Product Type: Technical Report

Product Title: Leaching, Geotechnical, and Hydrologic Characterization of Coal Combustion Products from a Closed Coal Ash Impoundment: Capped Unit

PRIMARY AUDIENCE: Electric utility environmental professionals responsible for landfill and impoundment management of CCPs.

SECONDARY AUDIENCE: Researchers and regulators interested in CCP leaching and chemistry.

KEY RESEARCH QUESTION

The appropriate use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field. The goals of this research were (i) to evaluate approaches for estimating porewater concentrations at CCP disposal facilities, and (ii) to explore potential connections between the CCP leaching performance of a disposal facility, based on porewater measurements or leaching tests, and monitoring of groundwater exterior to the facility.

RESEARCH OVERVIEW

Coal ash samples were collected at three locations from a closed and capped disposal impoundment. During field activities, porewater access and subsurface gas access points were established and monitored for 13 months. Collected solids were characterized for leaching and geotechnical/hydrologic properties. The hydraulic conductivity of intact cores was measured in context of the distribution of particle sizes in the coal ash samples and the overburden pressure associated with disposal at depth within the pond. The leaching test results for the Leaching Environmental Assessment Framework (LEAF) (i.e., EPA Methods 1313 and 1314) were compared to those for traditional tests (i.e., ASTM, TCLP, and SPLP). In addition, leaching test results were compared to porewater concentrations determined from field samples, and field-sampled porewater concentrations were compared to groundwater concentrations, to evaluate similarities and dissimilarities between these results.

KEY FINDINGS

- The hydraulic conductivity of intact ash samples is strongly dependent on the fraction of fines in the material. The measured hydraulic conductivity of finer, less permeable coal ash samples was lower (ranging from approximately $7x10^{-4}$ cm/s to $1x10^{-5}$ cm/s) than the hydraulic conductivity of coarser, more permeable samples (approximately $1x10^{-3}$ cm/s). In general, the measured hydraulic conductivity decreased with increasing effective stress, or overburden pressure; however, the hydraulic conductivity of coarser, more permeable coal ash samples decreased three times as much as that of finer, less permeable coal ash.

- The subsurface gas measurements and concentrations of redox-sensitive constituents in field porewater samples suggest that reduction-oxidation conditions of the closed disposal impoundment were more bio-chemically reduced than indicated by porewater analysis alone. Monitoring of subsurface gas concentrations shows the presence of hydrogen sulfide and methane, indicating strongly reducing conditions. Monthly data indicate that reducing conditions are spatially variable in extent and may be seasonally dependent. In addition, arsenic concentrations in the porewater are at the high end of previously reported ranges for coal ash. At intermediate reducing conditions, elevated concentrations of arsenic are likely due to loss of hydrous ferric oxides as ferric oxides are reduced and solubilized (conversion of insoluble Fe^{3+} to soluble Fe^{2+}). Under very low redox conditions, arsenic porewater concentrations decrease due to conversion of As(V) to As(III) and likely precipitation as sulfides. Conversely, the porewater concentrations of antimony and selenium in the reduced pond environment are suppressed due to formation of reduced species with lower solubility.
- Traditional leaching tests (i.e., TCLP, SPLP, and ASTM) are poor indicators of measured porewater concentrations. Low liquid-to-solid ratio (L/S) eluates from EPA Method 1314 were better indicators than the traditional tests for concentrations for available content-limited constituents (B, Ca, Cl, Mo, SO_4, Tl) because of the strong L/S-dependence. However, additional information (e.g., available content and porewater L/S) would be needed to provide a reasonable approximation of porewater concentrations. For constituents with solubility-controlled liquid-solid partitioning (Sb, As, Ba, Cr, F^-, Se, V, Zn), pH-dependence tests (e.g., EPA Method 1313) may provide valuable information for geochemical modeling, but, for this site, the natural or own pH responses did not reliably estimate field porewater concentrations, in part due to differences in redox as noted in the next bullet.
- When the field environment is highly reducing, laboratory leaching results for redox-sensitive elements (e.g., As, Cr, Sb, Se, and Fe) do not directly reflect the leaching anticipated in porewater. This is, in part, because reduced materials collected in the field are inevitably partially oxidized during sampling, handling, and testing.
- Porewater concentrations were not a reliable indicator for which constituents would have elevated concentrations, relative to background, in downgradient groundwater or for future prediction of downgradient concentrations at this site.

WHY THIS MATTERS

This research provides a unique opportunity to compare a field porewater sample set to laboratory leaching test results on samples collected from the same location and depth interval as the porewater sampling point and provides information to guide appropriate use of these tests. It also provides information on, and comparison of, the spatial and temporal/seasonal variability in both porewater quality and laboratory leachate quality at a CCP site. Data collected during this research will inform EPRI physical and geochemical modeling of leaching within coal ash landfills and impoundments.

HOW TO APPLY RESULTS

The results of this research are site-specific, yet when considered with known differences in L/S associated with different leaching tests, and geochemical differences between the field and laboratory environment, they provide information for generalizing the best uses of different leaching tests and porewater data. Companies interested in performing similar comparisons between leaching tests and porewater will be interested in the

field and laboratory methodologies described in Sections 2 and 3. Companies and stakeholders interpreting leaching test and porewater results will be interested in the results summarized in Sections 4 and 5, as well as the detail provided in Appendices C through G.

LEARNING AND ENGAGEMENT OPPORTUNITIES

- A framework using geochemical modeling and porewater data to predict long-term leaching at CCP sites is being developed under EPRI Program 49A's hydrogeochemistry project. A series of reports published from 2018 through 2020 describe results of this research. These reports can be accessed by searching epri.com for "Hydrogeochemical Assessment of Long-Term Leaching Characteristics at Coal Combustion Product Sites."
- Stakeholders, including regulatory agencies, reviewing leaching test analyses may be interested in results of this research to understand the relationship between the different leaching tests, and the relationship between leaching tests and porewater within CCPs.

ABBREVIATIONS, ACRONYMS, AND SYMBOLS

Abbreviations and Acronyms

AMSL	above mean sea level
BGS	below ground surface
CCP(s)	coal combustion product(s)
CFR	Code of Federal Regulations
CH_4	methane gas
CO_2	carbon dioxide gas
DIW	deionized water
DIC	dissolved inorganic carbon
DO	dissolved oxygen
DOC	dissolved organic carbon
EC	electrical conductivity (mS/cm)
Eh	redox potential (mV)
EPA	Environmental Protection Agency
EPRI	Electric Power Research Institute
GAP(s)	gas access point(s)
HDPE	high-density polyethylene
HFO	hydrous ferric oxides
HNO_3	nitric acid
HSA	hollow-stem auger
H_2S	hydrogen sulfide gas
H_2SO_4	sulfuric acid
IC	ion chromatography
ICP	inductively coupled plasma
ICP-MS	inductively coupled plasma – mass spectrometry
ICP-OES	inductively coupled plasma – optical emission spectroscopy

ID	internal diameter
KOH	potassium hydroxide
LEAF	Leaching Environmental Assessment Framework
LLOQ(s)	lower limit(s) of quantitation
LOI	loss on ignition
LSP	liquid-solid partitioning
L/S	liquid-to-solid ratio
MDL(s)	method detection limit(s)
NDIR	non-dispersive infrared
NH_3	ammonia gas
NIST	National Institute of Standards and Technology
OD	outer diameter
ORP	oxidation-reduction potential
O_2	oxygen gas
PAP(s)	porewater access point(s)
pe	electron concentration
PSD	particle size distribution
QA/QC	quality assurance/quality control
RCRA	Resource Conservation and Recovery Act of 1986
SU	standard unit(s)
TC	total carbon
UVA	University of Virginia (Charlottesville, VA)
VU	Vanderbilt University (Nashville, TN)
wt%	weight percent (percent by mass)
XRF	x-ray fluorescence

Groundwater/Porewater Sample Points

AD1	upgradient, background groundwater well
VB-1	porewater access point in the closed impoundment
VB-2	porewater access point in the closed impoundment
VB-3	porewater access point in the closed impoundment
6AR	downgradient compliance groundwater well

Leaching/Extraction Tests

ASTM	ASTM D3987: Practice for Shake Extraction of Solid Waste with Water
1313	EPA Method 1313: Liquid-Solid Partitioning as a Function of Eluate pH Using a Parallel Batch Procedure
1314	EPA Method 1314: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using an Up-Flow Percolation Column Procedure
1313_L/S=1	EPA 1313 modified for L/S=1 mL/g-dry and abbreviated to 5 target endpoint pH values about the own pH of the material
1313_3pt	EPA 1313 abbreviated to 3 target endpoint pH values (<2, natural pH, and 9)
SPLP	EPA Method 1312: Synthetic Precipitation Leaching Procedure
TCLP	EPA Method 1311: Toxicity Characteristic Leaching Procedure

Equation and Parameter Variables

F	Faraday constant (23,061 cal/(V mol))
MC	moisture content on a dry basis (%)
m_{wet}	mass of “wet” solid (g)
m_{dry}	mass of oven-dried solid (g-dry)
n	porosity (m^3_{pore}/m^3)
SC	solids content on a wet basis (%)
R	1.987 (cal/(K mol))
T	temperature (K)
ρ_d	dry density (mg-dry/m^3)
θ_s	saturated water content (m^3_{water}/m^3)

1
INTRODUCTION

The appropriate use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is highly dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field. For example, traditional leaching tests, including EPA Method 1311: Toxicity Characteristic Leaching Procedures (TCLP), EPA Method 1312: Synthetic Precipitation Leaching Procedure (SPLP), and ASTM D3987: Shake Extraction of Solid Waste with Water (ASTM), provide only a snapshot of leaching performance under conditions that often deviate substantially from current conditions and anticipated future field conditions.

In 2012, the United States Environmental Protection Agency (EPA) published four leaching methods from the Leaching Environmental Assessment Framework (LEAF) as draft methods available for use. The four methods have since been validated (Garrabrants et al., 2012a; 2012b) and incorporated as final methods into the Agency's compendium of laboratory methods (SW-846). The four LEAF methods are:

- EPA Method 1313: Liquid-Solid Partitioning as a Function of Eluate pH Using a Parallel Batch Procedure
- EPA Method 1314: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using an Up-Flow Percolation Column Procedure
- EPA Method 1315: Mass Transport Rates of Constituents in Solid Materials Using a Tank Leaching Procedure
- EPA Method 1316: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using a Parallel Batch Procedure

The LEAF approach differs from traditional leaching assessment methodologies in that the leaching tests are designed to provide a series of eluates characteristic of leaching behavior dependent on one or more controlling factors rather than a single eluate that is representative of field leachate from a designed scenario. The EPA has provided a guide for how LEAF tests may be incorporated into common leaching assessment practices (EPA 2019, Garrabrants et al., 2019a, 2019b).

There remains uncertainty as to the selection of specific test methods to represent (i) the range of pH and liquid-to-solid ratio (L/S) within a waste mass and (ii) the current and long-term geochemical conditions of the porewater of CCP impoundments and landfills. Thus, leaching

tests have been widely applied, but often without consideration of their inherent limitations for providing information suitable for evaluation of long-term leaching performance. In addition, little information is available that directly compares measured field porewater concentrations at CCP disposal sites to the results of various leaching test results.

The Electric Power Research Institute (EPRI), Vanderbilt University (VU), and University of Virginia (UVA) collaborated on a study to evaluate relationships between the geochemistry of the disposed CCPs and the measured and predicted concentrations for inorganic constituents in the porewater of CCP disposal units. In addition, this study investigates the potential relationship between porewater concentrations and the concentrations in groundwater measured at adjacent monitoring wells. CCP materials were collected from two disposal sites. During field activities, porewater access and subsurface gas access points were established for eight to twelve months of monthly monitoring. Collected materials were characterized for leaching and geotechnical/hydrologic properties. A framework for integrating these data is being developed under a separate EPRI project. This report provides the methodology for sampling and characterization of disposed CCPs collected from a closed ash impoundment at Plant 42201, also referred to as "KSP." This report summarizes the results of leaching tests and monitoring data with respect to groundwater and impoundment porewater collected at the facility as well as vadose zone subsurface gas concentrations monitored within the impoundment.

Project Goals and Objectives

The goals of this research were (i) to evaluate approaches for estimating porewater concentrations at CCP disposal facilities, and (ii) to explore potential connections between the CCP leaching performance of a disposal facility, based on porewater measurements or leaching tests, and monitoring of groundwater exterior to the facility.

The specific objectives of this project include:

- Collecting field materials to qualify the spatial and temporal variability of materials disposed in the closed impoundment and to allow for characterization of leaching and geotechnical/hydrologic property determination.
- Correlating the characterization of leaching from bulk samples using traditional leaching tests (i.e., TCLP, SPLP, and ASTM) and LEAF pH- or L/S-dependence leaching tests with measured porewater concentrations monitored at the site.
- Assessing the ability of leaching tests (traditional or LEAF tests) to directly estimate porewater concentrations within the closed impoundment.
- Identifying the relationship, if any, between porewater concentrations within the closed impoundment and downgradient groundwater concentrations.

Site Description

The closed impoundment, represented in Figure 1-1a, is a triangular 25-acre area divided from a larger coal ash landfill constructed in the 1950s. The impoundment was used to collect storm water and process water from Plant 42201 before discharge into an adjacent river. Between 2012 and 2015, the impoundment received sluiced CCPs from the plant. In 2016, the inactive impoundment was closed, with the closure project completed approximately one month prior to

the field collection of field samples and establishment of groundwater sampling points. The closure project involved removal of free water from the impoundment, regrading of the coal ash to level the surface, and installation of a composite geosynthetic soil cover system as illustrated in Figure 1-1b. The cover is typically about 5 feet thick; however, the thickness of the cover system varies based on the ash layer elevations. At the time of the field investigation, phreatic porewater occurred approximately 6 feet below the surface of the ash layer. At the center of the impoundment, the ash layer is approximately 20 feet thick.

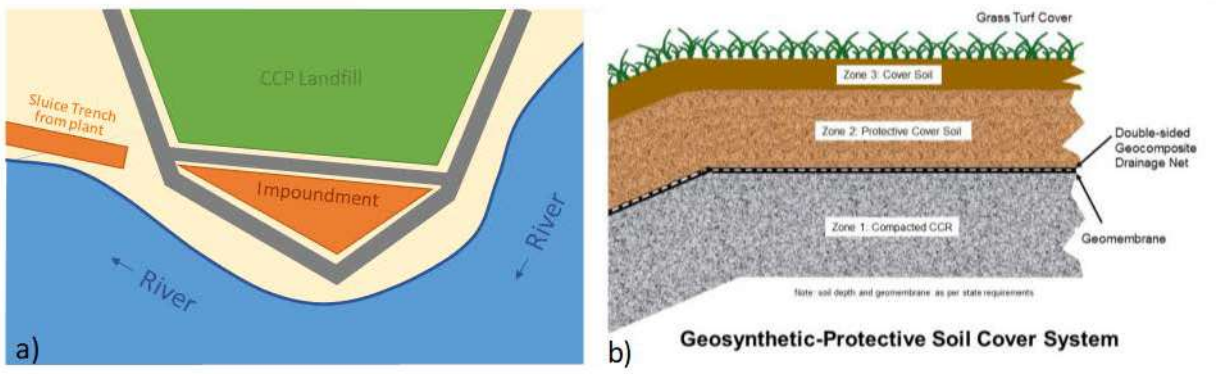

Figure 1-1

Sampling and Testing Approach

Fieldwork for this project included: (i) advancement of boreholes into the coal ash deposit to improve the understanding of stratigraphy and to sample contained solids (i.e., ash, cover fill, and native clay liner); (ii) installation of porewater access points (PAPs) and subsurface gas access points (GAPs) within boreholes in the ash deposit; and (iii) monthly sampling of groundwater and porewater and subsurface gas compositions. At each of three locations within the closed impoundment, bulk ash samples were collected from continuous split spoon sampling to evaluate the constituency of material in the ash deposit and leaching properties of the collected ash. In parallel, intact ash cores were collected to determine geotechnical characteristics and hydraulic conductivity of the disposed ash. At monthly intervals after the completion of initial field work, porewater was collected from each PAP along with groundwater collection at upgradient (background) and downgradient wells to provide points of comparison to porewater samples.

Characterization of leaching properties was carried out by personnel in the Department of Civil and Environmental Engineering at VU. Leaching characterization tests included EPA Method 1313 to determine leaching behavior as a function of eluate pH, EPA Method 1314 to evaluate L/S-dependent leaching from a percolation column, and a trio of single-batch extraction tests (i.e., TCLP, SPLP, and ASTM). For all leaching tests, the pH of all eluates was measured and recorded so that comparisons could be made between leaching evaluations. The reported constituents include most of those found in the Code of Federal Regulations, Title 40, Section 257 (40 CFR 257), Appendix III for detection monitoring and Appendix IV for assessment monitoring, as well as several additional constituents as listed in Table 3-3, Table 3-4, and Table

3-5 of this report. Relative to 40 CFR 257 App III and IV, a broader suite of approximately 40 constituents was quantified to provide a comprehensive basis for geochemical modeling of leaching test results. Although listed in 40 CFR 257 App III and IV, radium and total dissolved solids were not analyzed.

The geotechnical and hydrologic properties of intact core samples were determined at the School of Engineering at UVA. Hydraulic conductivity of intact samples was measured using flexible-wall permeameters following the methods in ASTM D5084. Tests were conducted over a range of effective stresses to evaluate how hydraulic conductivity varies with packing configuration and overburden found at depth. Particle size analysis was conducted on each sample using the methods in ASTM D6913 to understand how the hydraulic conductivity varies with the composition of the ash.

At UVA, a complementary series of tests to that of EPA Method 1314 was conducted on undisturbed samples collected in thin-wall sampling tubes for hydraulic conductivity testing in flexible-wall permeameters. Although the primary purpose of these tests was to measure the hydraulic conductivity of the coal ash samples, eluates collected from hydraulic conductivity testing served as a point of comparison to percolation leaching tests on composite samples according to EPA Method 1314. These tests on undisturbed samples in flexible-wall permeameters contrasted with conventional Method 1314 tests conducted on remolded (including partially oxidized) samples in rigid-wall columns, providing a direct assessment of the impacts of sample handling, column packing, and potential sidewall flow on percolation leaching. Additional discussion of these tests is included in the section on hydraulic conductivity test methods.

2
COLLECTION OF FIELD MATERIALS

Sample Locations

Ash, porewater, and gas samples were obtained at three boring locations (VB-1, VB-2, and VB-3). The approximate locations of these boreholes are shown in Figure 2-1 relative to the closed impoundment and the adjacent river. These locations were selected to be within the area of the closed impoundment and were considered to capture the vertical and horizontal heterogeneity of ash materials. When the impoundment was active, coal ash was sluiced from the main plant using process water into the impoundment near the location of VB-1. The water flowed toward VB-3 and onto the outfall to the river near location VB-2. Ash chemistry of the three locations is assumed representative of materials across the closed impoundment.

Figure 2-1
Schematic representation of the closed KSP ash impoundment, showing the approximate locations of three porewater access points (PAPs), VB-1, VB-2, and VB-3, and existing groundwater wells, 6AR and AD1 (out of frame).

Initial Site Sampling

The field sampling included continuous split spoon sampling to obtain bulk ash for leaching characterization and to provide an understanding of the ash deposit after closure, followed by discrete Osterberg sampling to obtain intact ash cores at approximate 5-ft intervals. All drilling

operations were conducted by a contracted drilling/engineering company. Prior to sampling, the top vegetation cover and geosynthetic cover in a 100-ft^2 area (10 ft by 10 ft) at each sampling location were removed by contractors. Bulk ash material was collected using 3-inch outside diameter (OD) x 24-inch long split spoons advanced through a 4.25-inch internal diameter (ID) hollow-stem auger (HSA) drilling a 9-inch diameter hole. Intact cores were collected at discrete depth intervals using thin-wall tube samplers pushed through an 8.25-inch ID HSA drilling a 13-inch hole. After the completion of the borings and installation of monitoring points, the geosynthetic cover was repaired and the cover fill replaced.

Bulk Material (Split Spoon Samples)

Split spoons were advanced from the upper cover-ash interface into the underlying native clay material (Table 2-1). Upon retrieval by the drilling contractor, each split spoon sample was opened and recorded by a licensed geologist and released to VU for documentation and collection. The borehole logs and an index with photographs of recovered split spoon material are provided in Appendix A and Appendix B, respectively. During field sampling, the activities included (i) preparation of ash extractions with de-oxygenated, deionized water (DIW) targeting an L/S of approximately 1 mL of water per estimated gram of dry ash and (ii) collection and preservation of bulk material for subsequent laboratory testing.

- L/S ≈ 1 Extractions: To protect the redox conditions of the sample and characterize the porewater composition for a screening analysis within each borehole, about 150-200 g of ash was placed into a certified, pre-tared 250-mL high-density polyethylene (HDPE) bottle (Nalgene I-Chem #N311-0250). The mass of the ash grab sample was measured and recorded. The bottle was filled with de-oxygenated DIW and weighed to quantify the mass of added water. The location of the ash grab sample within the split spoon was selected based on visual representativeness of ash.
- Bulk Ash Collection: Remaining ash from each split spoon was vacuum-sealed in plastic bags (Figure 2-2) and stored on ice for transport to the laboratory. To the extent possible, the bulk ash was maintained in its original split spoon shape and the top and bottom of the core were marked on the plastic bag.

Sample labels included “KSP” as a site identifier, the borehole number (VB-1, VB-2, or VB-3), and the depth below ground surface (BGS) from which the samples were taken. For example, the sample labeled “KSP_VB-3_15-17” in Figure 2-2 was collected from the split spoon at 15 to 17 feet BGS at borehole VB-3. For split spoons that penetrated an interface (e.g., between ash and the bottom native clay layer or between coal ash layers with visually different properties), the separate materials were collected as separate bulk samples in two vacuum-sealed bags. The upper portion was labeled with an “A” extension, while the lower portion was labeled with “B” at the same split spoon interval. All samples were preserved in coolers with ice and transported to the VU lab within 48 hours. During transport, the cooler temperature was monitored and recorded by an Elitech RC-5 USB temperature data logger. At the VU lab, all bulk materials were stored in an environmentally controlled room at 5 °C prior to processing for leaching tests.

b)

Figure 2-2
Examples of split spoon cores: a) as recovered and photo-documented and b) vacuum-sealed bulk sample from borehole VB-3 (KSP_VB-3_15-17) preserved for testing

A schematic summary of the split spoon samples and the numbers of total samples preserved at each location are shown in Figure 2-3. In this figure, the depths BGS for each sample have been converted to elevations in feet above mean sea level (AMSL) after surveying of the PAP casings and ground elevations.

Intact Cores (Tube Samples)

Immediately following completion of the continuous split spoon borehole, the drilling rig was moved forward in its tracks 5 feet to advance an 8.25-inch HSA for push core sampling of ash. At each boring location, 3-inch OD by 36-inch long thin-wall tube samplers were pushed into the ash layer and obtained intact cores at intervals according to the observations from split spoon boring. The locations of the cores were targeted to collect samples across interfaces with the cover material and clay liner as well as major ash deposits within the ash column. Each recovered thin-walled tube was sealed at both ends using plastic expanding inserts, capped with plastic endcaps, and sealed with duct tape. The thin-walled tubes were vacuum-sealed in plastic bags and kept upright for transport. Sample identification was based on the interval BGS from which the samples were recovered. For example, the tube sampler recovered from the interval from 12 to 14.5 feet BGS at borehole VB-1 was labeled "VB-1_OST_12-14.5." The associated elevations for the three tube samples collected at each borehole are summarized in Table 2-1.

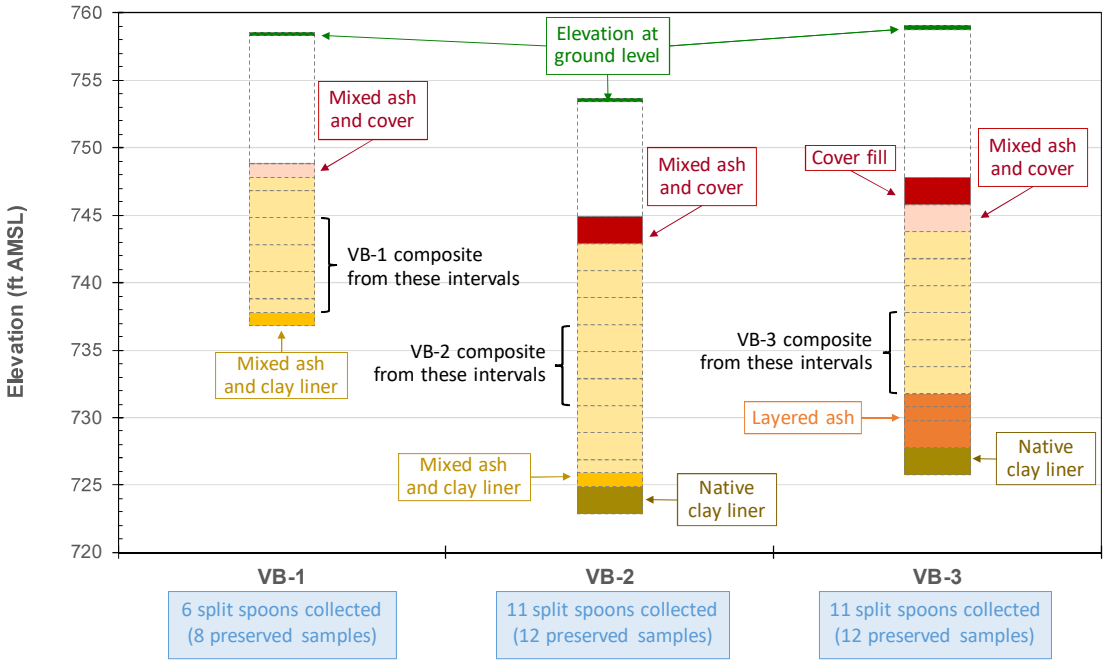

Figure 2-3
Collection of bulk material samples by split spoon, showing bulk samples composited around well screening levels

Porewater Access Points

Once the 8.25-inch ID HSA was advanced to the target depth for placement of the PAP, a 2-inch OD Schedule 40 PVC pipe was installed through the HSA. At each well location, the contractor installed a pre-packed, 2-foot screened section in agreement of the field team leads for VU, EPRI, and KSP after review of saturated zone observed for the continuous sampling borehole. Each 13-inch diameter borehole was backfilled with 1 foot of clean sand before the well screen was set, and after setting the screen, was backfilled with sand to 2 feet above the top of the well screen. The sand pack was sealed with bentonite clay pellets, and bentonite chips were used to backfill the borehole to within ½ foot of the GAP depth. Boring logs are presented in Appendix A.

Subsurface Gas Access Points

The composition of subsurface gas within the ash pond was sampled through GAPs set between 2 and 3 feet below the top of the ash deposit. Each GAP consisted of a ¼-inch diameter stainless steel tube set at depth within a 1-foot thick layer of round river rock and sealed from above and below with a 1-foot thick layer of expanded bentonite clay. The lower end of the GAP tubing was protected from rock, ash, and clay debris with an inverted steel cup. The stainless steel tubing was zip-tied to the PVC well and finished with a 2-way shutoff valve. The bed of river rock, nominal size of between ¾ inch and ¼ inch, ensures sufficient subsurface gas volume for measurement. A conceptual diagram and photograph are presented in Figure 2-4.

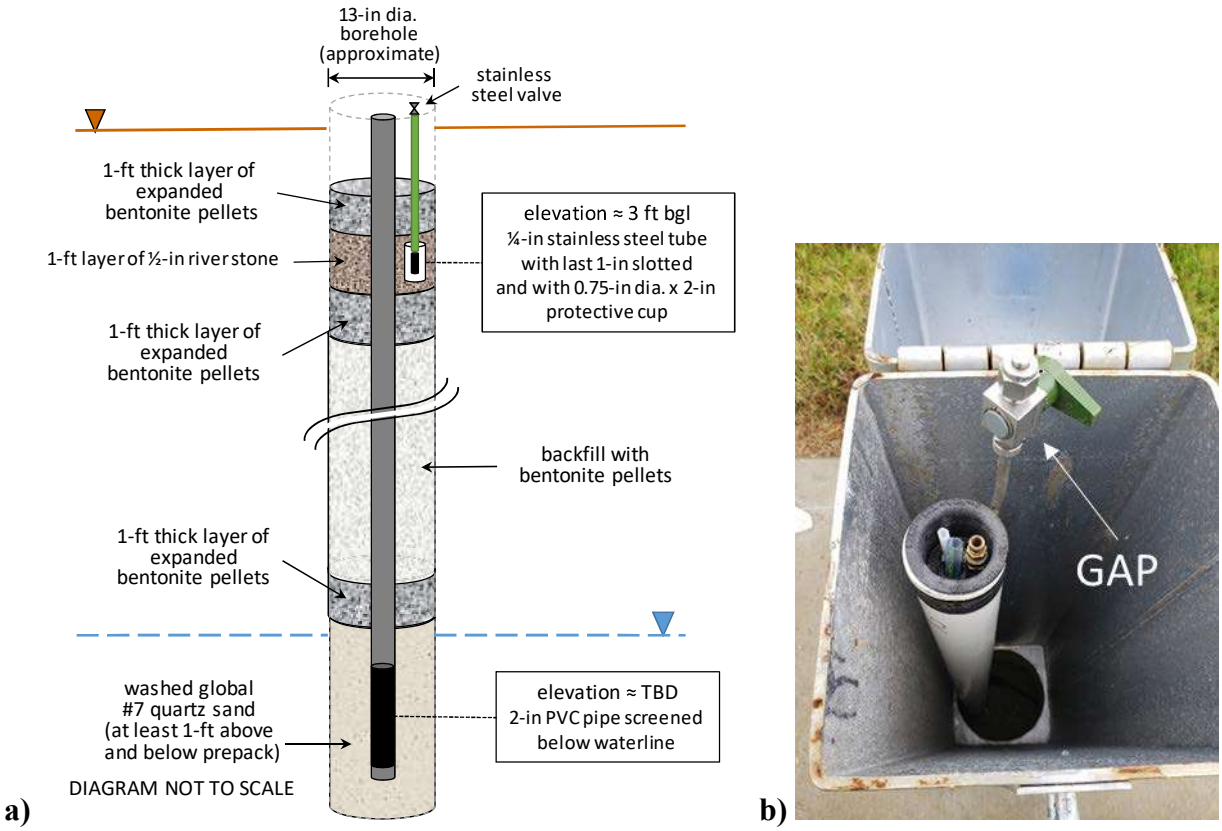

Figure 2-4
Porewater and gas access points: a) conceptual design of PAP and GAP installation and b) picture of installed PAP and GAP within a metal riser

Summary of Borehole Stratigraphy, Ash Collection, and PAP/GAP Installation

Within two weeks of field sampling, the drilling contractor installed dedicated pumps, developed the wells, and protected the borehole locations with a metal riser and concrete base. As part of this process, the horizontal location of the PVC riser, as well as the elevations of the well riser and ground level, were surveyed by a professional land surveyor. A summary of the elevation survey results and elevation of pertinent strata and sampling locations for the VB-1, VB-2, and VB-3 boreholes are tabulated in Table 2-1 and presented graphically in Figure 2-5 along with the stratigraphy for the upgradient background well (AD1) and downgradient compliance well (6AR).

Table 2-1
Elevations Above Mean Sea Level (AMSL) for KSP Boreholes Including the Range of Continuous Bulk Ash Sampling and Discrete Tube Samples

	VB-1	VB-2	VB-3
	Elevation (ft AMSL)	Elevation (ft AMSL)	Elevation (ft AMSL)

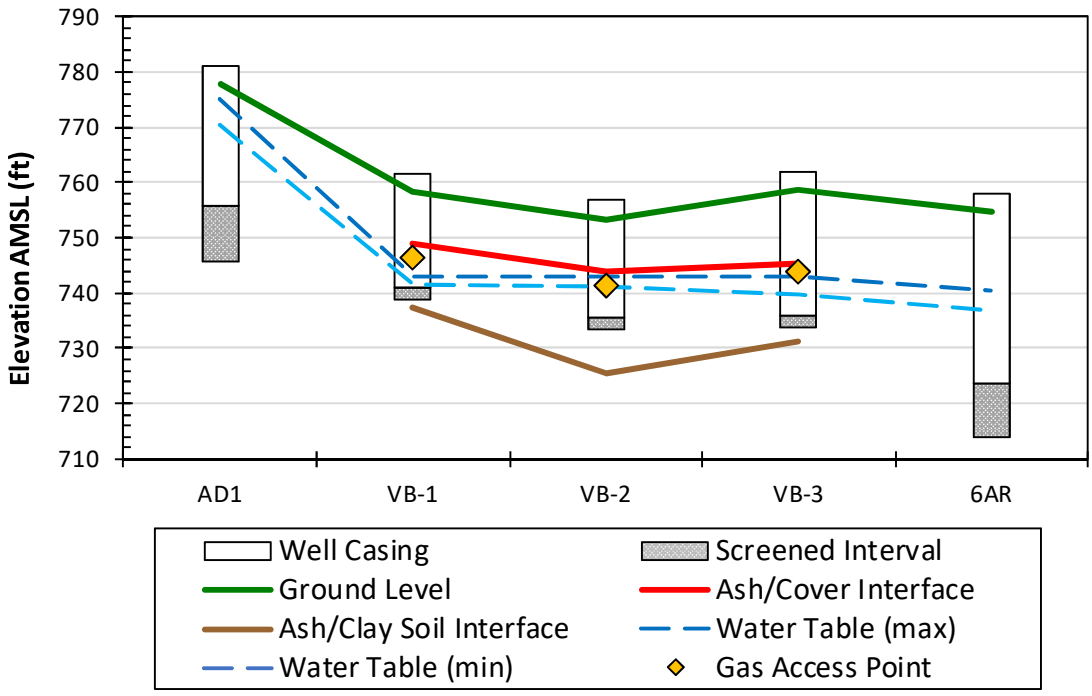

Figure 2-5
Summary of the groundwater well and PAP elevations including pond stratigraphy and location of GAPs

Monthly Field Monitoring

Porewater and subsurface gases were monitored monthly at each PAP location over a 13-month period from September 2018 through September 2019. In addition, groundwater samples were analyzed from one upgradient (AD1) and one downgradient (6AR) monitoring well.

Collection of Groundwater and Porewater

Figure 2-1 shows the relative locations for the three installed PAPs (VB-1, VB-2, and VB-3) and the two existing groundwater sampling wells. Although the location of the upgradient well (AD1) is out-of-frame relative to this figure, the general direction of the well is indicated. KSP field personnel accessed each well, stabilized the well using low-flow sampling techniques according to company standard operating procedures, and allowed the VU field team access to the effluent line for collection of groundwater and porewater samples. At no time did the site owners' personnel retain custody of any samples used for this analysis.

The sampling flowrates for groundwater wells averaged approximately 150 mL/min and 300 mL/min for AD1 and 6AR, respectively. Porewater was sampled at approximately 50 mL/min to minimize drawdown of the water level in each PAP. At 5-minute intervals, the pH, dissolved oxygen (DO), electrical conductivity (EC), oxidation-reduction potential (ORP), temperature, and turbidity of the sampled water were measured through a multi-parameter sonde and separate turbidity meter, while water level was measured with a portable electronic water level meter. All measured parameters were recorded by KSP field personnel. The criteria used to determine well stability were (i) turbidity less than 10 NTUs and (ii) pH stable within 0.1 standard unit over three consecutive 5-minute readings.

Groundwater and porewater samples were collected in 50-mL SCP Science Digitubes including duplicate samples collected for anion analysis via ion chromatograph (IC) and duplicate samples collected for metals and other cation analysis via inductively coupled plasma (ICP) techniques (see *Chemical Analysis of Eluates, Groundwater, and Porewater* for details). Samples for ICP analysis were preserved in the field by addition of 1.5 mL of Tracemetal® grade nitric acid (3% total acid addition) using a 100-1000 µL Oxford Benchmate manual pipette and disposable tips. A set of four samples was collected unfiltered followed by a set of samples passed through a Quickfilter, 609 cm^2, 0.45-mm inline filter. In total, eight 50-mL Digitubes were collected at each sampling location. All liquid samples were stored in a cooler of ice with an Elitech RC-5 USB temperature data logger to record the temperature within the cooler. Samples were transported by the field team to VU for immediate storage at 5 ºC prior to analysis.

Subsurface Gas Monitoring

A description of the monitoring process for subsurface gas and a picture of gas monitoring apparatus are provided in Section 3.

3
LABORATORY MATERIALS AND METHODS

The follow sections include brief descriptions of the laboratory test methods and analytical methods used in this study. Also included are the quality assurance/quality control (QA/QC) samples and criteria for each analytical method.

Collected Materials

Materials recovered during initial sample collection from the ash deposit included bulk samples from split spoons and intact cores contained in thin-wall tubes. Processing of bulk material for leaching tests included (i) homogenization within each split spoon sample and (ii) compositing samples near the screening level.

Subsampling and Homogenization of Bulk Samples

Homogenized split spoon samples were used to evaluate the vertical and horizontal variability of ash deposits and provide materials for developing a representative composite for characterization of leaching parameters to be compared to monthly porewater monitoring. Each recovered split spoon sample was removed from its vacuum-sealed bag and bisected along the longitudinal axis as shown in Figure 3-1a. If the structure of split spoon material was not intact, the preserved sample was bisected vertically along the axis of the plastic bag Figure 3-1b. One-half of the material was immediately vacuum-sealed into a plastic bag and stored in the environmentally controlled room at 5 ºC for future use.

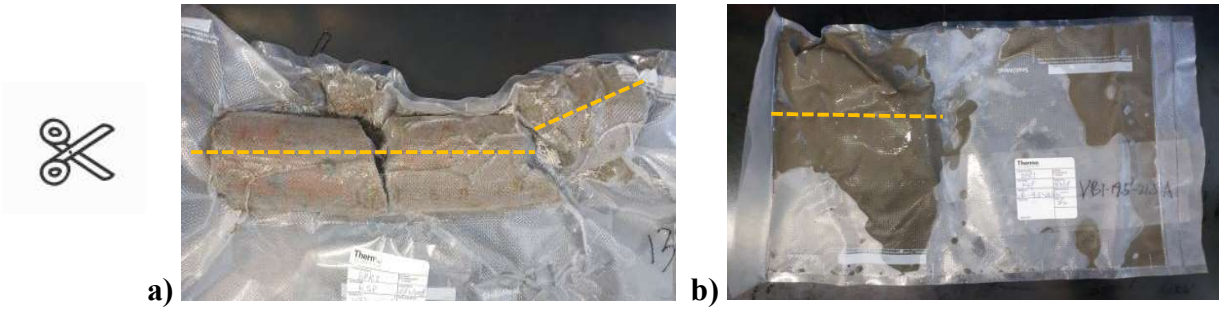

Figure 3-1
Schematic showing bisection of a) structurally sound split spoon material and b) bulk split spoon material

The remaining half of the split spoon material was placed in a plastic bag and sealed with lab tape to minimize exposure to air. This material was crushed with a rolling pin and homogenized by hand through the plastic bag until the contents were well mixed. This homogenized material was used as test material (i) in laboratory L/S=1 extractions for comparison to field L/S~1 extractions and (ii) for limited pH-dependence leaching methods to evaluate vertical heterogeneity within borehole samples.

Borehole Composite Materials

Homogenized split spoon material was used to develop a composite test material that would be representative of the bulk ash deposited near the screened interval of the PAP for each borehole. Table 3-1 shows the split spoon samples used to create each borehole composite sample. The selection of these intervals was based on the evaluation of laboratory L/S=1 extractions and considering the mass of composite that would be required to complete the testing program.

Table 3-1
Intervals (BGS) and Elevations (AMSL) of Split Spoon Samples Used in Borehole Composites

VB-1		VB-2		VB-3	
Interval (ft BGS)	**Elevation (ft AMSL)**	**Interval (ft BGS)**	**Elevation (ft AMSL)**	**Interval (ft BGS)**	**Elevation (ft AMSL)**
PAP Screen	740.8-738.8	PAP Screen	735.4-733.4	PAP Screen	735.8-733.8
13.5-15.5	744.8-742.8	16.5-18.5	736.9-734.9	21-23	737.8-735.8
15.5-17.5	742.8-740.8	18.5-20.5	734.9-732.9	23-25	735.8-733.8
17.5-19.5	740.8-738.8	20.5-22.5	732.9-730.9	25-27	733.8-731.8
19.5-21.5 (A)	738.8-737.3	-	-	-	-

The material was composited by mixing equal dry mass equivalents (i.e., the mass of "as received" material that equates to a prescribed mass of dry material) from each homogenized split spoon in a plastic bag. For VB-2 and VB-3 composites, each of three split spoons was used with 450 g-dry taken from each sample. However, for the VB-1 composite, there was not enough material in the three split spoons nearest the well screen, so a fourth split spoon was included with 250 g-dry taken from each homogenized split spoon sample. The plastic bag was sealed with lab tape to minimize air exposure and the composited material was homogenized by hand through the plastic bag until well mixed. This composited sample was used for total content analysis and characterization using LEAF leaching tests and traditional leaching tests (i.e., ASTM, TCLP, and SPLP).

Material Properties

Total Content by EPA Method 3052

The total elemental content of composite samples was determined by acid digestion following EPA Method 3052 with subsequent analysis of the digestate by Eurofins TestAmerica (Nashville, TN). According to the Method 3052, a solid sample of up to 0.5 g (wet) is digested in 9 mL of nitric acid and 3 mL of hydrofluoric acid for 15 minutes in a microwave to accelerate the digestion reactions. Addition acid and reagent combinations, including hydrochloric acid and hydrogen peroxide, are added to ensure that the solid is dissolved. The microwave temperature profile includes reaching 180 ± 5 ºC in approximately less than 5.5 minutes and remaining at 180 ± 5 ºC for 9.5 minutes for the completion of specific reactions. After cooling, the vessel contents were centrifuged and decanted. The small volume of remaining digestate was diluted to a volume of 100 mL and chemically analyzed. Inductively coupled plasma-optical emission

spectrometry (ICP-OES) following EPA Method 6010B was used to determine digestate concentrations for Ag, Al, As, Ba, Be, Ca, Cd, Cr, Co, Cu, Fe, K, Li, Mg, Mn, Mo, Na, Ni, Pb, Sb, Se, Sr, Ti, V, and Zn. Mercury in digestates was measured by using cold vapor atomic absorption following EPA Method 7470A. The total content (mg/kg) is calculated by multiplying the concentration measured in the digestate (mg/L) by the L/S of the extraction procedure (L/g). For this study, the resultant total content is effectively on a dry mass basis (mg/kg-dry) because the material submitted to the laboratory for testing was oven dried.

X-Ray Fluorescence Analysis

The elemental composition of coal ash samples was determined at UVA using x-ray fluorescence (XRF) quantitative analysis on an Epsilon 3X energy-dispersive XRF spectrometer (PANalytical, Malvern, UK) with a silver anode X-ray tube and 50-micron beryllium window. Five-gram subsamples of coal ash were taken from the undisturbed core samples, air-dried for 24 hours at room temperature, and ground by hand to less than 0.075 mm using an agate mortar and pestle. For analysis, ground samples were packed into an 18-mL sample cup (28 mm ID x 30 mm). Each subsample was analyzed in duplicate following ASTM 8064-16 for the XRF analytical method of silicate rocks.

Loss on Ignition

Loss on ignition (LOI) was measured at UVA for subsamples of undisturbed coal ash to quantify total organic matter content. LOI was conducted in accordance with ASTM D2974-14 by sintering a pre-weighed sample at 550 °C using a Lindberg/Blue M 1200 ºC box furnace (ThermoFisher Scientific, Waltham, MA). The mass lost during sintering was associated with the total organic matter.

Moisture Content

As part of the leaching test characterization using the LEAF methods, the moisture content of each study material was determined following ASTM D2216-19. Moisture content on a dry mass basis was calculated as the difference in the mass of a “wet” subsample compared to the sample after oven-drying to constant mass at 105 ± 5 ºC. The solids content is defined as the mass of solid material in an “as-tested” or “wet” subsample, measured on a “wet” basis. The determination of moisture content and solids content provides uniform bases for reporting of total content and leaching behavior results, allowing for comparison between moist and dry materials.

Porosity or Saturated Volumetric Water Content

Dry density (ρ_d) and porosity (n) of each material were determined at UVA using weight-volume computations, following the procedure in ASTM D7263-09. Under saturated conditions (i.e., when all voids are filled with water), the saturated volumetric water content (θ_s) equals the porosity.

Particle Size Distribution

Particle size distribution (PSD) of each coal ash sample was determined at UVA by a combination of mechanical analysis following ASTM D6913-17 and sedimentation analysis

following ASTM D7928-17. For mechanical analysis, a 100-g sample was oven-dried at 110±5 °C and passed through a series of US standard sieves: No. 10 (2 mm), No. 20 (0.85 mm), No. 60 (0.25 mm), No. 100 (0.15 mm), and No. 200 (0.075 mm). The fraction of the 100-g mass retained on each sieve was measured gravimetrically. Particle size distribution of the fraction coarser than the No. 200 sieve (0.075 mm) was calculated as the weight of solid retained on each sieve.

For sedimentation analysis, 50 g of dry solid that had passed the No. 200 (0.075 mm) sieve was soaked in 4% sodium metaphosphate, $(NaPO_3)_6$, solution for 12 hours and then transferred to a 1-L graduated cylinder. The graduated cylinder was capped, then agitated end-over-end for 60 seconds, and then settling of particles was monitored using a hydrometer. Stokes' law was used to compute the PSD from the hydrometer data for the fraction of particles finer than the No. 200 sieve.

Saturated Hydraulic Conductivity

Hydraulic conductivity tests were conducted in flexible-wall permeameters following the methods in ASTM D5084-16. Sections of undisturbed coal ash were extruded from the 73-mm ID, thin-wall sampling tubes (Figure 3-2) and cut into 76-mm long specimens. Non-woven geotextile disks and porous stones were placed on both ends of each coal ash specimen (Figure 3-3a) to ensure uniform flow distribution and to retain particles. Specimens were wrapped in a latex membrane and placed into a flexible-wall permeameter (Figure 3-3b).

In lieu of the more traditional tap water or 0.01 M $CaCl_2$ solution suggested in ASTM D5084, DIW was used as the permeant solution to ensure that the water entering the specimen had no ionic species that might alter the hydraulic conductivity or the leachable constituents in the coal ash. Effluent from the permeameter was collected following the procedure in ASTM D7100-11. Effluent samples were collected from the tests and stored in Teflon sample bottles with minimal headspace. Effluent samples were shipped under chain of custody to VU for chemical analysis.

The falling headwater-constant tailwater method was used with an average hydraulic gradient of 15. No backpressure was applied to simulate field conditions and to minimize alterations in geochemistry. All tests were conducted at an initial effective stress of 20 kPa and continued until the hydraulic conductivity reached hydraulic equilibrium as defined in ASTM D5084 (steady hydraulic conductivity, incremental outflow divided by inflow was constant within 1.0 ± 0.25). At the conclusion of the test, weight-volume calculations were used to determine that all specimens were fully saturated during testing.

After testing at 20 kPa was complete, three specimens, representing coarser, finer, and mid-range particle size distributions, were consolidated to 100 kPa and permeated again until hydraulic equilibrium was established (steady hydraulic conductivity, steady flow ratio 1.0 ± 0.25). The initial stress (20 kPa) was selected to replicate the stress condition of the coal ash with a burial depth of 1 m in the basin. The consolidation/permeation procedure was repeated at consolidation pressures of 250, 400, and 500 kPa to simulate stress at greater depths within the basin. The highest stress (500 kPa) corresponded to a depth of approximately 35 m. Effluent samples from these higher-stress experiments were not collected or chemically analyzed.

Traditional Extraction Tests

EPA Method 1311 – Toxicity Characteristic Leaching Procedure

EPA Method 1311, or TCLP, is a single-point batch leaching test used to determine the toxicity characteristic of a material and the disposal options for a material under the Resource Conservation and Recovery Act of 1986 (RCRA). At the time of test development, TCLP was designed to simulate eluate concentrations for a plausible mismanagement scenario where hazardous waste is disposed in a municipal solid waste landfill. Thus, a solution of acetic acid in DIW is the extraction fluid to represent the primary acidity in municipal solid waste landfill leachate. Selection of an extraction fluid is based on a pretest of the buffering capacity of a test sample for acetic acid. Extraction Fluid #1 is dilute acetic acid buffered at a pH of 4.93 ± 0.05 with sodium hydroxide, while Extraction Fluid #2 is dilute acetic acid at a pH of 2.88 ± 0.05 without added base. The test-specific L/S of 20 mL/g is based on a filtered sample after pressure filtration at 15 psi. Since the filtered solid may still contain moisture, the final dry-basis extraction L/S is typically greater than 20 mL/g-dry. The filtrate from pressure filtration was preserved and chemically analyzed in parallel to TCLP extracts.

For this study, 80 grams of filtered solid was mixed with 160 mL of Extraction Fluid #1 and tumbled at 28 ± 2 rpm for 18 ± 2 hours. Although not specified in the method, the pH of the final eluate was measured and recorded so that test results could be compared to other leaching methods. The eluate from the extraction was pressure-filtered through a 0.22-µm borosilicate glass fiber filter and preserved for analysis. Filtrate from pressure filtration and the extraction eluate were analyzed separately and an "effective" extraction concentration was calculated for each constituent as a volume-weighted average concentration of the two liquids. For QA/QC purposes, a method blank, with the filter paper and extraction fluid only, and a duplicate sample for VB-2 were conducted in parallel using the same reagents.

EPA Method 1312 – Synthetic Precipitation Leaching Procedure

EPA Method 1312, or SPLP, is a single-batch leaching test used to evaluate the leaching behavior of a waste material in contact with acidic rain. The test is performed in the same manner as in the TCLP, but with extraction fluids of 60/40 weight percent (wt%) sulfuric acid (H_2SO_4) and nitric acid (HNO_3) in DIW (Extraction Fluids #1 and #2) or DIW (Extraction Fluid #3). The selection of extraction fluid depends on the location of the site under investigation and the constituents being tested. Extraction Fluid #1 is used for sites east of the Mississippi River, Extraction Fluid #2 is used for sites west of the Mississippi River, and Extraction Fluid #3 is used only when cyanides or volatiles are to be analyzed.

For these tests, 100 grams of filtered solid was mixed with 160 mL of Extraction Fluid #1 and tumbled at 28±2 rpm for 18±2 hours. Although not specified in the method, the pH of the final eluate was measured and recorded so that test results could be compared to other leaching methods. The eluate from the extraction was pressure-filtered through a 0.22-µm borosilicate glass fiber filter and preserved for analysis. Filtrate from pressure filtration and the extraction eluate were analyzed separately and an "effective" extraction concentration for each constituent was calculated as a volume-weighted average of the two liquids. A method blank—extraction fluid with no solid carried through the test process—and a duplicate sample for VB-2 were analyzed.

ASTM D3987 – Shake Extraction of Solid Waste with Water

ASTM D3987-12, or ASTM, is a single-point extraction test that is used to estimate leaching concentrations when no acid or base is added to the extraction. Since the method is patterned after TCLP, the procedure is similar to the EPA method; however, DIW is used as the extraction fluid.

For these tests, a subsample of ash (70±0.1 g) was tumbled at 28±0.2 rpm with DIW at an L/S of 20 mL/g for 18±0.25 hours. After tumbling, the extract was separated from the solid by vacuum filtration through a 0.45-m polypropylene membrane and the pH of the final eluate was measured and recorded. Reagent and method blanks were analyzed, and a duplicate test was conducted on the VB-3 sample.

Leaching Environmental Assessment Framework (LEAF) Test Methods

EPA Method 1313 – Liquid-Solid Partitioning as a Function of Eluate pH Using a Batch Extraction Procedure

EPA Method 1313 is standardized, parallel batch extraction method used to evaluate the liquid-solid partitioning (LSP) of inorganic constituents as a function of eluate pH. The general procedure consists of nine batch extractions of a particle-size reduced subsample material that is contacted with leaching solution at an L/S of 10 mL/g-dry material and tumbled end-over-end over a specified contact interval. The leaching solution is DIW with additions of HNO_3 or potassium hydroxide (KOH) to adjust the final pH of the eluate to a target of nine specific pH values (i.e., pH values of 2, 4, 5.5, 7, 8, 9, 10.5, 12, and 13). An additional extraction without addition of acid or base was carried out to measure constituent leaching at the natural pH of the material.[1] After 24 hours of tumbling, the contact time associated with a sample particle size of 85 wt% less than 300 µm, the solid and liquid phases were separated by settling or centrifugation, and the pH, EC, and ORP of the clarified eluate were measured. The remaining slurry was vacuum-filtered through 0.45-µm pore size membranes prior to chemical analysis by ICP-OES, IC, and carbon analysis.

EPA Method 1313 provides (i) a titration curve of the pH response to additions of acid or base, (ii) the available content of constituents in the solid material, and (iii) the LSP curve for constituents over the tested pH range. Furthermore, the results of EPA Method 1313 are suitable for use in geochemical speciation modeling for the estimation of the solid phase mineralogy and surface chemistry that controls constituent release.

Variants of EPA 1313 Methods

In this program, the full EPA 1313 method and variants of EPA 1313 were carried out on ash materials for different purposes:

- An abbreviated, 3-point EPA 1313 (1313_3 pt) was conducted on two homogenized samples of individual split spoon samples from each borehole. Since the natural pH of the CCP

[1] The "natural pH," sometimes referred to as "own pH," is defined as the eluate pH in response to extraction in deionized water (i.e., no acid or base added) at an L/S of 10 mL/g-dry. To distinguish the natural pH at L/S=10 mL/g-dry (Method 1313 or 1313_3pt) from the pH response to DIW at L/S of 1 mL/g-dry measured using 1313_L/S=1, the former will continue to be called with "natural pH" while latter will be referred to as "own pH."

materials was expected to be near neutral, the pH targets selected included $1.5 \leq pH \leq 2$, the natural pH, and pH=9.0±0.5. The pH targets near pH 2.0 and 9.0 are useful for determining the available contents of cationic and oxyanionic constituents, respectively. The results of these 3-point pH-dependence tests on individual split spoon samples were compared to the full-range EPA 1313 of composite samples as an indicator of vertical heterogeneity within a borehole.

- EPA 1313 was carried out on composited ash samples from each borehole but using an L/S of 1 mL/g-dry and abbreviated to the natural pH and two pH targets on either side of the natural pH, for five pH values in total. This modified 1313 test, referred to as 1313_L/S=1, was used to evaluate how changes in L/S may influence LSP concentrations and to provide verification data for development of geochemical speciation models.

EPA Method 1314 – Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using a Percolation Column Procedure

EPA Method 1314 is a standardized, up-flow column procedure used to evaluate release of inorganic constituents from percolating solid materials as a function of cumulative L/S (i.e., the volume of liquid that passes through the column relative to the dry mass of material in the column). In this study, EPA 1314 was used to characterize the L/S-dependent leaching of constituents in 250-400 g-dry composited ash samples (e.g., VB-1, VB-2, and VB-3). A 5-cm diameter by 30-cm glass column was packed with coal ash in a series of five lifts with moderate tamping between lifts. DIW was used as the eluent solution since CCPs in general have relatively low organic carbon and clay contents compared to soils. The eluent was pumped at a flow rate of 0.75±0.25 L/S per day through the column in an up-flow direction to minimize air entrapment and flow channeling. Eluates were collected at predetermined cumulative L/S values (i.e., 0.2, 0.5, 1, 1.5, 2, 2.5, 4.5, 5, 9.5 and 10 mL/g-dry). For each eluate fraction, the pH and conductivity were recorded prior to filtration and preservation for chemical analysis. To present the results, the concentrations of constituents in the eluates (mg/L) as well as the cumulative release through the end of each eluate fraction (mg/kg-dry) were plotted as functions of L/S in separate graphs.

Comparison of Leaching Test Parameters and Conditions

All leaching tests conducted for this program are designed to measure the LSP of constituent release from a material under the specified test conditions shown in Table 3-2. TCLP, SPLP, and ASTM are single-batch leaching tests. Similarly, the EPA 1313 test and its variants are batch procedures, but with parallel extractions to provide data over a range of test conditions. These batch tests, however, differ in the chemical makeup of extraction fluid as well as in the specified L/S. Moving from left to right in Table 3-2, the leaching test conditions are presented in order of decreasing L/S from left to right. In the last column are the test conditions for EPA 1314, designed to measure LSP as a function of cumulative L/S.

Table 3-2
Leaching Test Parameters and Test Conditions

Parameter	TCLP	SPLP	ASTM	1313	1313_3-pt	1313_L/S=1	1314

Chemical Analysis of Eluates, Groundwater, and Porewater

Eluate pH

Eluate pH was measured on all aqueous extracts following EPA Method 9040C using an Accumet XL20 meter and a combined pH electrode on approximately 5 mL of eluate. Prior to testing, the electrode was calibrated with two National Institute of Standards and Technology (NIST) traceable pH buffer solutions that bounded the anticipated range of pH to be measured. A third mid-range NIST buffer was used to verify the calibration.

Specific Conductance

Specific conductance, or EC, is a measure of the ability of an aqueous solution to carry an electrical current. The property is dependent on (i) the presence of ions; (ii) total concentration, mobility, and variance of ions in solutions; and (iii) the temperature of the measurement. Conductivity of all leaching test eluates was determined following EPA Method 9050A using a standard conductivity probe calibrated to an appropriate standard conductivity solution for the conductivity range of concern.

Oxidation-Reduction Potential

ORP is a voltage differential related to the redox state of a solid-liquid solution and its effect on chemical composition (e.g., reduced/oxidized iron, dissolved oxygen, biological activity). ORP voltage of all eluate solutions was measured with a probe, consisting of a platinum electrode and a reference electrode, placed in contact with the soil solution. In laboratory tests, the ORP voltage reading was converted to redox potential (Eh) by addition of a probe-specific correction factor of 228 mV at 25 °C. In field measurements, however, the probe correction factor was automatically compensated for by the instrument and are output as Eh values.

Since, redox reactions vary with pH and the mineral species present, redox is parameterized in geochemical modeling as the pH+pE, where pE is the negative logarithm of the free electron concentration, or –log([e^-]). The corrected Eh values of leachates and eluates were converted to a pE value using the following equation:

$$pE = \frac{F}{2.303RT}(Eh/1000)$$

where F is the Faraday constant (23,061 cal/(V mol)),

Eh is the redox potential of the solution (mV),
2.303 is a conversion (ln[e^-]/2.303 log[e^-]),
R is the gas constant (1.987 cal/(K mol)),

T is the temperature (K), and

1000 is a unit conversion (1,000 mV = 1 V).

Inductively Coupled Plasma Spectrometry

The eluate concentrations of trace elements and material major species (e.g., Al, Ca, Si) were determined using a combination of ICP-OES and inductively coupled plasma – mass

spectrometry (ICP-MS). The choice of instrumentation was determined based on detection limits, expected concentrations, and environmental threshold values. Table 3-3 provides the method detection limits (MDLs) and lower limits of quantitation (LLOQs) used in this project along with the working ranges for each constituent.

Major species and trace elements present at higher concentrations were determined using a Varian Model 720-ES ICP-OES (Agilent Technologies, Santa Clara, CA) following EPA Method 6010D. The ICP-OES was calibrated to a 5-point standard curve with an analytical range of 25 to 25,000 µg/L. For some high-concentration trace elements, the standard curve was extended up to 500,000 µg/L using a 7-point standard curve. For low-level trace analysis, concentrations were determined by ICP-MS using a Perkin Elmer Elan DRC II (Perkin Elmer, Waltham, MA) following EPA Method 6020A. The ICP-MS was calibrated to a 5-point standard curve with range between approximately 1 and 250 µg/L and extended with a 7-point curve to 1,000 µg/L for some constituents.

Analytical QA/QC included initial and continuing calibration checks and blanks, matrix spikes, and method blanks. Calibration check standards and matrix blanks were evaluated every 10 to 20 samples with the requirements that check standards were within 15% of the specified value and blanks were below LLOQs. Matrix spikes were required to have recoveries within 20% of the calculated concentration considering the spiked mass. Initial and continuing calibration check standards for ICP-OES and ICP-MS were 0.5 mg/L and 0.050 mg/L, respectively. Analyte concentrations measured at less than the MDL were reported as <MDL and graphed at one-half the MDL values to indicate that the measurement was conducted. Analytical results measured at less than the LLOQ but greater than the MDL are estimated values.

Table 3-3
Methods, MDLs, and LLOQs for Analysis of Eluates by ICP-OES and ICP-MS

Analyte	Symbol	Method	MDL (mg/L)	LLOQ (mg/L)

Ion Chromatography

The concentrations of anions in leaching test eluates were determined by IC using a Metrohm 881 Compact IC Pro (Metrohm USA, Riverview, FL) with a Metrosep A Supp 5 column and a conductivity detector following EPA Method 9056A. A 7-anion calibration standard was diluted to form a 5-point calibration curve with the MDLs and LLOQs shown in Table 3-4. Since the calibration standards are diluted from a bulk multi-analyte standard, the calibration range differs for each analyte (e.g., 0.050-50 mg/L for Cl^- and 0.150-150 mg/L for SO_4^{-2}). Calibration check standards were required to be within 15% of the specified value, while acceptable analytical blanks were measured below the quantitation limits.

Table 3-4
MDLs and LLOQs for Analysis of Eluates by IC

Analyte	Symbol	MDL (mg/L)	LLOQ (mg/L)
Bromide	Br^-	0.0064	0.025
Chloride	Cl^-	0.0101	0.05
Fluoride	F^-	0.0063	0.02

Phosphate	PO_4^{-3}	0.0247	0.15
Sulfate	SO_4^{-2}	0.0254	0.15

Carbon Analysis

Carbon analysis for eluate samples included analyses for dissolved inorganic carbon (DIC) and dissolved organic carbon (DOC). Carbon analysis was conducted using a Shimadzu TOC-V CPH/CPN (Shimadzu Scientific Instruments, Inc., Columbia, MD) by catalytic oxidation/non-dispersive infrared detection (NDIR) following EPA Method 9060A. Total carbon (TC) in the eluate is converted to carbon dioxide via oxidation or decomposition, carried by a zero-CO_2 air stream into the NDIR. For analysis of DIC, liquid samples are acidified with 2-molar hydrochloric acid to liberate carbonates and other forms of inorganic carbon from solution as carbon dioxide, which is sparged from the liquid sample into the NDIR by the zero-CO_2 carrier gas. DOC is determined by measuring the TC of a sample after purging of IC. The instrument was calibrated using sodium hydrogen carbonate and potassium hydrogen phthalate over a 5-point calibration curve for DIC and DOC, respectively. The resultant analytical range was between 0.1 and 100 mg/L, with MDL and LLOQ values shown in Table 3-5. Checks on QA/QC at a frequency of every 10 analytical samples included calibration checks with a required recovery within 15% of the specific value, and method blanks with a requirement that the concentration was less than quantifiable limits.

Table 3-5
MDLs and LLOQs for Eluate Analysis for Carbon

Analyte	Symbol	MDL (mg/L)	LLOQ (mg/L)
Inorganic carbon	DIC	0.15	0.50
Organic carbon	DOC	0.18	0.50

Subsurface Gas Analysis

The composition of subsurface gas was monitored monthly from September 2018 through September 2019. Subsurface gas was monitored for oxygen (O_2), carbon dioxide (CO_2), methane (CH_4), ammonia (NH_3), and hydrogen sulfide (H_2S) using a hand-held field meter (Figure 3-4a). Table 3-6 shows the measurement units and calibration ranges for the five gases. To avoid any moisture from subsurface gas fouling the vacuum pump, the subsurface gas was drawn through a 250-mL syringe filled with desiccant (Figure 3-4b).

Methane	CH_4	%	0	5
Oxygen	O_2	%	0	30

Data Management with LeachXS™

Information on how leaching tests were conducted was recorded by the laboratory technician in Microsoft Excel® spreadsheets specifically designed for each test for use as templates for data collection and archiving. Analytical data documenting concentrations of constituents from each leaching test were entered into the same spreadsheets. These data templates were used as the interface for loading laboratory and analytical data into LeachXS™ (VU, 2019), a database-driven data management and reporting software program. LeachXS was used to (i) archive the laboratory and analytical data from leaching tests; (ii) compare test results between composite materials (e.g., VB-1, VB-2, or VB-3) or test results (e.g., TCLP, SPLP, ASTM, and LEAF); and (iii) generate the Excel plots used for this report.

4
TEST RESULTS AND DISCUSSION

A large volume of data was generated during this research. The discussion that follows presents representative example figures that illustrate observations based on all data. Graphs and data tables reflecting all data are provided in the appendices. In addition, key observations within subsections are denoted by underscored text.

Physical and Hydraulic Properties

Physical properties of the fly ash samples used for measurement of hydraulic properties are summarized in Table 4-1, composition of the solids is summarized in Table 4-2, and the hydraulic conductivities are summarized in Table 4-3.

Particle size distributions of the coal ash samples are shown in Figure 4-1. All samples contained a broad range of particle sizes ranging from those associated with coarse-to-fine sand, silt, and clay-size (<2 μm) particles. Each has a broadly graded distribution with relatively comparable fractions of all sizes and no gaps. The fines content (i.e., silt and clay-size particles finer than 75 μm) ranges from 36.6 to 92.2%, and the clay-size (i.e., finer than 2 μm) ranges from 5.2 to 19.8%. No particles coarser than sand-size were observed.

Table 4-1
Physical Properties of Coal Ash Samples Used for Hydraulic Conductivity Assessment

Sample ID	Sample Elevation at Bottom (ft AMSL)	Sample Elevation at Top (ft AMSL)	Water Content (%)	Dry Unit Weight (mg/m^3)	Particle Size Fractions			
VB-1_OST_12-14.5	743.8	746.3	41.5	1.14	0.0	15.5	84.5	15.1
VB-1_OST_17-19.5	738.8	741.3	52.0	1.00	0.0	25.2	74.8	10.0
VB-2_OST_13.5-15.5	737.9	739.9	37.5	1.11	0.0	64.4	36.6	5.2
VB-2_OST_18.5-21.5	731.9	734.9	28.7	1.35	0.0	23.1	76.9	12.6
VB-3_OST_17-20	738.8	741.8	36.3	1.28	0.0	34.5	65.5	14.0
VB-3_OST_24-27	731.8	734.8	27.9	1.26	0.0	7.8	92.2	19.8

Sample VB-2_OST_13.5-15.5 was notably coarser than the other samples and was classified as silty sand (SM) in ASTM D2487. This classification is characteristic of bottom ash mixed with fly ash. All other samples were classified as fine-grained “elastic silt” (ML) as defined in ASTM D2487, which is characteristic of fly ash.

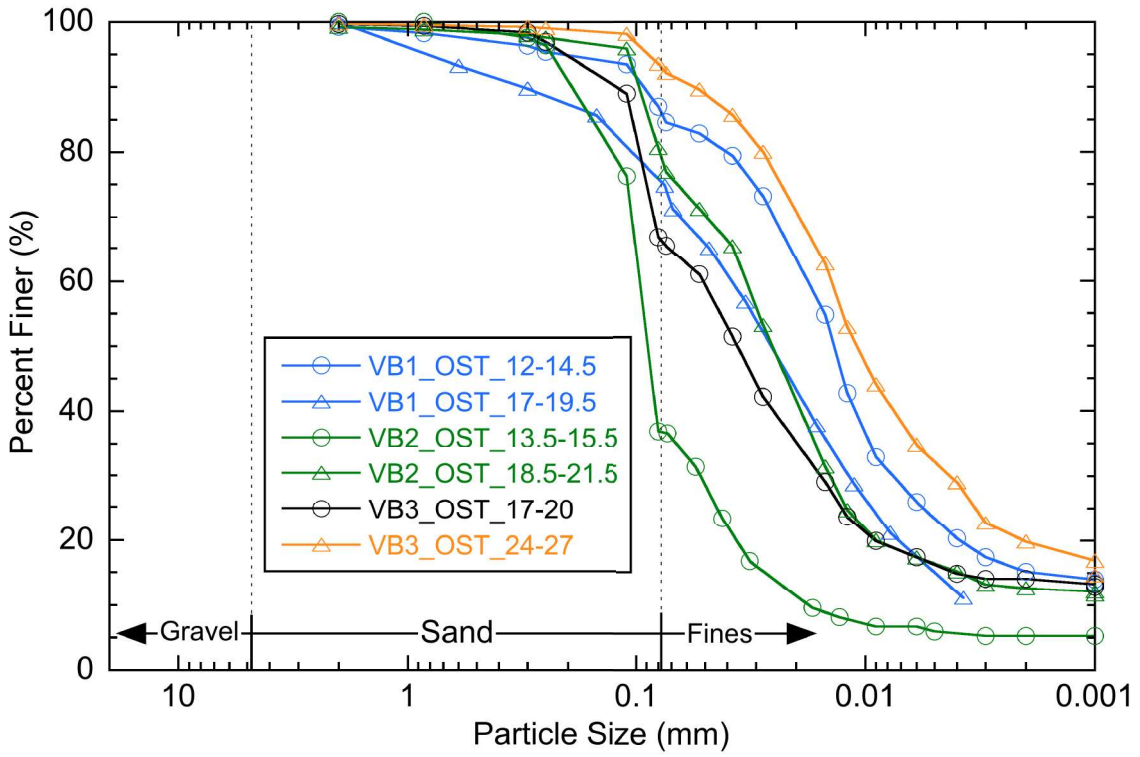

Figure 4-1
Particle size distribution of coal ash samples

Table 4-2 indicates that all of the ash samples are predominantly composed of Al and Si oxides, which reflects the predominant alumino-silicate mineral structure of the particulate. All samples contain modest amounts of Ca, K, Fe, and Ti. The VB-2 series samples are richer in iron than the other samples. The LOI varies considerably, from 0.50 to 11.83%.

Table 4-2
Composition of Solids (%) from LOI and XRF of Coal Ash Samples Used for Hydraulic Conductivity Assessment (elements exceeding 1.0%)

Composition	VB-1		VB-2		VB-3
	12-14.5	17-19.5	13.5-15.5	18.5-21.5	17-20
LOI	0.98	1.89	0.50	11.83	4.95

CaO	1.35	1.44	1.36	1.32	1.50
Fe_2O_3	16.14	11.34	22.99	19.45	12.61
K_2O	5.70	3.66	4.78	3.79	3.74
SiO_2	45.42	51.10	41.86	39.74	46.87
TiO_2	2.04	1.48	1.99	1.64	1.59

The hydraulic conductivities fall into two groups: the coarser, more permeable samples (VB-1_OST_17-19.5, VB-2_OST_13.5-15.5, and VB-3_OST_17-20) and the finer, less permeable samples (VB-1_OST_12-14.5, VB-2_OST_18.5-21.5, and VB-3_OST_24-27). The coarser samples have hydraulic conductivities in the range of 10^{-4} to 10^{-3} cm/s and fines content less than 75%, whereas the finer samples have hydraulic conductivities closer to 10^{-5} cm/s and fines content greater than 75%. There is a strong relationship between the hydraulic conductivity and fines content (Figure 4-2), with hydraulic conductivity diminishing as the fines content increases. The hydraulic conductivities also align well with hydraulic conductivities generally associated with the geotechnical classifications.

Table 4-3
Hydraulic Conductivity of Coal Ash Samples

Sample ID	Percent Fines (%)	Effective Stress (kPa)	Hydraulic Conductivity (cm/s)
VB-1_OST_12-14.5	84.5	20	2.0×10^{-5}
		100	2.0×10^{-5}
		250	1.4×10^{-5}
		400	1.3×10^{-5}
		500	1.3×10^{-5}
VB-1_OST_17-19.5	74.8	20	3.6×10^{-4}
VB-2_OST_13.5-15.5	36.6	20	1.3×10^{-3}
VB-2_OST_18.5-21.5	76.9	20	4.2×10^{-5}
		100	4.1×10^{-5}
		250	3.0×10^{-5}
		400	2.7×10^{-5}
		500	1.2×10^{-5}
VB-3_OST_17-20	65.5	20	6.3×10^{-4}
		100	6.9×10^{-4}
		250	2.5×10^{-4}
		400	2.3×10^{-4}
		500	9.7×10^{-5}
VB-3_OST_24-27	92.2	20	2.7×10^{-5}
		100	2.7×10^{-5}
		250	2.6×10^{-5}
		400	2.4×10^{-5}
		500	2.3×10^{-5}

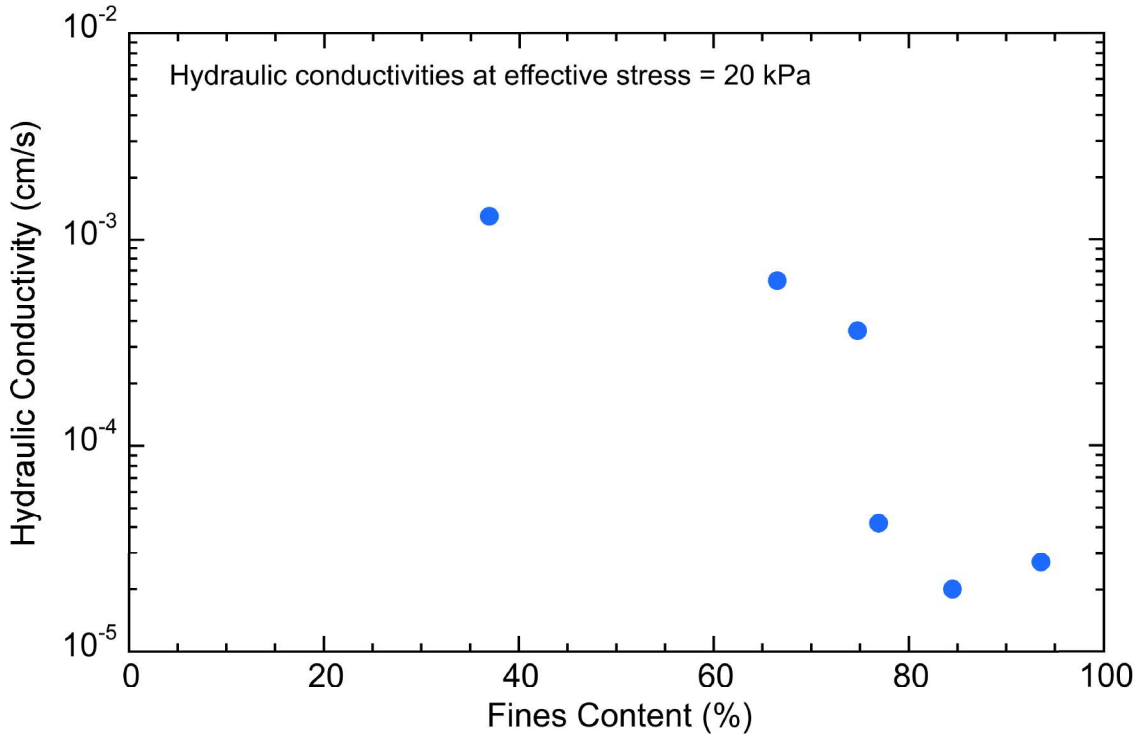

Figure 4-2
Hydraulic conductivity of coal ash at 20 kPa effective stress as a function of fines content

The hydraulic conductivity of the coal ash samples as a function of confining stress is shown in Figure 4-3. In general, the hydraulic conductivity decreases modestly with increasing effective stress. The hydraulic conductivity of the coarser, more permeable sample (VB-3_OST_17-20) is more sensitive to effective stress than the finer, less permeable samples. As the stress increased from 20 to 500 kPa, the hydraulic conductivity of the coarser sample decreased by a factor of 6.5. In contrast, the hydraulic conductivity of the finer, less permeable samples decreased by a factor of 2.1 on average over the same range of stresses. The greater sensitivity to stress for VB-3_OST_17-20 may reflect closure of larger pores between the sand-size particles, with the finer particles filling the remaining pores and resulting in lower hydraulic conductivity.

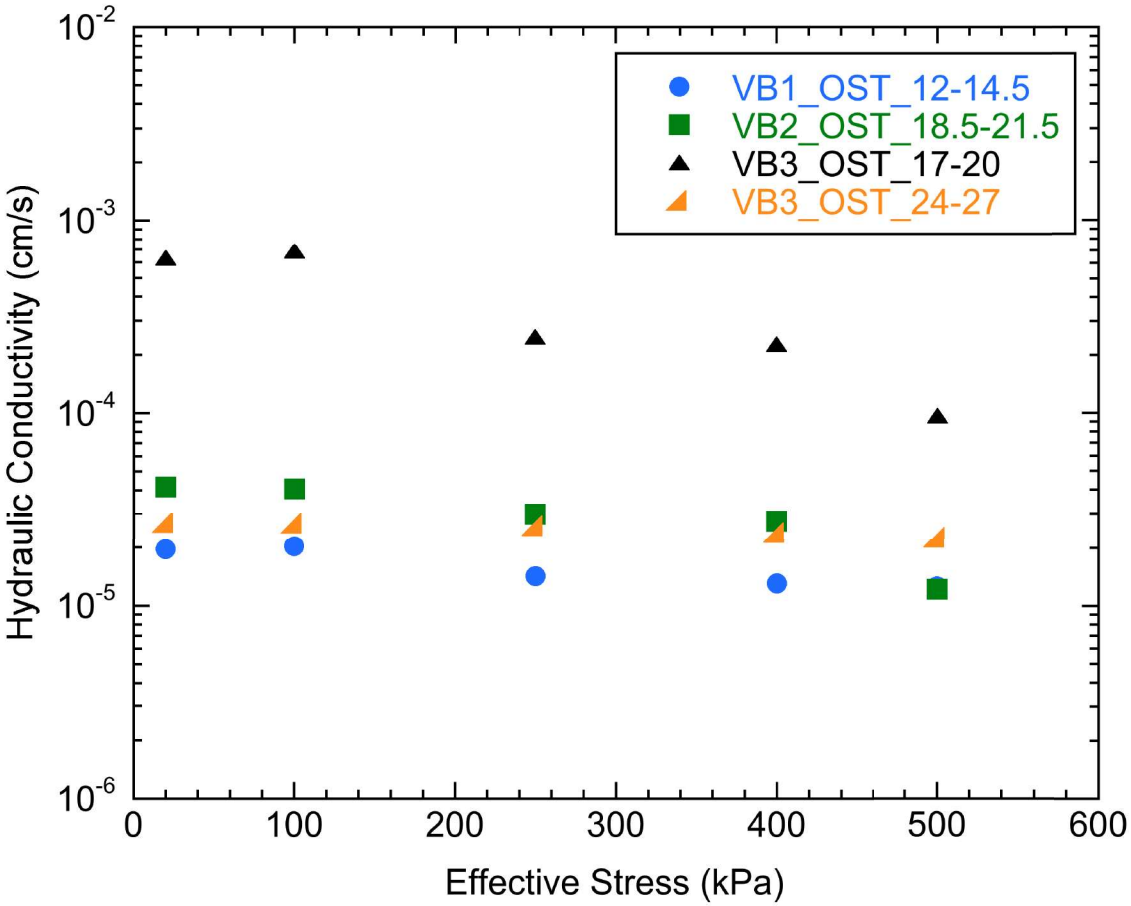

Figure 4-3
Hydraulic conductivity of coal ash samples as a function of effective stress

Individual Split Spoon Sample Testing

Evaluation of Field Extractions (L/S~1 vs. L/S=1)

During field sampling, extractions of split spoon materials were conducted using de-oxygenated water at an L/S~1. For each extract, approximately 150-g grab samples of recovered material from the center of the split spoon were contacted with approximately 150 mL of DI water that had been deoxygenated with nitrogen prior to field operations. If the split spoon indicated an interface between dissimilar materials (e.g., across the ash-cover or ash-liner interfaces or in layered ash), two extractions were conducted on grab samples of distinctive material types. Because the moisture content of the split spoon material varied with depth and texture, the resultant L/S of field extractions varied between 1.7 and 3.3 mL/g-dry.

The variation in L/S of field-extracted materials confounds the comparison of material within a borehole or between boreholes based on concentrations. Therefore, extractions at a constant L/S ratio were conducted in the laboratory. Collected bulk materials that had been vacuum-sealed to preserve the redox conditions of split spoon samples were homogenized within each split spoon. 100-g subsamples of homogenized material were extracted with DI water at an L/S=1 mL/g-dry. Figure 4-4 shows a comparison between field extractions (L/S~1) and laboratory extractions (L/S=1) as a function of pH and L/S. Comparisons of field and laboratory extraction data for all constituents are presented in Appendix C.1.

In these figures, the color of the data points indicates the borehole (e.g., VB-1 in blue, VB-2 in green, and VB-3 in orange), with lighter colors indicating field extractions and darker colors indicating laboratory extractions. The shape of the data point refers to the primary type of material used in the extraction (ash samples are shown as dots, cover material as squares, and liner material as diamonds). Solid data points are confirmed material types that fall within the material classification provided in the bore logs by the licensed geologist, while open data points indicate materials near interfaces that are likely to be a blend of two or more material types (e.g., open squares indicate blended samples of the ash and cover materials while open diamonds refer to blends of ash, layered ash, and liner material).

The data in Figure 4-4 show that the primary difference between laboratory tests is L/S ratio, which is most noticeable in the L/S-dependence plot. The pH range for the laboratory extractions is primarily the same as that of the field extractions.

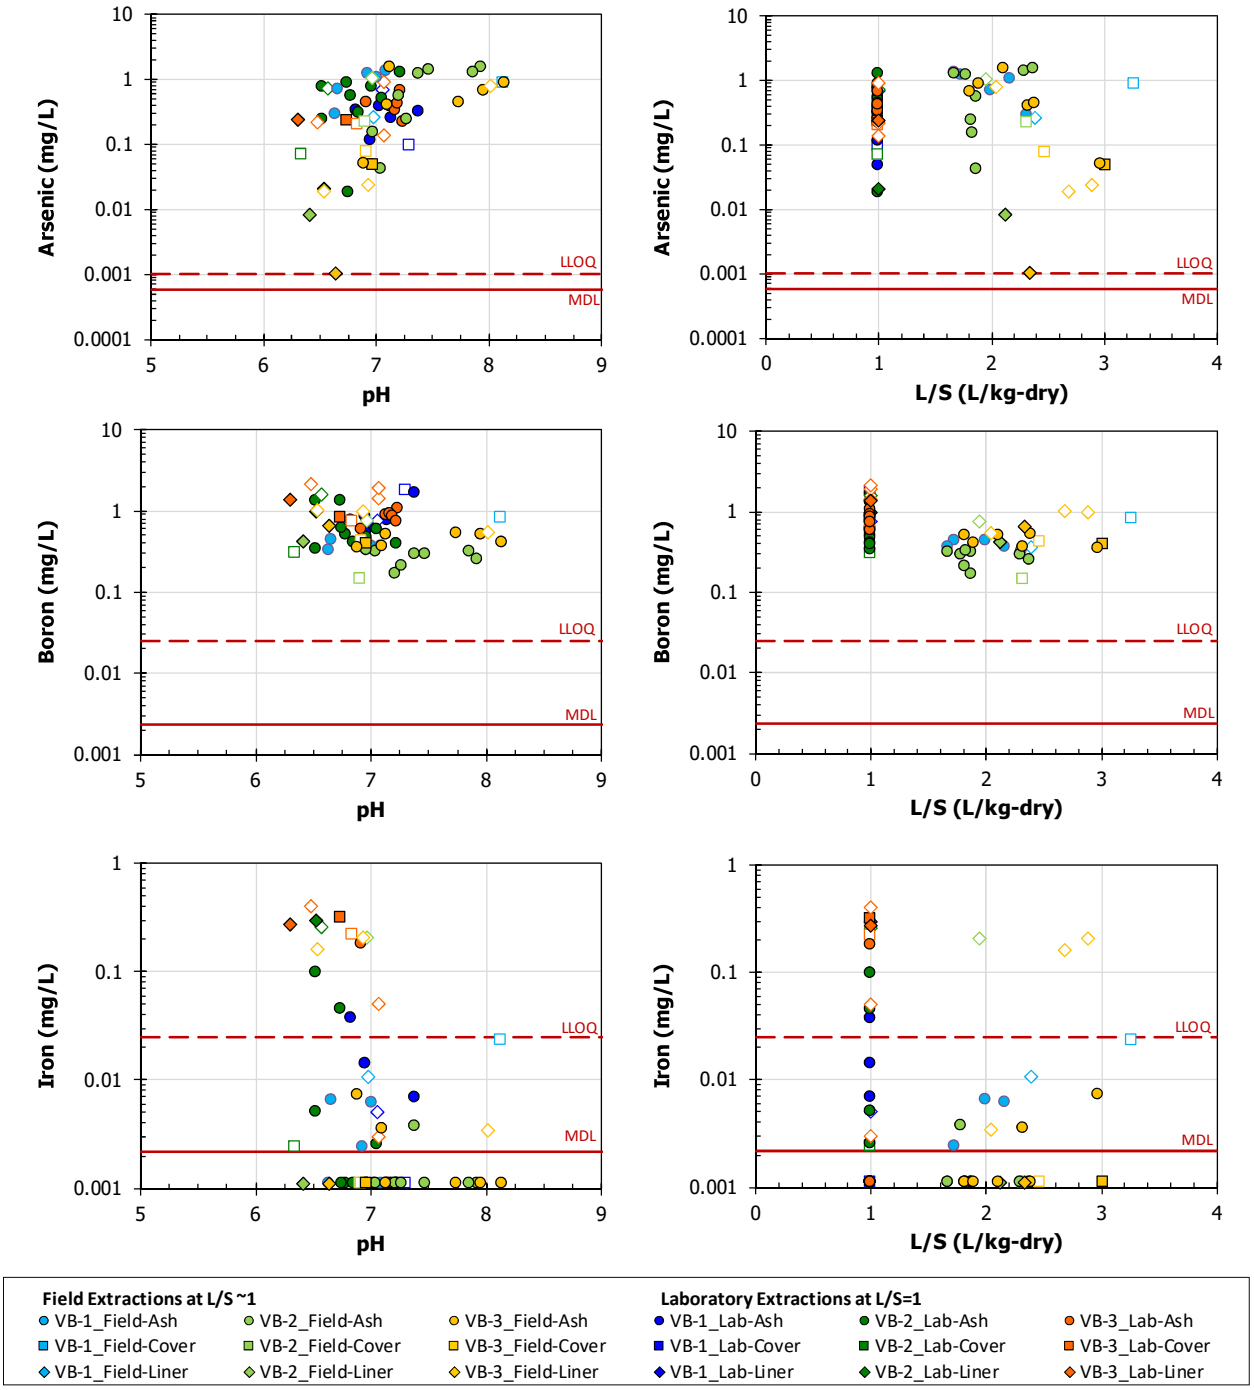

Figure 4-4
Comparison of field extractions at L/S~1 (lighter colors) to laboratory extractions at L/S=1 (darker colors) for individual split spoon materials shown as a function of pH (left) and L/S (right)

Vertical Heterogeneity Within and Between Boreholes

Profile Plots of Field and Laboratory Extraction Data

After surveying of the borehole and PAP locations and elevations, depths below grade that were monitored during sample recovery were converted to elevations ASML. The concentrations from field extractions (L/S~1) and laboratory extractions (L/S=1) of individual split spoon materials were plotted as a function of elevation to provide a visual metric of material heterogeneity with depth within a borehole. An example of these borehole profile plots is presented in Figure 4-5.

Each line of the figure represents the concentration profiles for a measured constituent in the laboratory extractions (L/S=1) for VB-1 in blue, VB-2 in green, and VB-3 in orange. The concentration is plotted along the x-axis, while the elevation for the center of the split spoon is plotted on the y-axis. The red horizontal line shows the elevation at the interface between cover material and the ash deposit, while the brown horizontal line indicates the elevation where the main ash deposit ended either at an interface with the underlying native clay liner material or in layers of different ash textures above the clay liner. The 2-foot wide shaded area indicates the screening interval for the PAP in each borehole. The 3 to 4 light-colored data points in each profile indicate the intervals from which material was taken to create the composite ash sample for each borehole used in detailed characterizations.

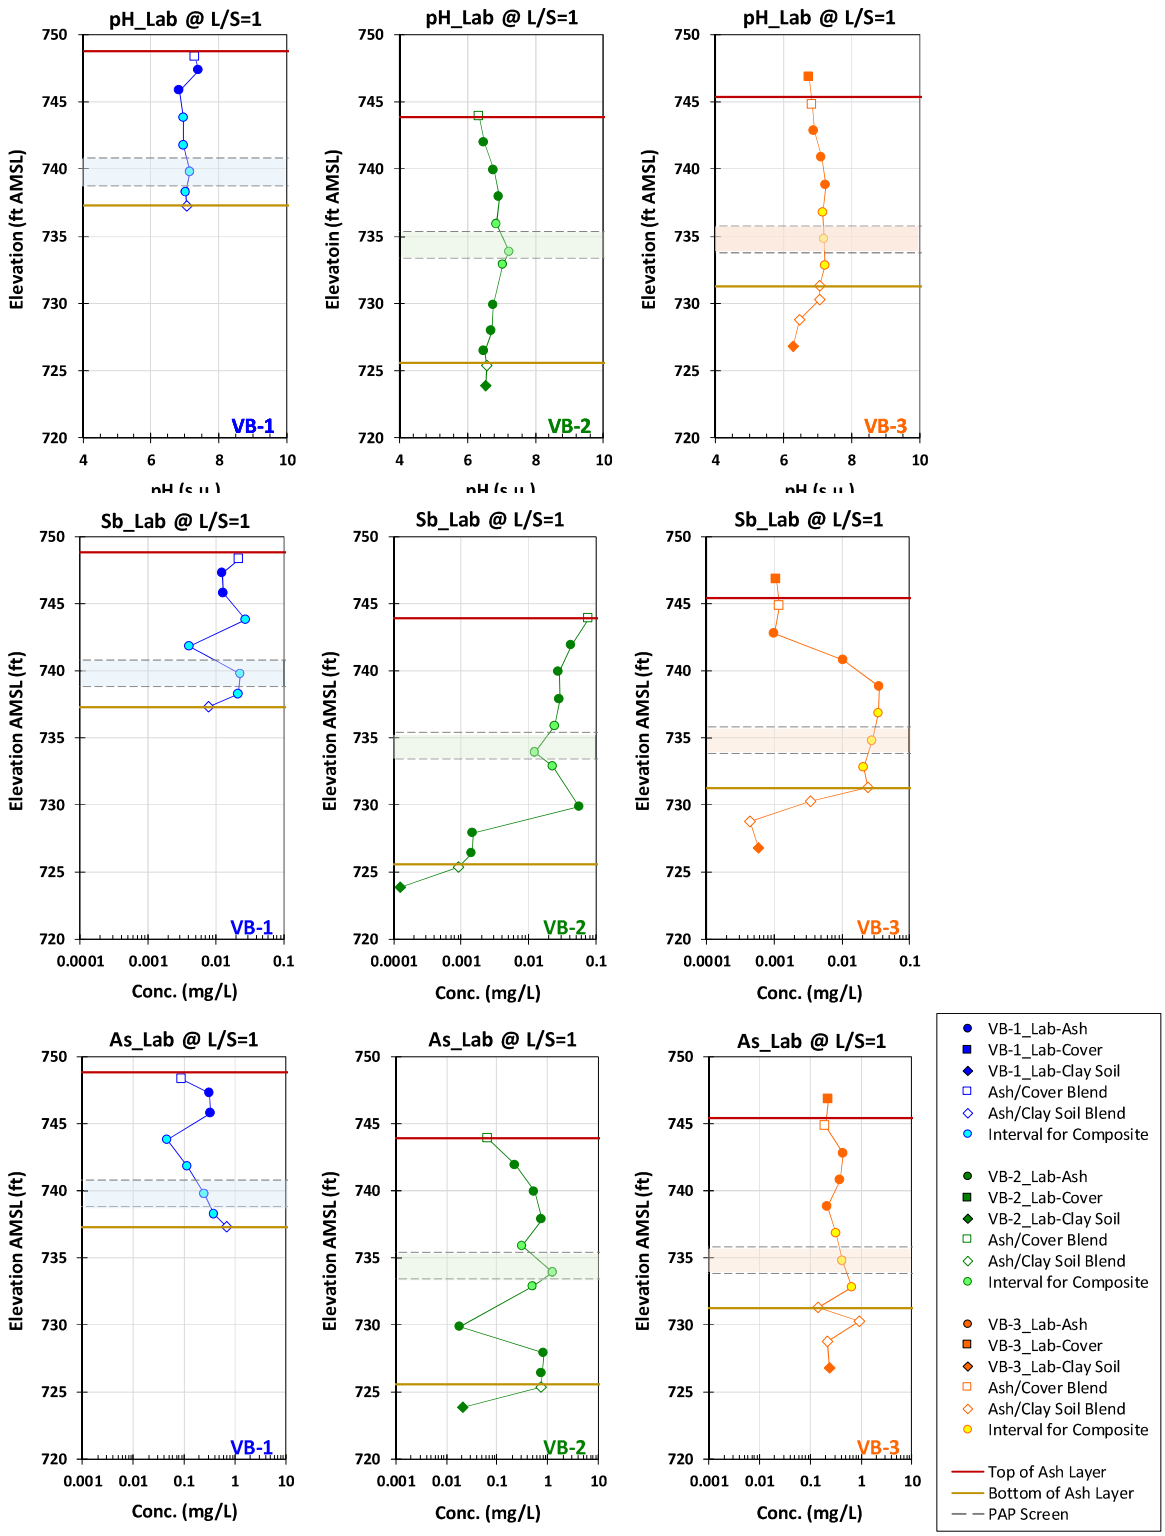

Figure 4-5
Laboratory extraction (L/S=1) concentration profiles within boreholes (VB-1, VB-2, VB-3) based on eluate concentration (SU or mg/L) for pH, antimony, and arsenic

Standardized Borehole Profiles of Laboratory Extraction (L/S=1) Concentrations

The concentration data for laboratory extractions of homogenized split spoon material were converted to standardized profile plots using the global mean and standard deviation for "known ash samples" in all boreholes based on geologist notes. The standardized concentration is calculated as:

$$\frac{x - \bar{x}}{s}$$

where x is the parameter (e.g., pH, concentration) from the extraction test,
$\bar{x}$ is the global mean of all "known ash samples" for all boreholes, and
s is the global standard deviation of all "known ash samples."

The standardized concentration provides a measure of the difference between the measured concentration and the mean as a number of standard deviations from the mean concentration. A homogenous material, for example, may have measurements within 2 standard deviations of the mean while measurements greater than 4 standard deviations may have more than random variations such as influence from cover or underlying material. Justification for use of ash sample global statistics, rather than within-borehole statistics, was based on the results of t-test results for pair-wise comparisons assuming unequal variances, which showed no statistical difference in means between boreholes. In addition, the use of global statistics in standardized concentration profiles allows for comparison between boreholes on the same basis.

Examples of the resulting standardized borehole profiles are shown in Figure 4-6 for major constituents and in Figure 4-7 for trace constituents. The standardized profiles for all constituents are presented Appendix C.2. The global mean and standard deviation for all constituents are tabulated in Table 4-4.

The process for collection of split spoon samples at boreholes VB-2 and VB-3 was designed to capture the interfaces at the cover and underlying materials, whereas the collection of split spoons at borehole VB-1 was centered on the ash material only. These sampling schemes are reflected in the results of the standardized profiles. Figure 4-6 shows that the concentration profiles for aluminum and iron from laboratory extractions (L/S=1) show very consistent response within the ash deposit, with clear influences from overlying and underlying materials. The profiles for antimony, arsenic, and boron in Figure 4-7 show more variation within the ash layers, with little to no influence from cover or underlying materials. Overall, the samples used in the composite materials for all boreholes were relatively consistent and are considered representative of the global mean of the stored ash.

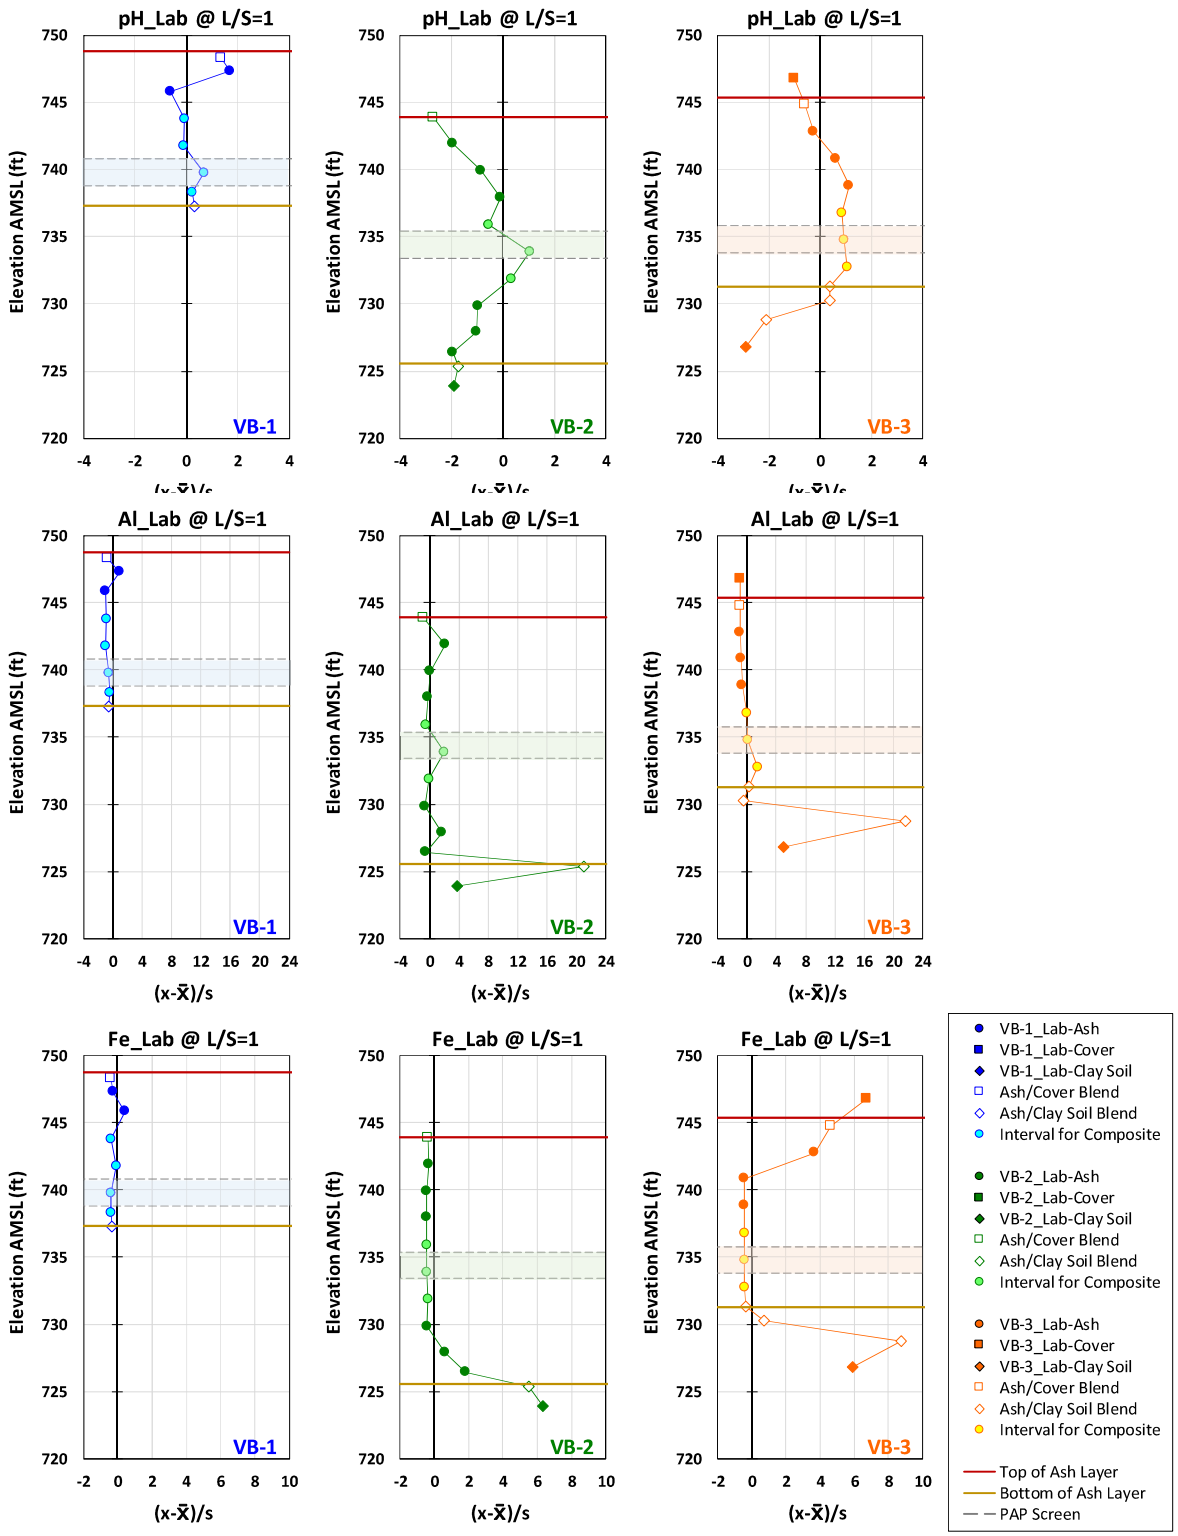

Figure 4-6
Laboratory extraction (L/S=1) concentration profiles within boreholes (VB-1, VB-2, and VB-3) standardized to the global mean (x̄) and standard deviation (s) of known ash samples for pH, aluminum, and iron

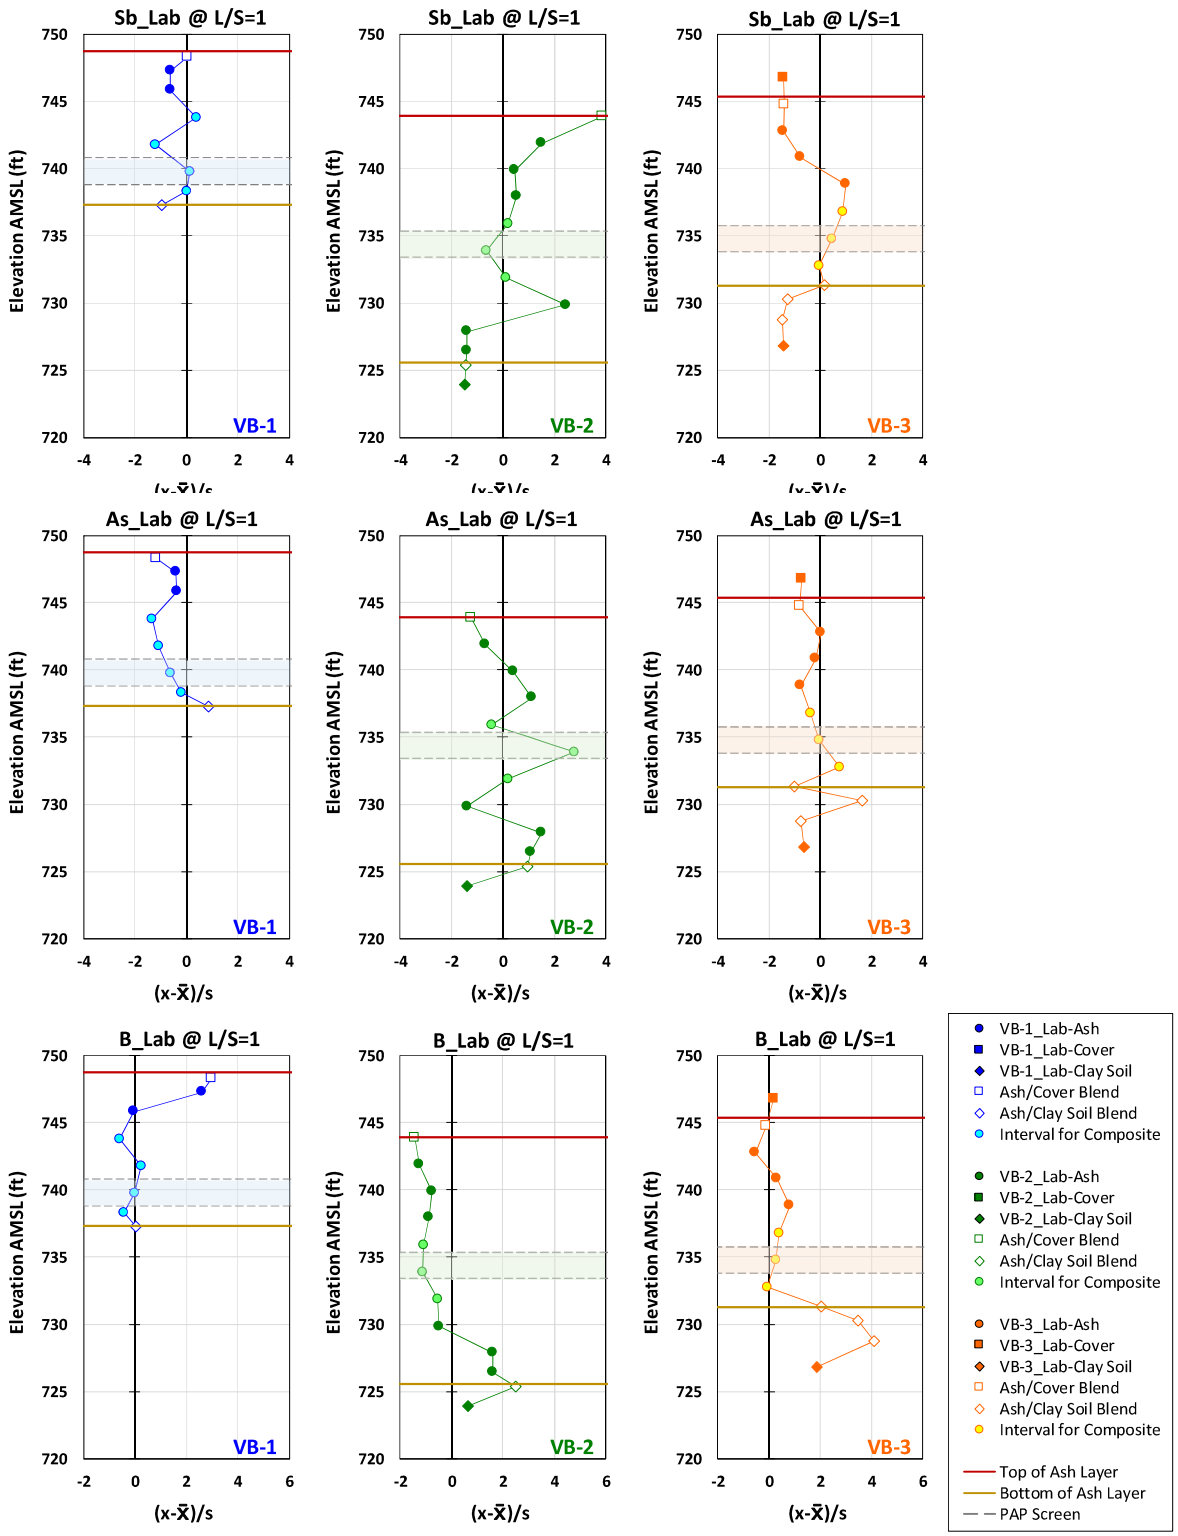

Figure 4-7
Laboratory extraction (L/S=1) concentration profiles within boreholes (VB-1, VB-2, and VB-3) standardized to the global mean (X̄) and standard deviation (s) of known ash samples for antimony, arsenic, and boron

Table 4-4

Zinc	mg/L	0.03	0.09

Notes: <MDL indicates all or most of the L/S=1 concentrations were less than the MDL

Comparison of Standardized Borehole Profiles for Field and Laboratory Extractions Based on Mass Release (mg/kg)

The standardized borehole variability graphs can be used to examine the differences between field extractions at L/S ~1 and laboratory extractions at L/S=1. Example comparisons for selected major and trace constituents are shown in Figure 4-8 and Figure 4-9, respectively, while the complete results for all measured constituents are presented in Appendix C.3.

In general, the variability of laboratory and field extraction are similar; however, the laboratory extractions are somewhat less variable than the field extractions. This observation is due to the homogenization within a split spoon sample that was conducted on the material used for laboratory extractions, especially for trace species where blending would matter most (see Figure 4-9). A secondary cause for lesser variability in the laboratory extraction data may be a result of redox changes between the laboratory and field extraction conditions.

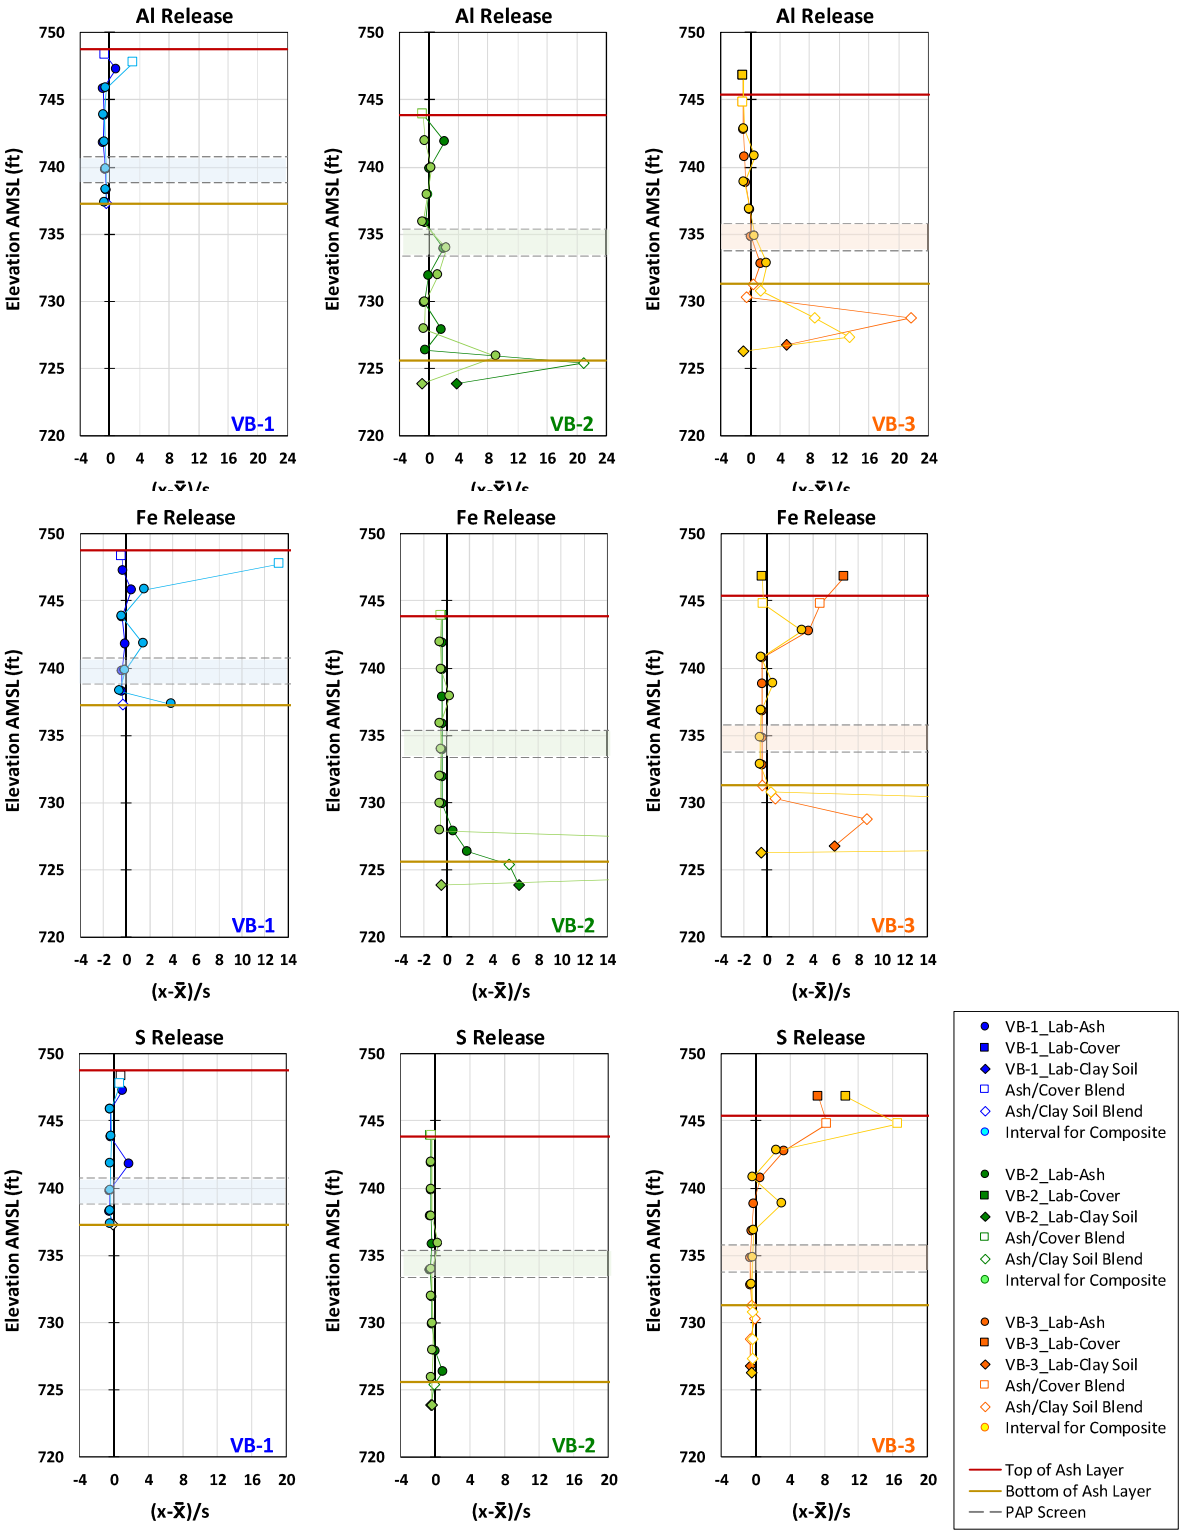

Figure 4-8
Comparison of standardized mass release profiles for field extractions (L/S~1) and laboratory extraction (L/S=1) of major constituents from VB-1, VB-2, and VB-3 for aluminum, iron, and sulfur

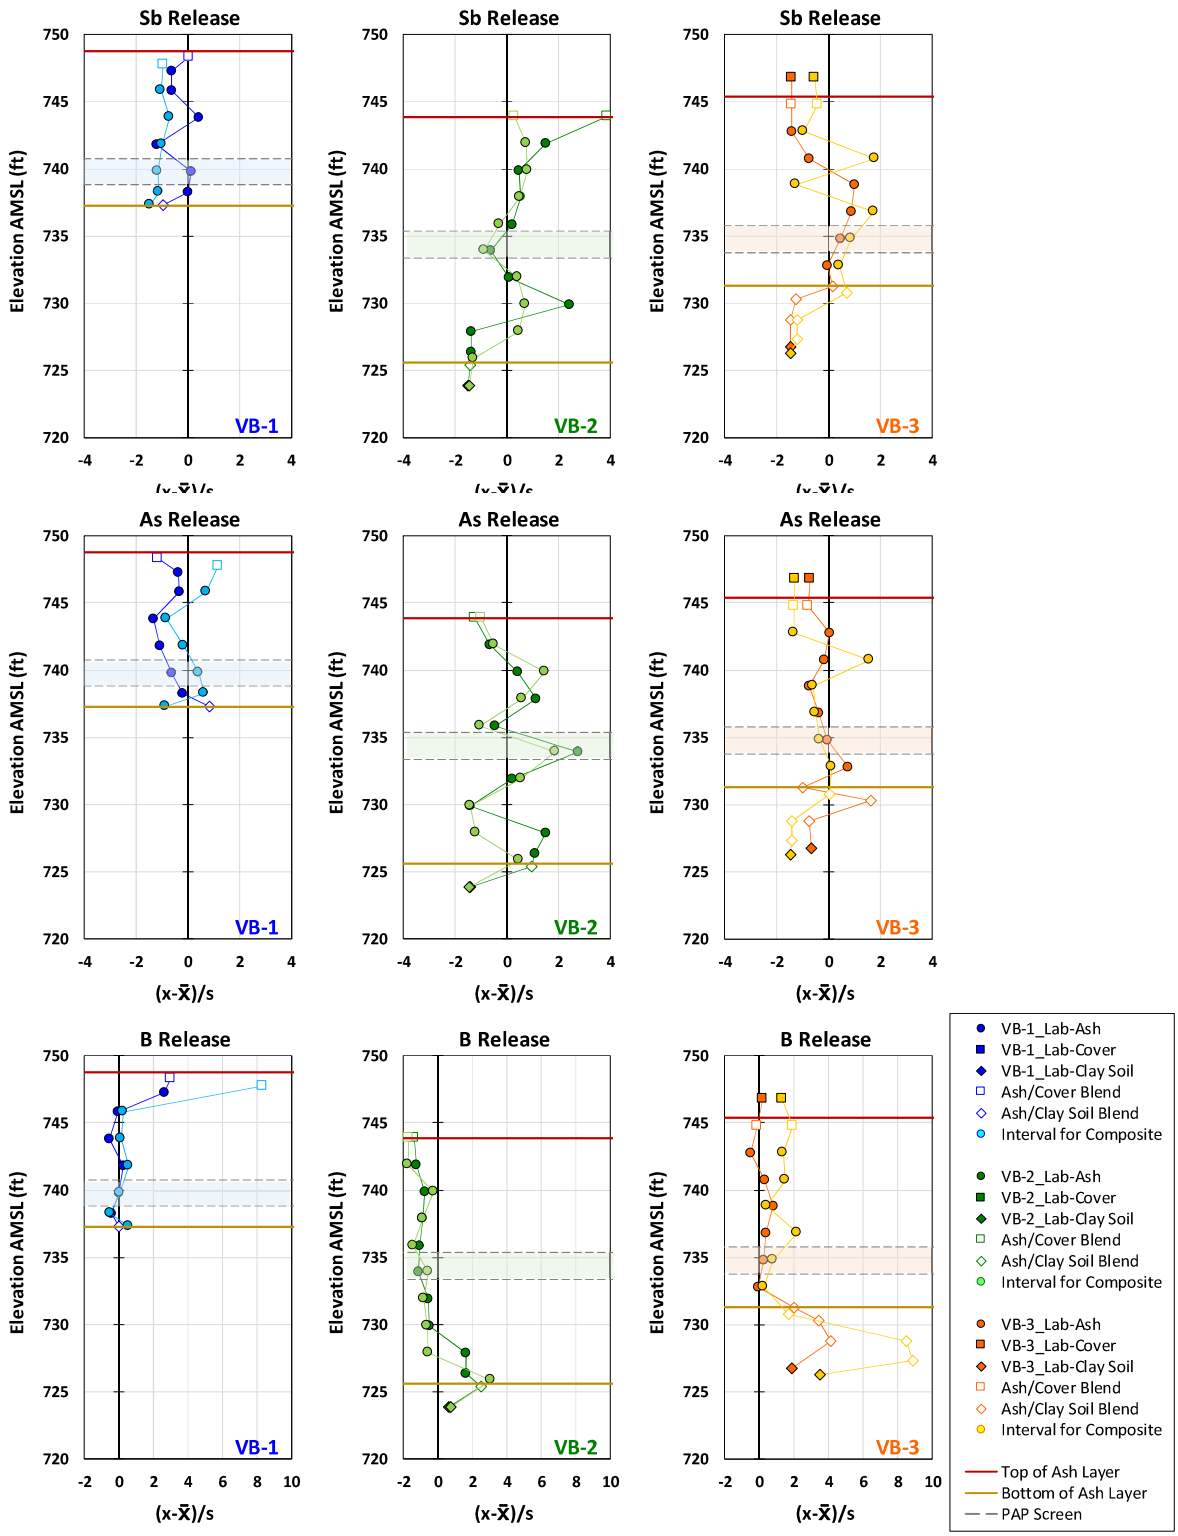

Figure 4-9
Comparison of standardized mass release profiles for field extractions (L/S~1) and laboratory extraction (L/S=1) of trace constituents from VB-1, VB-2, and VB-3 for antimony, arsenic, and boron

Composite Ash Sample Test Results

Subsamples of bulk material collected from split spoon sampling were homogenized within each bulk storage packet and then composited by equal mass over intervals around the PAP screening intervals. These composites were subject to detailed investigation of total and available content, leaching characteristics as a function of pH and L/S, and comparison between leaching tests and to porewater concentrations. The complete set of pH- and L/S-dependent results for all measured constituents is presented in Appendix D.1.

Total Content

In preparation for EPA Method 3052, ash samples were dried under nitrogen and ground to pass a No. 100 (150 μm) sieve. Therefore, although the EPA method is based on "as received" solid sample, which can include the inherent moisture within the material, the results presented on an "as received" mass (mg/kg) are, in this case, based on dry-mass (mg/kg-dry) like the LEAF tests. The total content reported for samples of the three composite materials is shown in Table 4-5. Of the 27 constituents analyzed, Sb, Mg, Hg, Se, Ag, and Tl were reported to have a total content less than the commercial laboratory's reporting limit shown in the table. Furthermore, the total content of thallium was not detected at a value greater than the shown MDL value. Based on the low total content and low eluate concentrations of initial leaching test results, Ag and Hg were not considered in the analysis of test leachates or the comparison to groundwater concentrations. The remaining constituents were retained because preliminary testing indicated that leaching concentrations were low, but quantifiable for most leaching tests.

Table 4-5
Total Content for Composite Samples VB-1, VB-2, and VB-3 Based on EPA Method 3052

Analyte	Symbol	MDL (mg/kg)	RL (mg/kg)	VB-1 (mg/kg)	VB-2 (mg/kg)	VB-3 (mg/kg)
Aluminum	Al	3.1	40	13,000	13,000	13,000

Iron	Fe	28	40	11,000	77,000	57,000
Lead	Pb	1.1	7.5	53	46	61
Lithium	Li	0.29	5.0	170	170	190

Table 4-5 (continued)
Total Content for Composite Samples VB-1, VB-2, and VB-3 Based on EPA Method 3052

Analyte	Symbol	MDL (mg/kg)	RL (mg/kg)	VB-1 (mg/kg)	VB-2 (mg/kg)	VB-3 (mg/kg)
Magnesium	Mg	3.7	500	110 J	110 J, F1	120 J
Manganese	Mn	0.11	1.5	250	210	170
Mercury	Hg	0.062	0.2	0.098 J	0.093 J	0.083 J
Molybdenum	Mo	0.16	4.0	8.2	4.5	5.0
Nickel	Ni	0.16	20	100	89	90
Potassium	K	100	1,000	12,000	15,000	15,000
Selenium	Se	1.7	7.5	6.1 J	4.4 J	5.3 J
Silver	Ag	0.11	3.0	1.8 J	1.7 J	1.9 J
Sodium	Na	260	500	1,400	1,700	1,800
Strontium	Sr	0.058	5.0	140	100 F1	120
Thallium	Tl	10	17	ND	ND	ND
Titanium	Ti	1.0	25	7,500	7,800	8,200
Vanadium	V	0.12	5.0	240	240	260
Zinc	Zn	2.0	12	120	110	120

Notes: B the compound was found in the blank and sample.

F1 the matrix spike recovery is outside of acceptance limits

J the result is less than the LLOQ but greater than or equal to the MDL; estimated concentration.

ND the compound was not detected at a concentration above the MDL.

pH-Dependent Leaching Tests

Titration curves from EPA 1313 and 1313_L/S=1 conducted on the VB-1, VB-2, and VB-3 composite samples are presented in Figure 4-10. The titration curve indicates the amount of acid or base (shown as acid additions less than zero) required to provide a specific eluate pH. This is sometimes referred to as the acid/base neutralization capacity of the material. Also shown in Figure 4-10 is the natural pH response for each composite material when no acid or base is added.

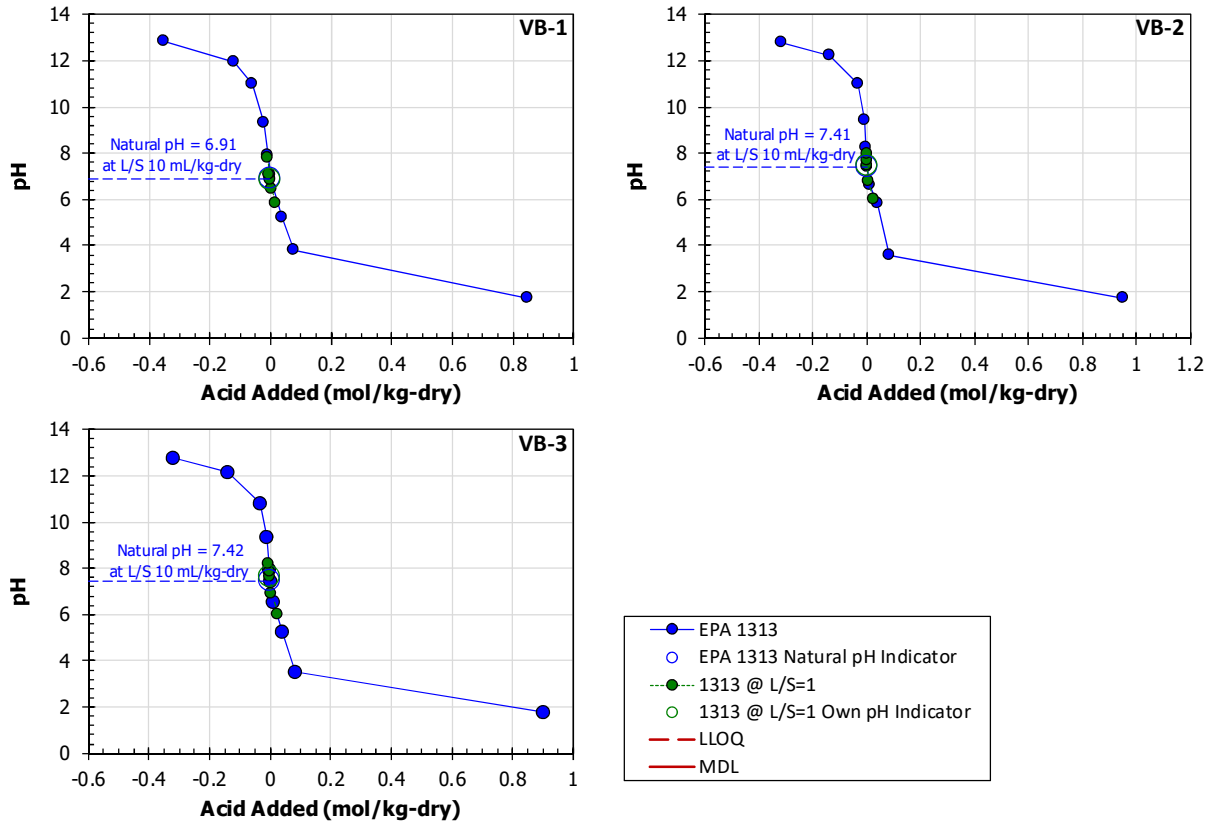

Figure 4-10
Titration curves from EPA 1313 test results from composite testing of VB-1, VB-2, and VB-3

The natural pH values for the three composites are presented in Table 4-6 along with the "own pH" values measured during 1313 testing at an L/S=1 mL/g-dry. Although the natural pH values for all composites are generally neutral, VB-1 is slightly more acidic (pH_{nat}=6.91) than the composites at VB-2 (pH_{nat}=7.41) or VB-3 (pH_{nat}=7.42). The different L/S ratios between natural pH and own pH had little effect on overall pH (less than 0.2 SU).

Table 4-6
Natural pH (EPA 1313) and Own pH (1313_L/S=1) of Composite Samples

	Method	L/S (mL/g-dry)	pH (SU) VB-1	pH (SU) VB-2	pH (SU) VB-3
Natural pH	EPA 1313	10	6.91	7.41	7.42
Own pH	1313_L/S=1	1	6.84	7.45	7.59

Constituent Concentrations

The concentration of a constituent in each eluate of a pH-dependent leaching test (i.e., EPA 1313 and 1313_L/S=1) is indicative of the LSP in equilibrium with the L/S, pH, EC, and ORP of the contacting fluid. Eluate concentrations are typically plotted as a function of eluate pH to indicate how LSP changes over a broad range of pH values. Example test results from EPA 1313 and

1313_L/S=1 are shown in Figure 4-11 through Figure 4-13 as pH-dependent eluate concentration (mg/L) and mass release (mg/kg-dry).

The pH-dependent leaching behavior of a constituent is useful when disposed materials may be contacted with water containing significant amounts of acid or base (e.g., pyrite-impacted groundwater or alkali process wastewaters). These data can be used to parameterize controlling mineral sets in geochemical speciation models, for example, LeachXS™/ORCHESTRA (Meeussen, 2015), to create a source term for fate and transport modeling.

Solubility-Controlled LSP vs. Available Content-Limited LSP

In addition, comparison of the effects of changing pH (e.g., within an EPA 1313 test) to the effects of changing L/S (e.g., between EPA 1313 and 1313_L/S=1 or EPA 1314) can be used to distinguish constituents with "solubility-controlled LSP" behavior from those with "available content-limited LSP." The following classifications are based on comparison of EPA 1313 test results to those of 1313_L/S=1 testing and, thus, the classifications are limited to a relatively narrow pH range about the natural pH. Outside of those bounds, constituents that were classified as available-content limited may show solubility-controlled LSP.

- Solubility-Controlled LSP – When the eluate concentrations are limited by mineral solubility and precipitation/dissolution, the LSP behavior is considered "solubility-controlled" and pH is a controlling factor for leaching. Eluate concentrations for these behaviors are often a strong function of pH. However, unless pH changes significantly when L/S is changed, eluate concentrations are a weak function of L/S. The pH-dependent results for Ba (Figure 4-11, top) as well as Cr, F^-, Sb, Se, V, and Zn (in Appendix D.1) are good examples of solubility-controlled LSP. For these constituents, eluate concentrations change by orders-of-magnitude as a function of pH but do not change when the L/S is reduced from L/S=10 mL/g-dry (EPA 1313) to L/S=1 mL/g-dry (1313_L/S=1).
- Similarly, adsorption/desorption processes can be highly pH-dependent and often can be classified along with solubility-controlled LSP. For example, the LSP behavior of arsenic (Figure 4-11, bottom) with regard to changes in pH and L/S has similar trends to the solubility-controlled LSP behavior of Ba; however, the primary mechanism for the pH-dependent LSP of arsenic is likely adsorption to hydrous ferric oxides (HFO) rather than solubility of arsenic species.

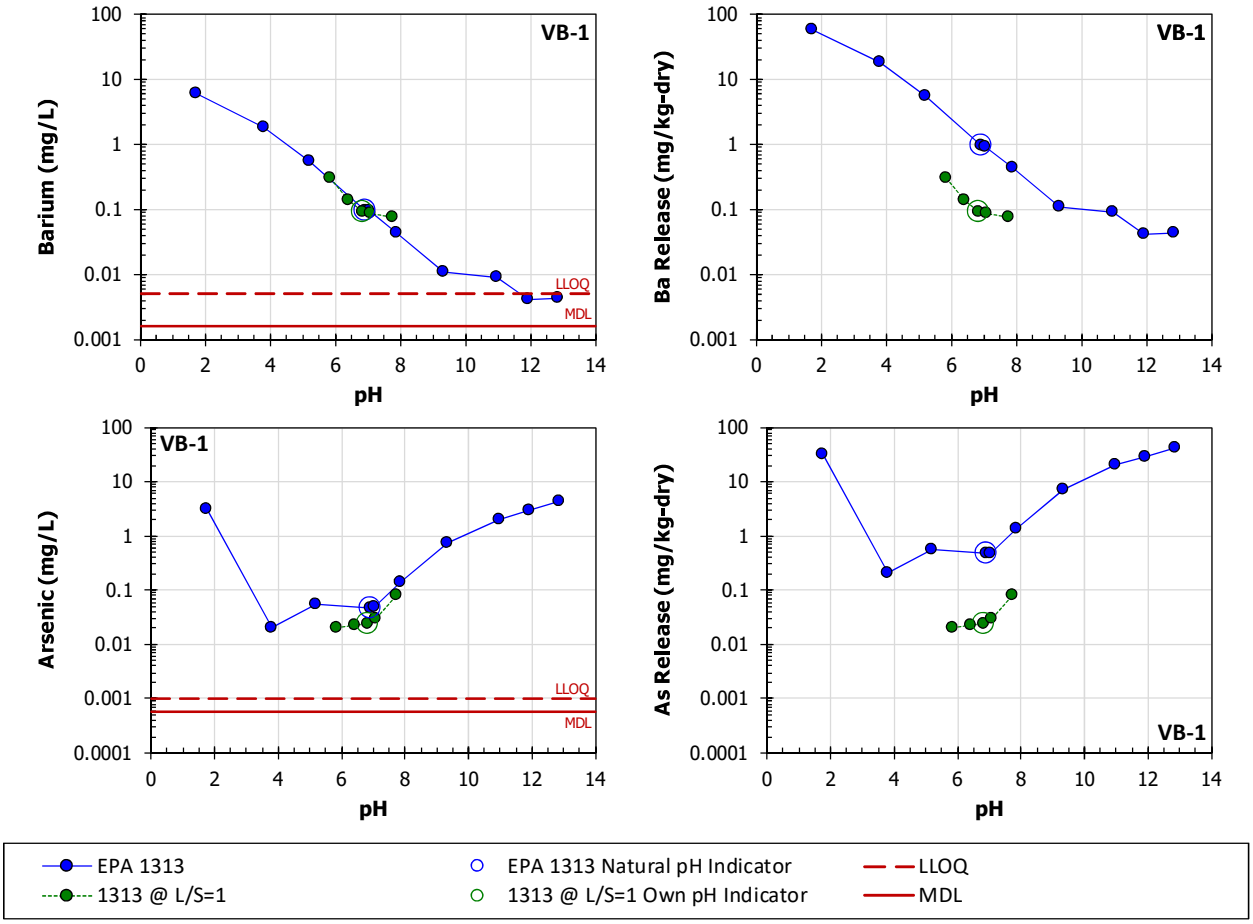

Figure 4-11
Example pH-dependent (EPA 1313) test results showing solubility-controlled LSP (barium) and adsorption-dominated LSP (arsenic)

- Available Content-Limited LSP – The concentration of some highly soluble constituents is not limited by the conditions of the eluate but by the amount of leachable mass in the solid. The characteristic pH-dependent behavior of these "available content-limited LSP" constituents is that eluate concentration curve is a weak function of pH but a strong function of L/S. Figure 4-12 presents examples of available content-limited LSP for B and SO_4^{-2} results from EPA 1313 and 1313_L/S=1. These figures show that pH-dependent concentrations within a test vary by approximately an order-of-magnitude across the entire pH range. However, when the L/S changes from L/S=10 mL/g-dry to L/S=1 mL/g-dry, the eluate concentration changes accordingly. Because the L/S effect is correlated to the magnitude of the L/S, the mass release (i.e., the eluate concentration multiplied by the L/S) is the same for both tests. Available content-limited LSP was observed for B, Ca, Cl^-, Mo, SO_4^{-2}, and Tl in VB-1, VB-2, and VB-3 composites (Appendix D.1).

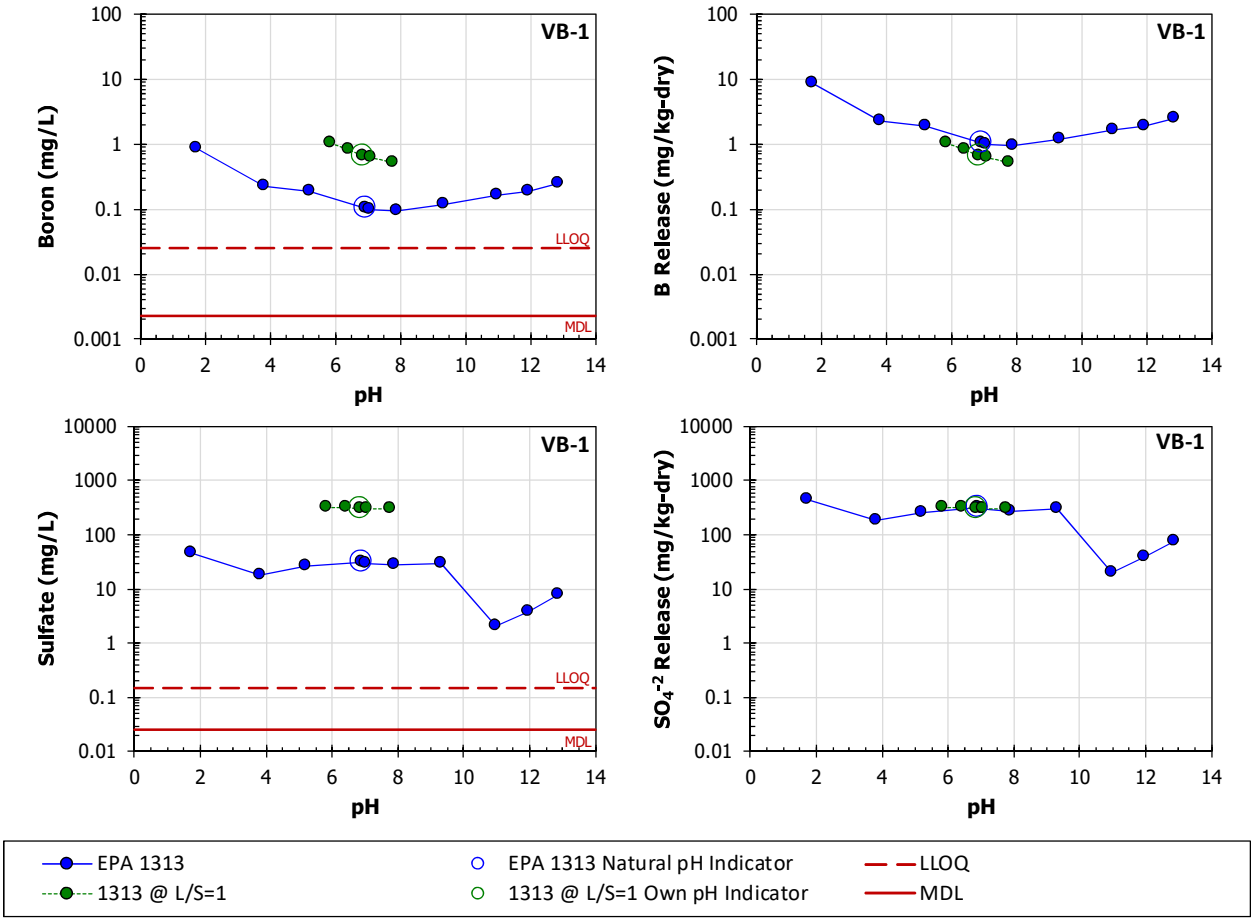

Figure 4-12
Example pH-dependent (EPA 1313) test results showing available content-limited LSP

For some constituents, the pH-dependent leaching data does not support the determination of LSP behavior, because eluate concentrations are less than the MDL for the analytical method. Figure 4-13 presents examples for Be and Li. Similar behavior was shown for Cd, Co, Cu, Fe, Ni, and Pb (Appendix D.1).

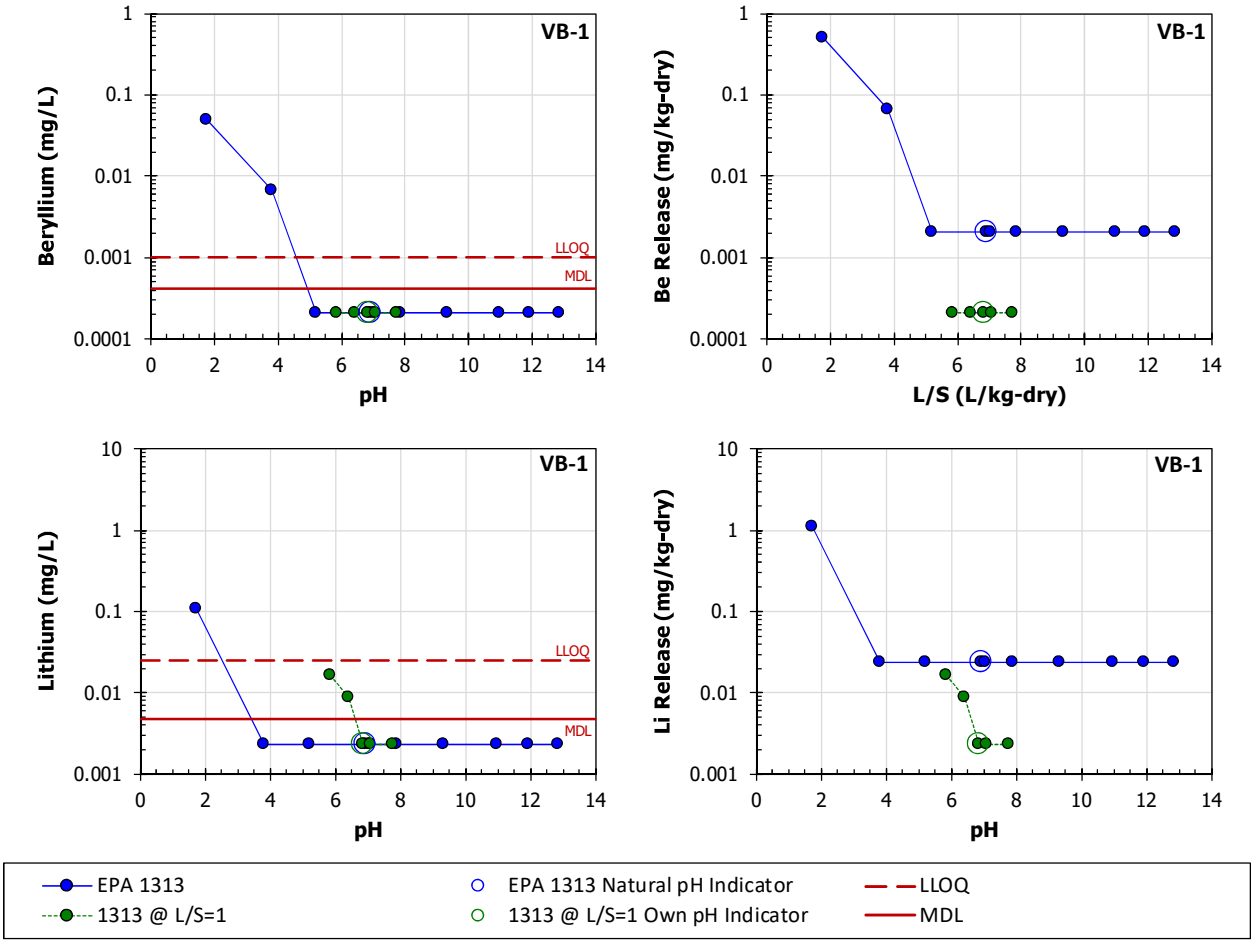

Figure 4-13
Example pH-dependent (EPA 1313) test results for constituents where LSP type could not be determined based on measured concentrations

Available Content Determination Using EPA 1313

The available content of the three borehole composites was determined from the maximum concentration over the pH range $2 \leq pH \leq 13$ from EPA 1313 testing. The available content values and pH locations for the maximum 1313 concentration are shown in Table 4-7. In Table 4-8, comparison of available content (mg/kg-dry) to the total content (mg/kg) shown in Table 4-5 indicates that only a small fraction of most constituents is leachable over a broad pH range. The high ratios of available Ca and Mg to their total content suggest either that digestion by EPA 3052 was not complete or that there is inherent error associated with multiplying a relatively small digestate concentration by a large effective L/S of 500 or more.

Table 4-7
Available Content for Composite Samples VB-1, VB-2, and VB-3 Based on the Maximum Concentration from EPA Method 1313

Analyte	Symbol	VB-1 (mg/kg-dry)	@ pH	VB-2 (mg/kg-dry)	@ pH	VB-3 (mg/kg-dry)	@ pH

Zinc	Zn	0.043	0.040	0.046

Notes:
- * total content data indicated an analytical anomaly (see error codes below).
- B the compound was found in the blank and sample of the total content analysis extract.
- F1 the matrix spike recovery for the total content analysis extract is outside of acceptance limits.
- J the total content result was less than the LLOQ but greater than or equal to the MDL; estimated value.

Comparison of pH-Dependent Leaching from Individual Split Spoon Samples to Composite Samples for Each Borehole

pH-dependent leaching data (EPA 1313) from composite samples was compared to laboratory extractions of individual split spoon materials to illustrate how the composite samples represented the strata of ash materials. Bulk materials collected by split spoon were homogenized within the vacuum-sealed bag prior to testing using a modified, 3-point version of EPA 1313. The 3-point version of EPA 1313 that was applied to individual split spoon samples included extractions at $1.5 \leq pH \leq 2$, the natural pH, and $pH = 9 \pm 0.5$, and the results were used as comparators to the full-range testing conducted on the composite samples. Example results are provided in Figure 4-14 and Figure 4-15 for major and trace constituents, respectively. The complete set of testing results are presented in Appendix D.2.

The data in these figures indicate the extent of agreement between individual split spoon data (individual points) and EPA 1313 testing of composites (continuous lines). The variability in leaching properties within a borehole (individual split spoons) is consistent with the laboratory and field extraction variability discussed above regarding variability of extraction tests within a borehole. The variability between composites and individual samples for trace constituents is dominated by the variability of composition for these constituents within the individual grab samples. When analyses approach quantitation limits (e.g., for trace constituents or LSP curves near the LLOQ), the variability is likely attributed to the measurement uncertainty.

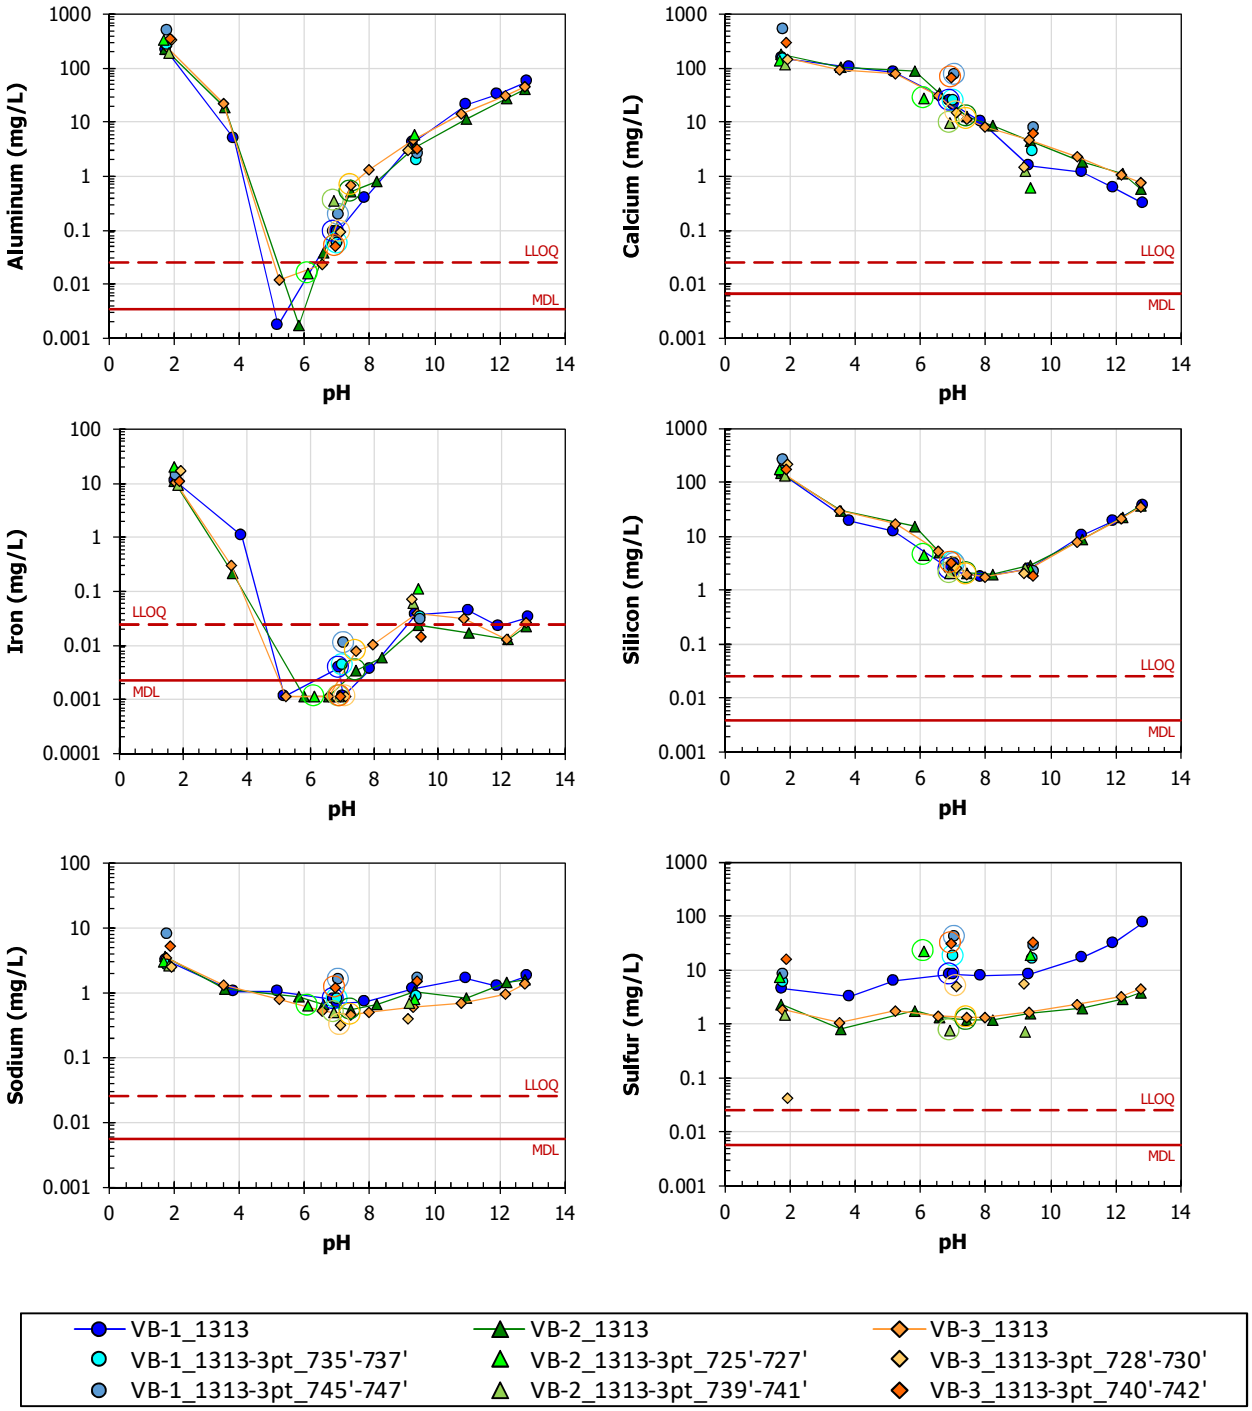

Figure 4-14
Comparison of pH-dependent leaching data for major constituents using individual split spoon samples (3-pt EPA 1313) and borehole composite materials (EPA 1313)

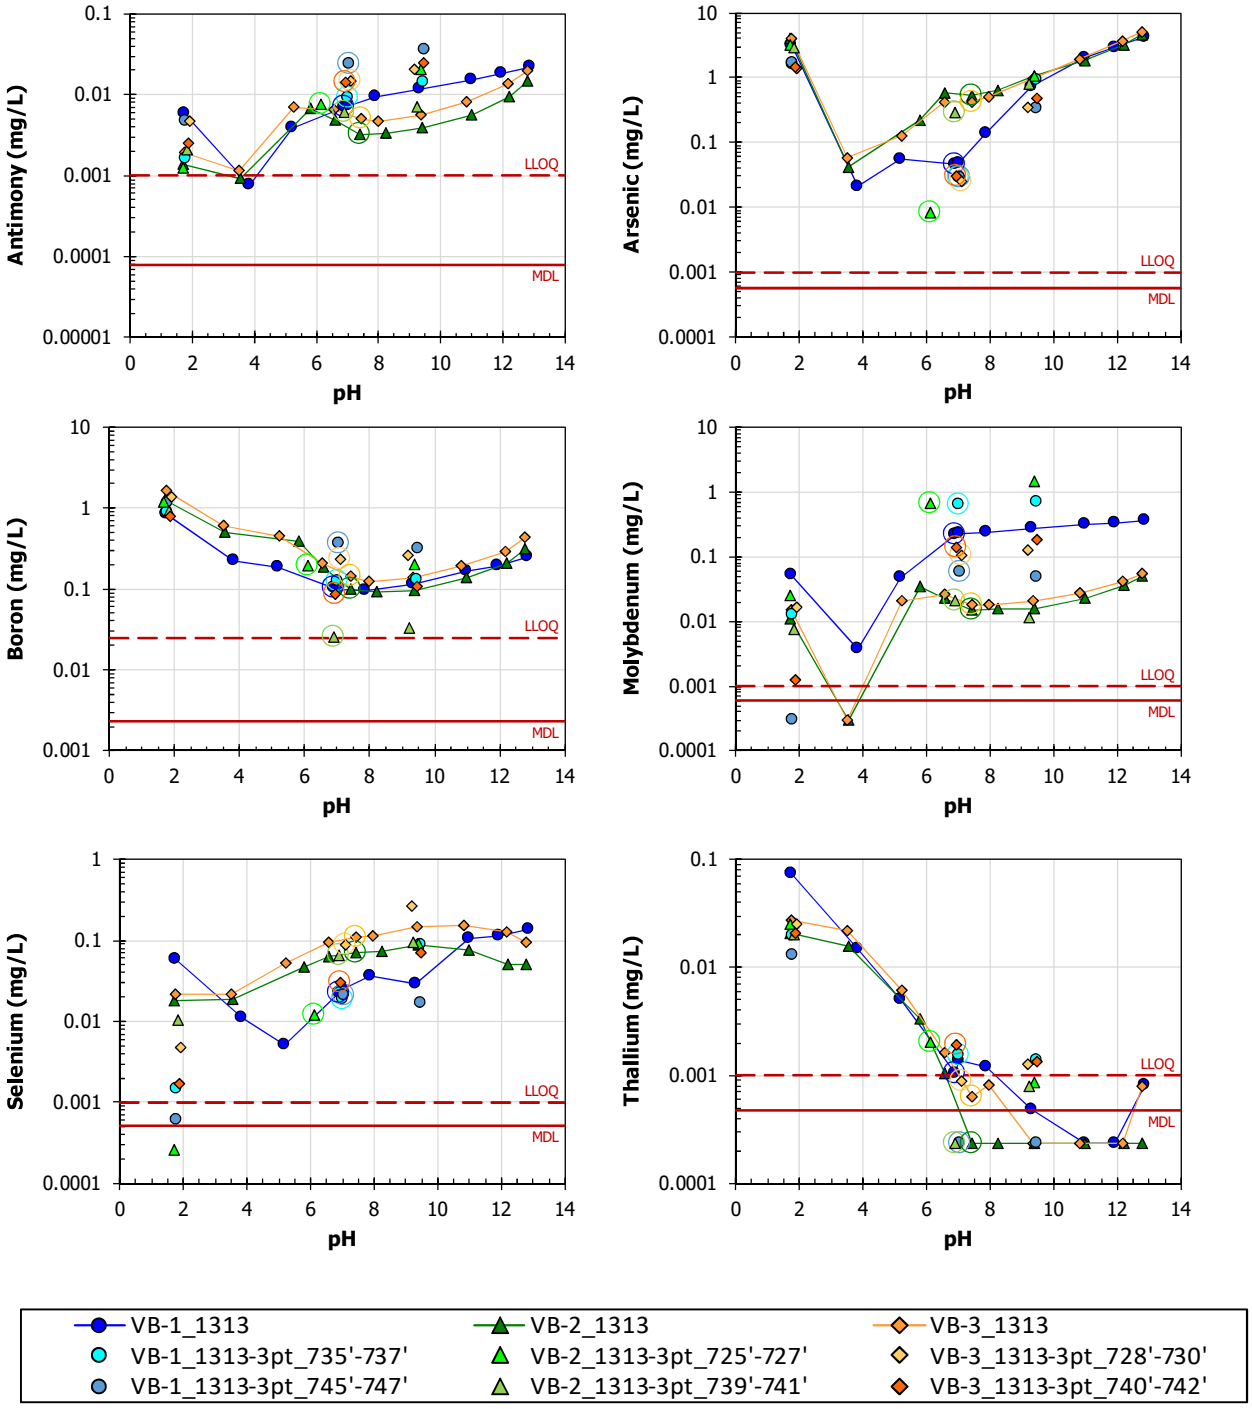

Figure 4-15
Comparison of pH-dependent leaching data for trace constituents using individual split spoon samples (3-pt EPA 1313) and borehole composite materials (EPA 1313)

L/S-Dependent Leaching Test Results

When conducted at low flow rate, the results of column tests (e.g., EPA 1314) indicate how the LSP of constituents changes as the cumulative L/S (i.e., the total amount of water passing through a column to the mass of solid in the column) increases. As soluble minerals dissolve and constituents are eluted from the material, different minerals control the release of constituents and the ionic strength of the eluate changes. In scenarios where L/S can be related to the rate of infiltration, column test data can provide an estimate of leaching concentration as a function of time (Garrabrants et al., 2019a; b).

Examples of typical L/S-dependent behavior from EPA 1314 conducted on the VB-1 composite are shown in Figure 4-16. In this figure, eluate concentration (mg/L) is presented in the left column while mass release (mg/kg-dry), determined by the accumulated interval mass released up through a cumulative L/S value, is shown in the right column. Interval mass release is calculated by multiplying the eluate concentration by the associated interval L/S value. In mass release graphs, the gray dashed line indicates the mass release proportional to the cumulative L/S expected if concentration is controlled by constant solubility.

- The eluate concentrations for Ba (Figure 4-16, top) are constant as a function of L/S and, thus, the mass release is proportional to the cumulative L/S and the mass release curve follows the solubility indicator line. This L/S-dependent behavior is consistent with a constituent that has solubility-controlled LSP. In the composites, As, F^-, Li, Sb, and V show the similar solubility-controlled LSP based on EPA 1314 data as Ba.
- For many constituents in the composite samples (Cd, Co, Cr, Ni, Se, Tl, and Zn), the L/S-dependent leaching data indicated that the constituent is quickly depleted from the matrix. For Tl (Figure 4-16, middle), the eluate concentration is a strong function of L/S but drops below the MDL when L/S increases beyond approximately L/S=3 L/kg-dry. This behavior is characteristic when the available content has been depleted.
- The L/S-dependent leaching of Cl^- (Figure 4-16, bottom) is an example of rapid release of a soluble fraction of the available content without depletion. This differs from the example behavior of Cd in that, after an initial "wash off" of a highly soluble fraction, leaching concentrations are detectable and relatively constant, suggesting a solubility-controlled fraction. Similar behavior was observed for B, Ca, Mo, and SO_4^{-2} in composite samples.
- Elements where EPA 1314 eluate concentrations were not detected include Be, Br^-, Cu, Fe, and Pb.

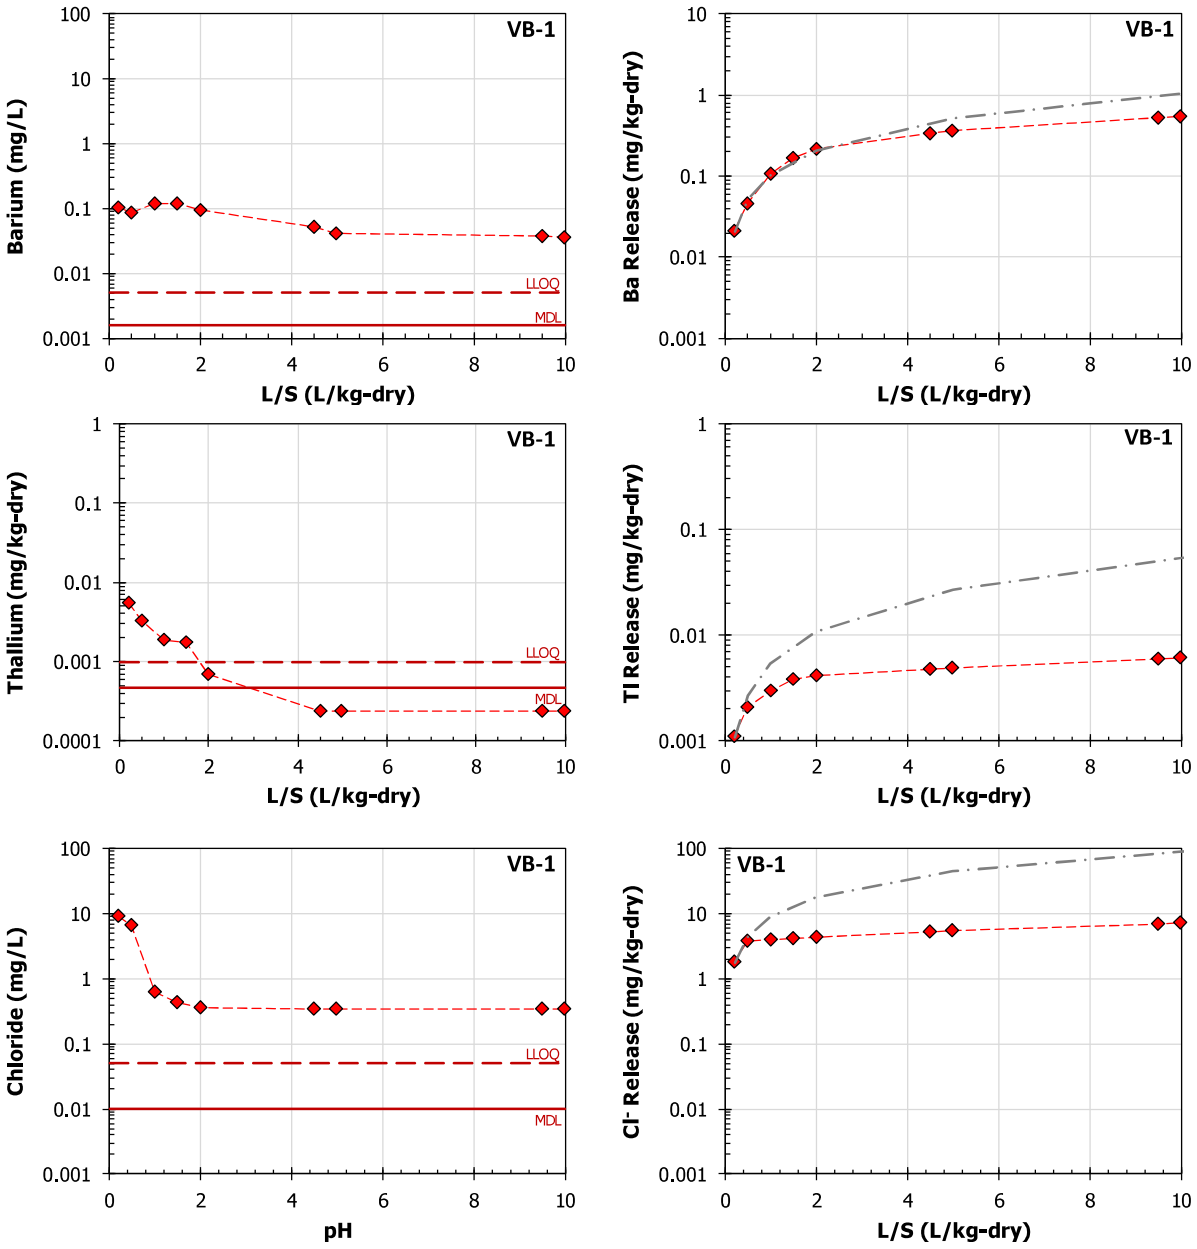

Figure 4-16
Example EPA 1314 test results from VB-1, showing a solubility-controlled constituent (barium), depletion of the available content (thallium), and wash-off of a soluble constituent fraction without depletion (chloride)

Traditional Extraction Test Results

The calculated L/S and measured pH from the extractions using the traditional leaching tests (TCLP, SPLP, and ASTM) are presented in Table 4-9.

Table 4-9
Liquid-to-Solid Ratio and Measured Extraction pH for Traditional Leaching Tests

Material	TCLP		SPLP		ASTM	
	L/S (mL/g-dry)	pH	L/S (mL/g-dry)	pH	L/S (mL/g-dry)	pH
VB-1	22.9	4.99	22.9	6.39	27.3	6.71
VB-2	22.1	5.00	22.1	6.89	28.1	7.27
VB-3	23.2	4.95	23.2	6.94	26.9	7.17

The amount of extraction fluid for ASTM is determined as the mass of the "as received" test material in grams divided by the test-specific L/S of 20 mL/g. The resultant L/S on a dry basis is greater than 20 because of the water inherent in the pores of the "as received" material. The procedures for TCLP and SPLP require a pressure filtration preconditioning of the test sample to remove excess liquid, which is analyzed separately. The extraction fluid is based on the mass of pressure-filtered solid material in grams divided by the same L/S of 20 mL/g. Therefore, the calculated L/S for TCLP and SPLP is lower than the L/S for the ASTM test that includes extra water.

The measured pH for ASTM, which uses DIW as an extraction fluid, is consistent with the natural pH (1313) and own pH (1313_L/S1) of the composites at VB-1, VB-2, and VB-3 reported in Table 4-6. The slight decrease in ASTM extraction pH compared to the natural pH (e.g., VB-1 pH_{ASTM}=6.71 versus pH_{Nat}= 6.91) may be attributed to the higher ASTM extraction L/S. For SPLP, the measured pH is slightly lower than the ASTM pH, consistent with the small amount of acid used in the extraction fluid. The stability of the measured pH for TCLP extracts across different composites reflects the buffering provided by the organic acetic acid.

The eluate constituent concentrations for TCLP, SPLP, and ASTM tests are presented in Table 4-10, Table 4-11, and Table 4-12, respectively. Since pH is an important factor for solubility-controlled LSP, these tables also include the final eluate pH. Recording of eluate pH allows for comparison of the results of these traditional tests to the pH- and L/S-dependent LEAF test results. In general, SPLP and ASTM concentrations were comparable to each other but were lower than TCLP concentrations due to the lower pH of TCLP eluates. Exceptions for this site (which may not be generalizable) include As, Mo, and SO_4^{-2}, where similar concentrations were measured in all three procedures, and PO_4^{-2}, Se, and V, where SPLP and ASTM eluates had higher concentration than TCLP eluates. All of these observations are consistent with the pH-dependent LSP curves discussed above.

Comparison of Traditional and LEAF Test Results

When the pH and L/S of leaching tests are recorded, the test results from different leaching tests can be compared based on pH- or L/S-dependence. An example comparison is shown in Figure 4-17 for SO_4^{-2} leaching from the VB-1 composite. Similar comparisons for all constituents are presented in Appendix E.

Figure 4-17 presents data as a function of pH on the left and as a function of L/S on the right. For a constituent with available content-limited LSP, for example sulfate, the traditional leaching test data are consistent with LEAF test results considering the shift in pH (TCLP) and the higher L/S for the traditional tests.

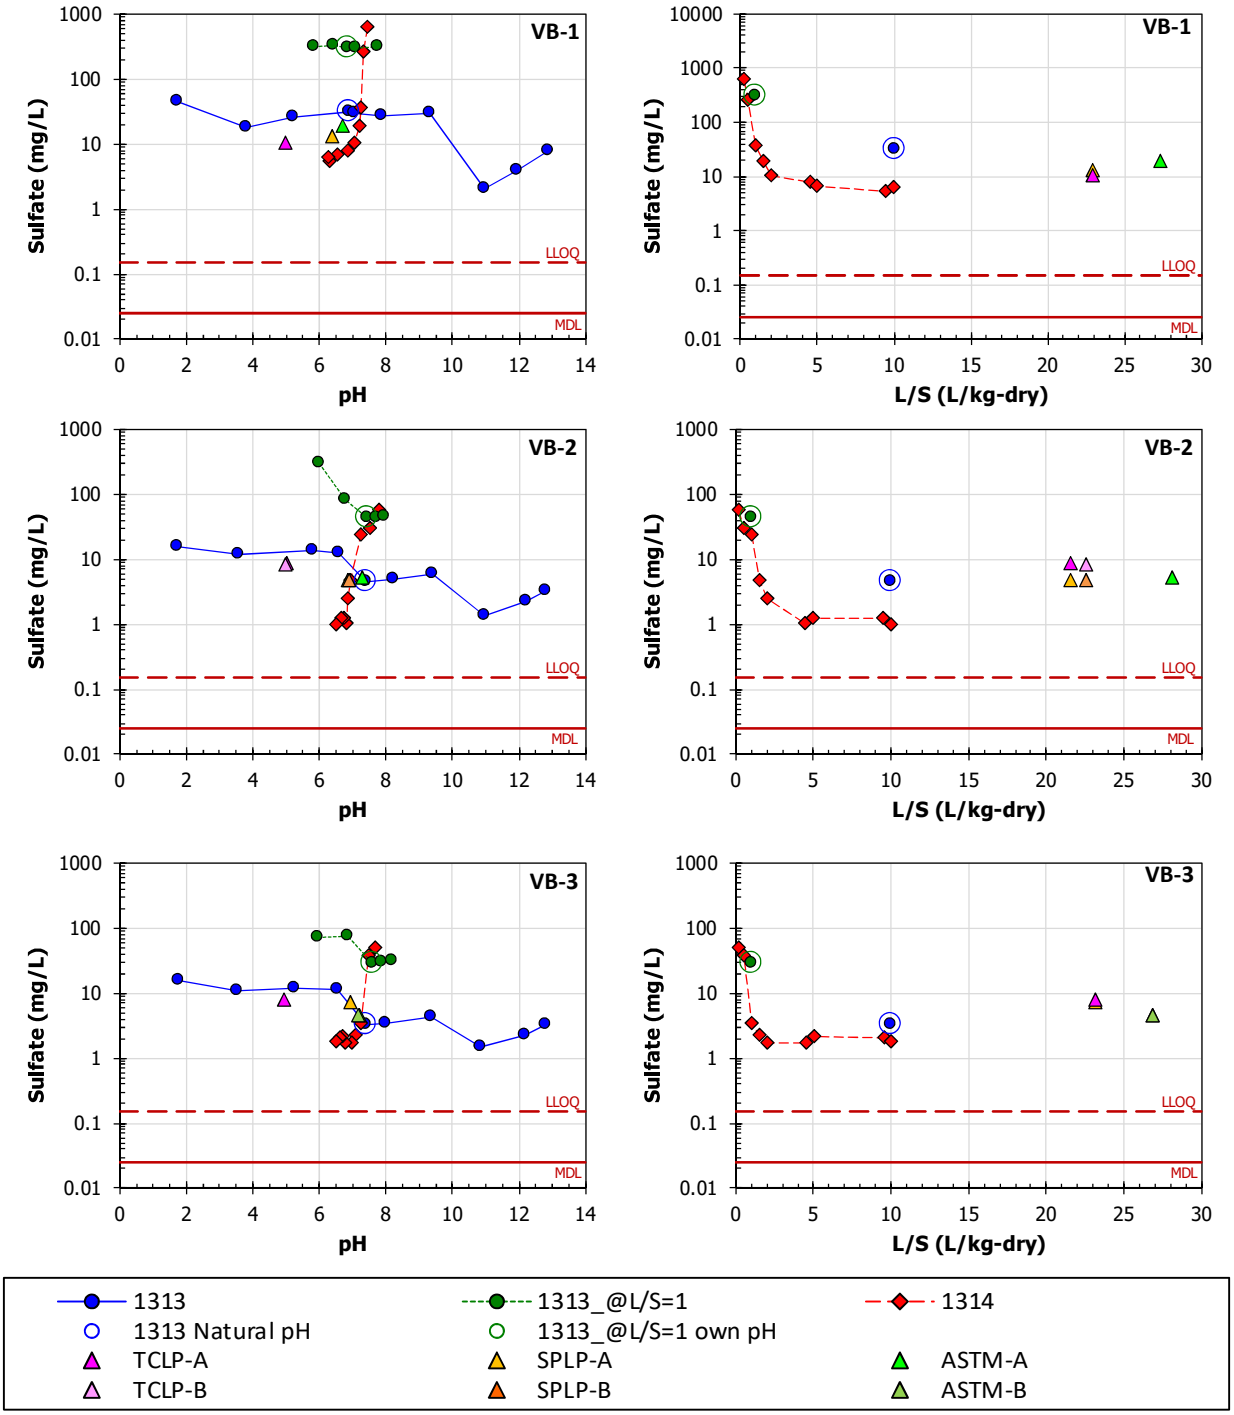

Figure 4-17
Comparison of sulfate concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

Groundwater, Porewater, and Subsurface Gas Monitoring

Measured field parameters for groundwater and porewater sampling as well as graphical presentation of groundwater and porewater concentrations are provided in Appendix F.1. These data represent the sampling period from September 2018 through September 2019.

Groundwater and Porewater Field Parameters

Plots of field measurements are shown in Figure 4-18 and Figure 4-19. Within each bar chart, data for groundwater sampled at the upgradient well (AD1) and downgradient well (6AR) are shown in light and dark gray, respectively, while data for porewater from the PAPs (VB-1, VB-2, and VB-3) are shown as blue, green, and gold bars, respectively.

The data in Figure 4-18 show that the water table elevation, pH, and electrical conductivity remain relatively constant over time at each sample point. No samples were collected in November due to a scheduling conflict. The mean water table at the upgradient well (773.4 ft AMSL) is approximately 30 feet higher in elevation than the mean water table of the three PAPs (741.6 ft AMSL) or the mean water table at the downgradient well (738.5 ft AMSL). The pH of the groundwater at the upgradient well is somewhat more alkaline ($pH_{ave\text{-}AD1}$=8.6±0.2) than the porewater in the PAPs ($pH_{ave\text{-}VB\text{-}1}$=8.1±0.1, $pH_{ave\text{-}VB\text{-}2}$=7.8±0.5, $pH_{ave\text{-}VB\text{-}3}$=7.7±0.4) and considerably more alkaline than in the downgradient well ($pH_{ave\text{-}6AR}$=4.8±0.1).

Figure 4-19 presents measured values of water temperature, ORP, and DO. Of these, water temperature and ORP show a seasonal trend. The decrease in ORP in the late summer and fall months may indicate an increase in biological activity. Although there is significant variability in the measured value, the mean dissolved oxygen in the downgradient well ($DO_{ave\text{-}6AR}$=1.0±0.5 mg/L) is somewhat lower than in the PAPs ($DO_{ave\text{-}VB\text{-}1}$=1.4±0.7 mg/L, $DO_{ave\text{-}VB\text{-}2}$=1.4±0.4 mg/L, $DO_{ave\text{-}VB\text{-}3}$=1.7±0.3 mg/L) and notably lower than in the upgradient well ($DO_{ave\text{-}AD1}$=2.6±0.5 mg/L). The expected value for dissolved oxygen at equilibrium with atmospheric oxygen at a temperature of 20 ºC is approximately 9.1 mg/L (USGS, 1998).

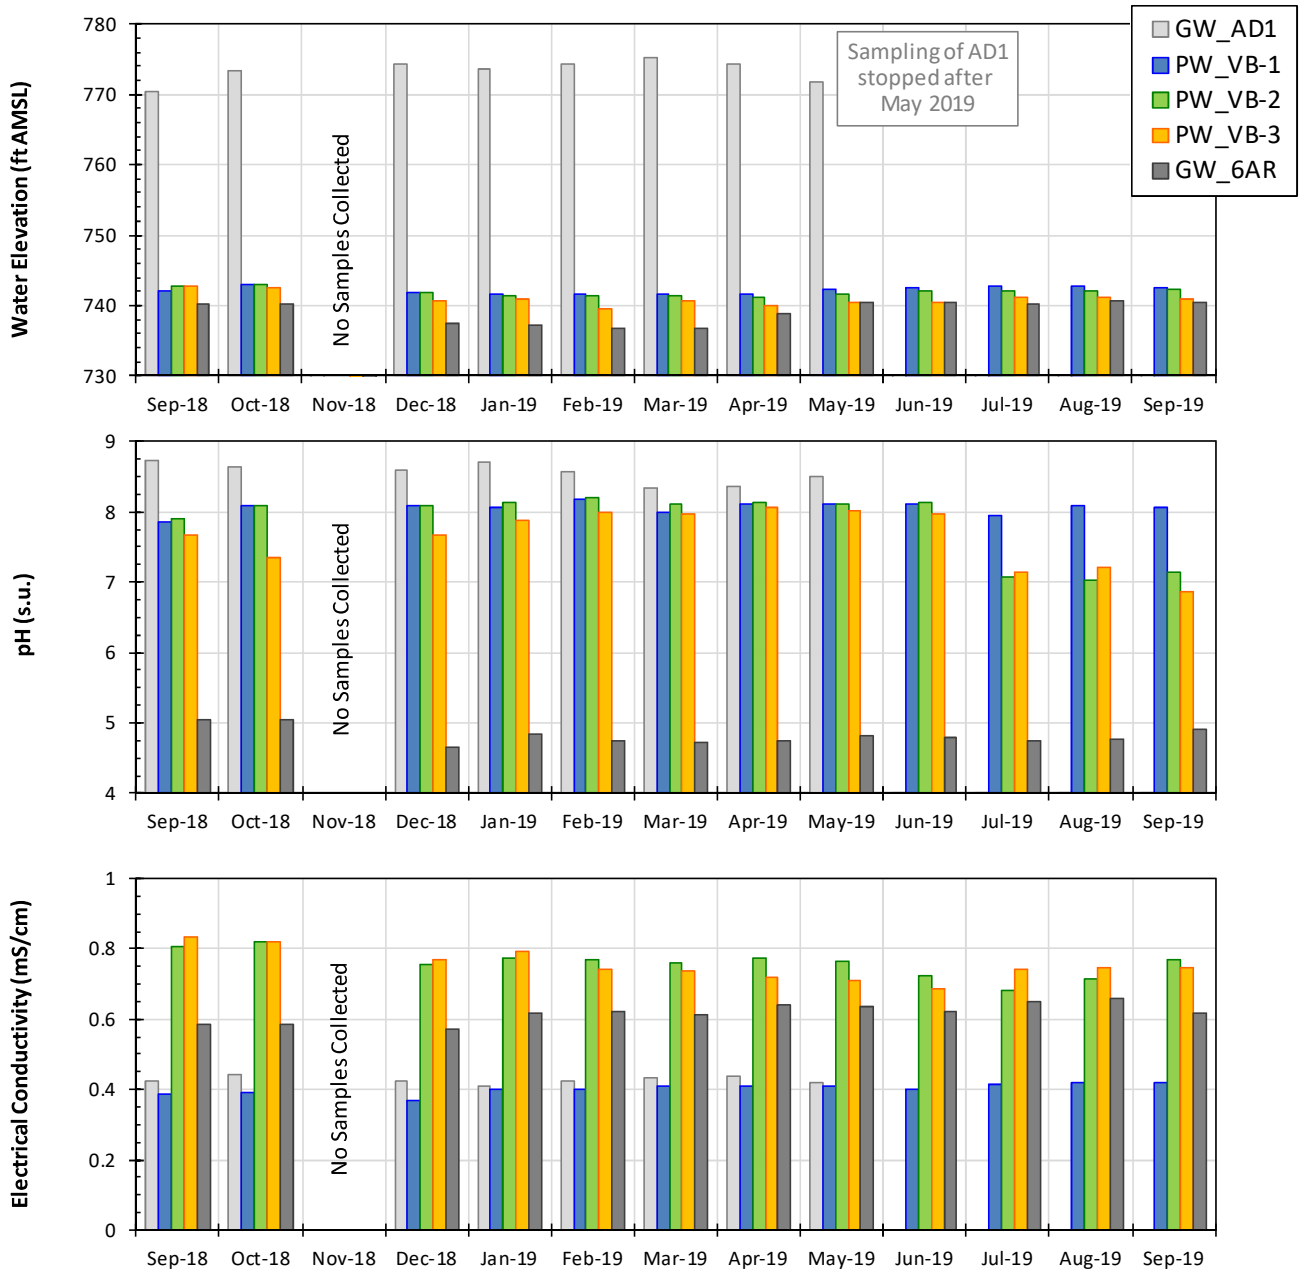

Figure 4-18
Groundwater and porewater field parameters from monthly sampling (elevation, pH, and EC)

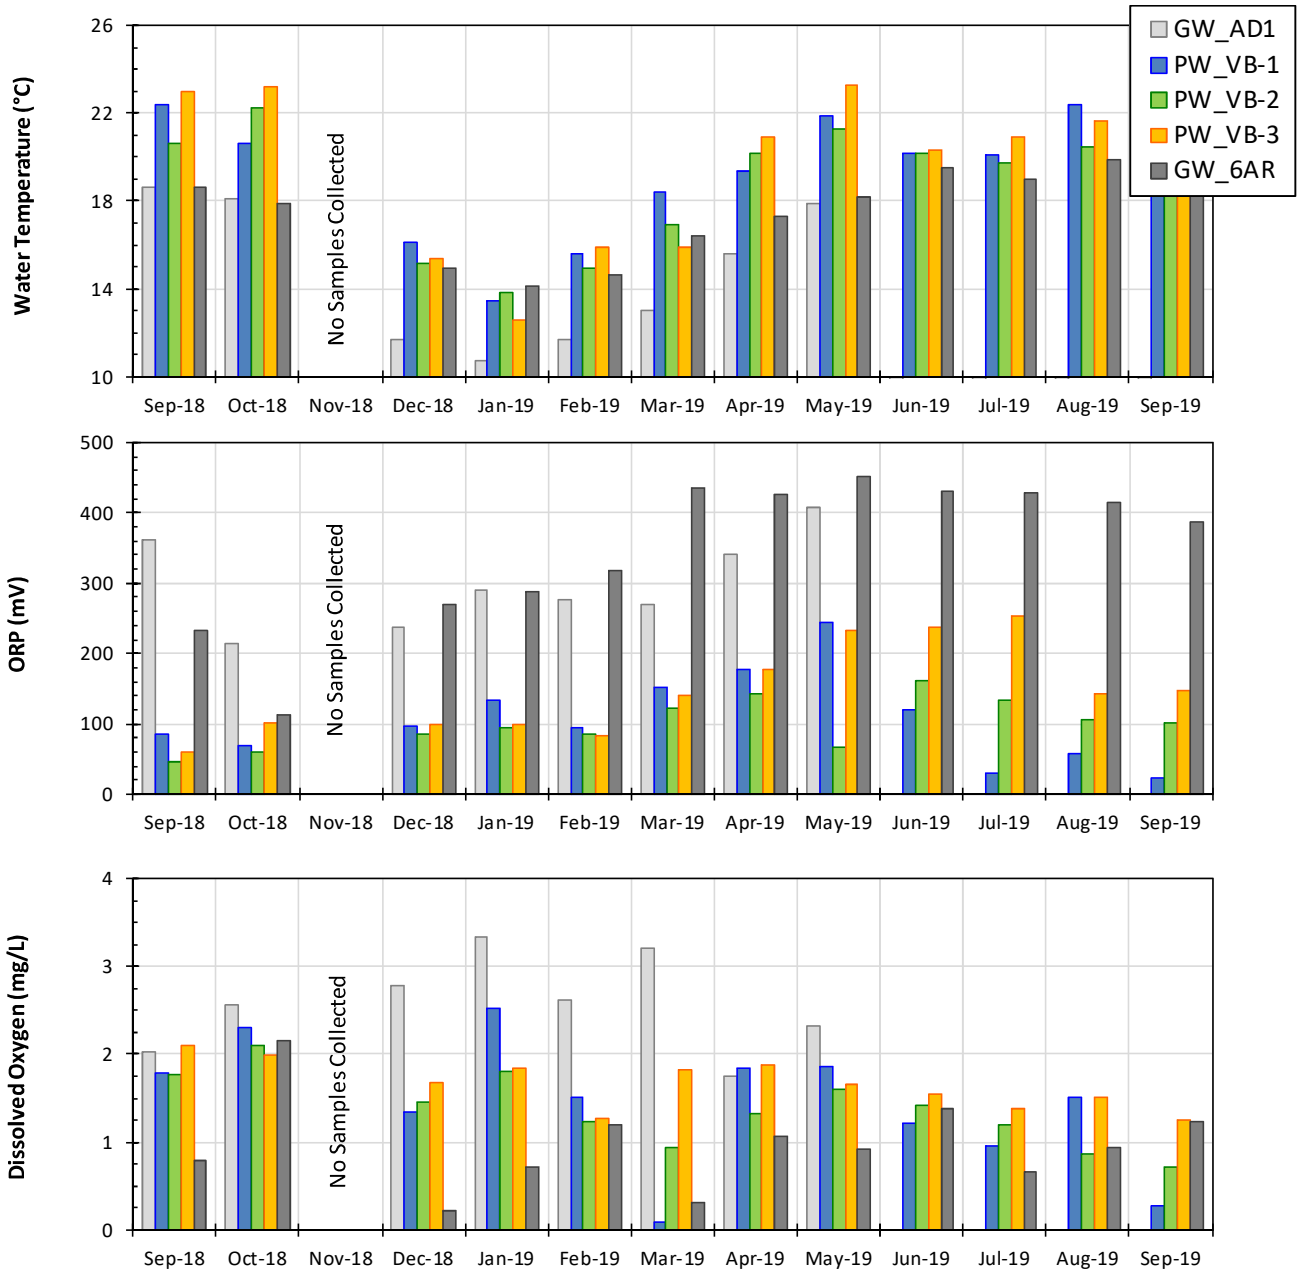

Figure 4-19
Groundwater and porewater field parameters from monthly sampling (temperature, ORP, and DO)

Concentrations in Groundwater and Porewater

Monthly analysis of groundwater wells and PAPs focused on 22 constituents, including 17 from 40 CFR 257 (As, B, Ba, Be, Ca, Cd, Cl^-, Co, Cr, F^-, Li, Mo, Pb, Sb, Se, SO_4^{-2} and Tl). Five additional constituents that were analyzed were Cu, Fe, Ni, V, and Zn. Examples of the results for selected constituents are presented in Figure 4-20 and Figure 4-21, while the graphical results for all 22 constituents are presented after the field parameter data tables in Appendix F.1.

Overall, concentrations in the downgradient groundwater well at 6AR are relatively low. A comprehensive review of impacts to groundwater based on one downgradient well (6AR) and one upgradient well (AD1) is not sufficiently robust to determine with confidence whether or not the groundwater quality at 6AR represents a release from the closed impoundment. Therefore, the discussion that follows allows for either possibility as the relationship between porewater and downgradient groundwater is explored. Table 4-13 groups the observed concentrations from monthly analysis to express the relationships between groundwater across the site (6AR vs. AD1) and porewater concentrations relative to downgradient groundwater (PAPs vs. 6AR). Of the 22 constituents analyzed, Pb, Sb, Tl, and V are not included in the table because the concentrations of these constituents were below the MDL in both porewater and groundwater.

Table 4-13
Relationships Between Upgradient Groundwater (AD1), Downgradient Groundwater (6AR), and Porewater at PAPs (VB-1, VB-2, and VB-3)

	Downgradient > Upgradient	Downgradient ≤ Upgradient
Porewater < Downgradient	Be**, Cd, Cr, Co, Fe,Ni, Se**, SO_4^{-2}, Zn	none
Porewater > Downgradient	B, Ca, Cl^-, Li	As*, Ba, Cu*, F^-, Mo*

Notes
* Indicates that groundwater concentrations mostly below the MDL
** Indicates that porewater concentrations all below the MDL

The following are observations from this review.

- Nine constituents (Be, Cd, Cr, Co, Fe, Ni, Se, SO_4^{-2}, and Zn) have higher concentrations in the downgradient monitoring well than in the upgradient background well, suggesting that there is a source for these constituents affecting the downgradient groundwater. However, these nine constituents also have higher concentrations in the downgradient well than in the porewater (e.g., Cd, Co, and Se in Figure 4-20), suggesting that porewater from the dewatered impoundment is not the primary source of the observed downgradient groundwater concentration. These observations suggest limited relationship between the recent porewater concentration and the downgradient groundwater concentrations at this site.
- Five constituents (As, Ba, Cu, F^-, and Mo) have higher concentration in porewater than in the downgradient monitoring well, suggesting that porewater has the potential to affect downgradient groundwater quality. However, the downgradient monitoring well has a concentration that is similar to or lower than concentrations in the upgradient monitoring well (e.g., As and F^- in Figure 4-21), indicating no change in groundwater quality for these constituents. Furthermore, porewater concentrations for As, F^-, and Mo are orders-of-magnitude higher than in the upgradient monitoring well, yet there is no increase in downgradient concentration relative to the upgradient well. These data suggest limited relationship between porewater and downgradient concentrations at this site.
- Four constituents (B, Ca, Cl^-, Li) have higher concentration in porewater than in downgradient groundwater, and higher concentrations in downgradient groundwater than in upgradient groundwater (e.g., B in Figure 4-21), suggesting a possible relationship between

the concentration in the ash deposit porewater and the concentration of groundwater in the downgradient well for these constituents. Furthermore, all four of these constituents may be considered indicators of coal ash leachate, but only B and Cl^- can be considered reasonably non-interacting with materials underlying the ash deposit.

The overall temporal means of porewater concentrations for B and Cl^- were calculated and compared to the difference in the temporal means of groundwater concentrations (i.e., temporal mean at 6AR minus temporal mean at AD1). If porewater concentrations can be used as an indicator of downgradient groundwater concentrations, this ratio should be similar between constituents. At VB-2, the closest PAP to the downgradient well at 6AR,[2] the ratios for B and Cl^- were both 2.8, indicating a potential relationship. In contrast, the same ratio for Ca was lower (1.4), while the ratio for Li was significantly higher (12). Increased Ca in the downgradient groundwater monitoring well relative to the upgradient well may be a consequence of the change in groundwater pH from ca. 8.5 to 4.5 and equilibrium with aquifer solids and/or influence from the ash porewater in conjunction with cation exchange and sorption within the aquifer. Similarly, increased Li concentrations may be a result of the change in groundwater pH or other influences, as well as uncertainty because the lithium concentrations in downgradient groundwater are near, and in some samples below, analytical method quantitation limits.

Overall, these observations indicate that porewater concentrations are unreliable as an indicator of whether or not a constituent will have an elevated downgradient concentration relative to upgradient groundwater. B and Cl^- are considered conservative ions, and the similar ratios suggest that these constituents can be tracers for evaluation of porewater migration into groundwater. However, porewater concentrations are not predictors of future groundwater concentrations because of the potential for rapid attenuation in proximity to the boundary of the disposal unit.

[2] These ratios do not vary significantly if all three PAPs are averaged.

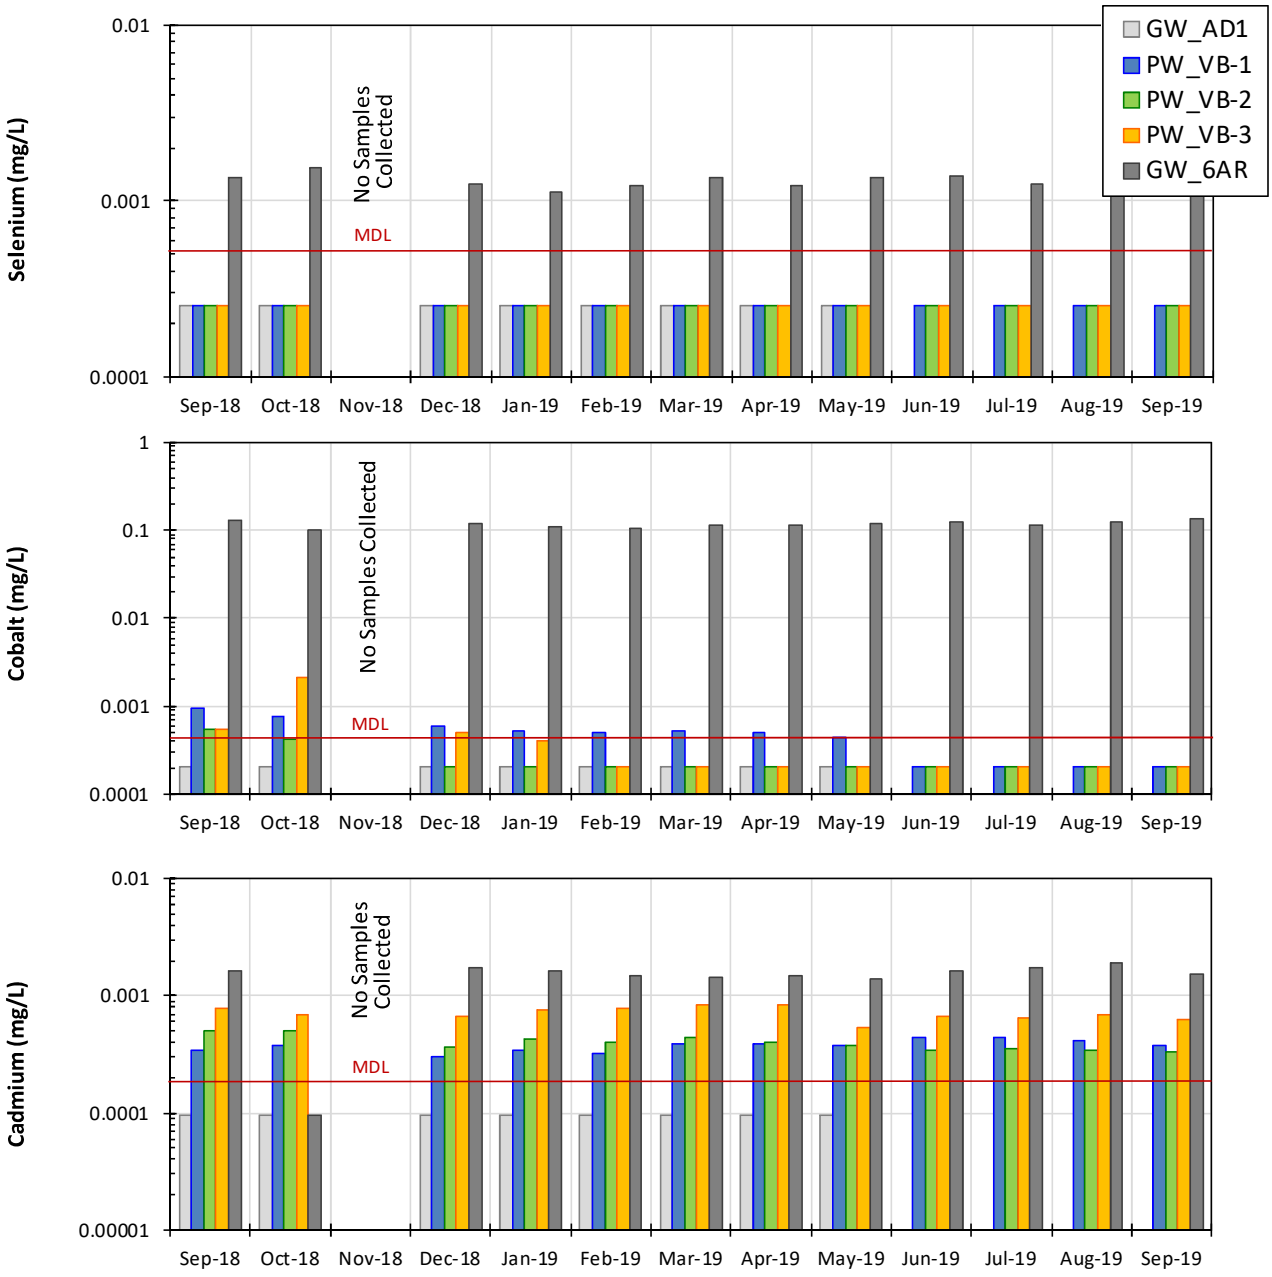

Figure 4-20
Groundwater and porewater monitoring from monthly sampling showing lower concentrations in ash deposit porewater (VB-1, VB-2, and VB-3) than in downgradient groundwater (6AR) (monitoring at AD1 was discontinued after May 2019)

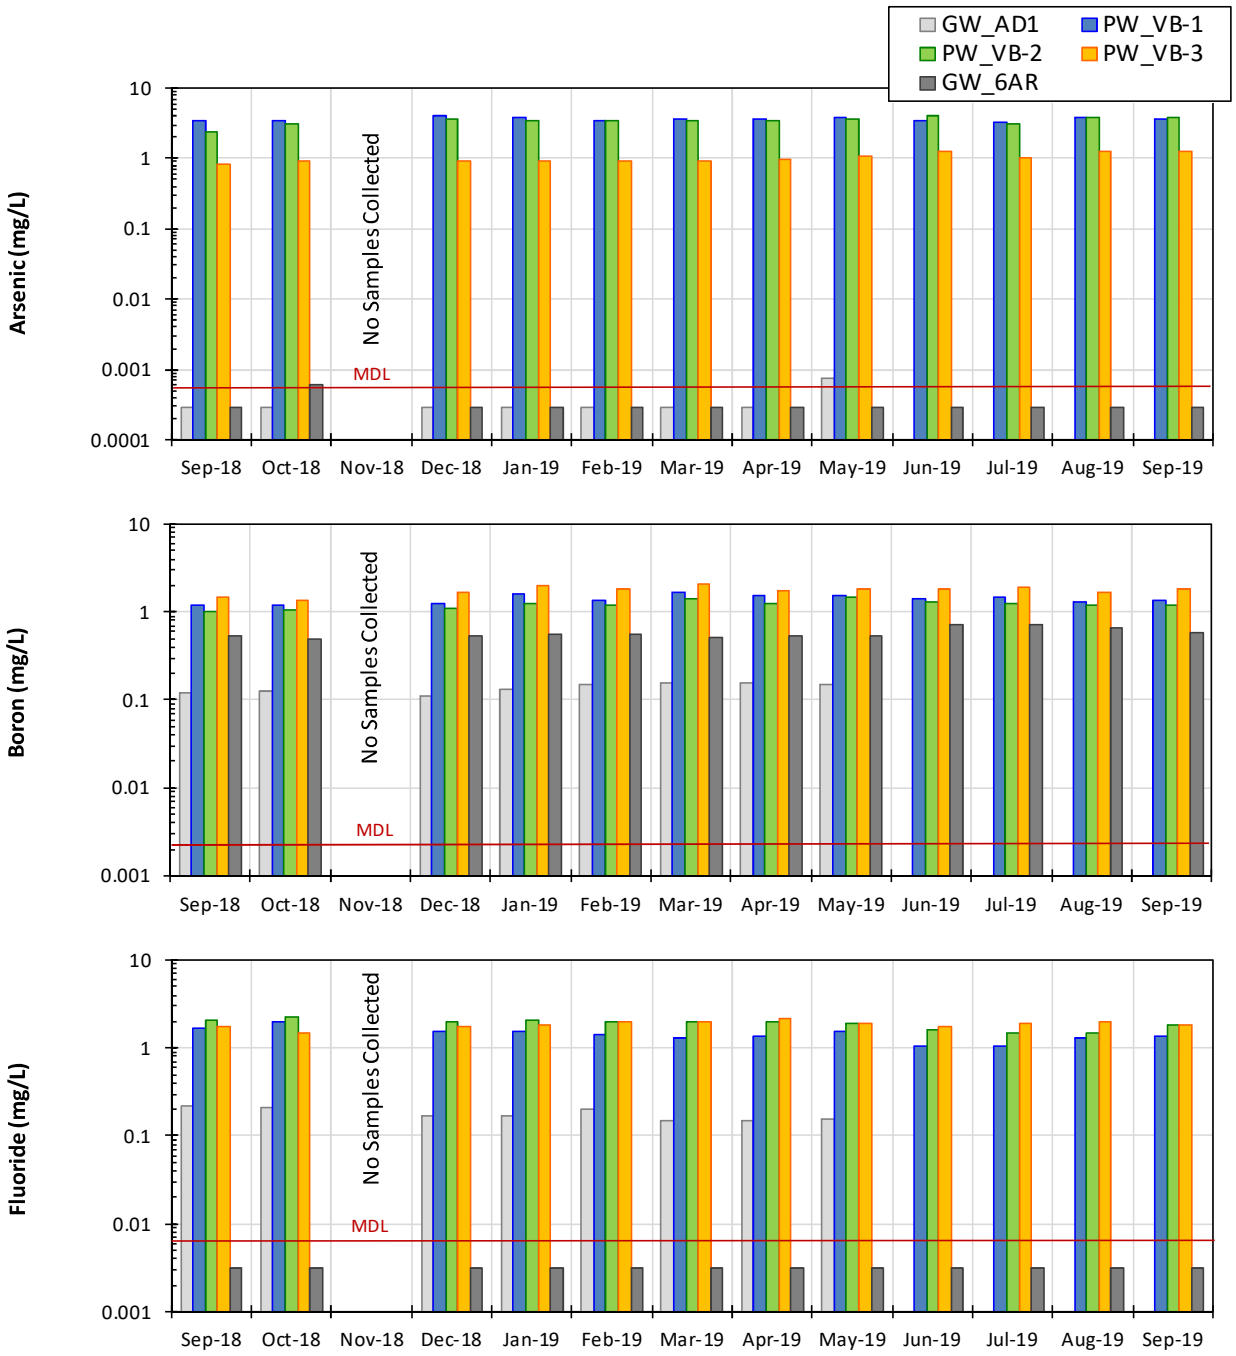

Figure 4-21
Groundwater and porewater monitoring from monthly sampling showing relatively higher concentrations in ash deposit porewater (VB-1, VB-2, and VB-3) than in groundwater (AD1 and 6AR) (monitoring at AD1 was discontinued after May 2019)

Variability in Porewater Concentrations

The temporal variability data for porewater parameters from monthly monitoring are presented as time-series plots as a function of date. The shapes of the time series show which porewater properties are relatively constant over the 13 months of sampling and which samples vary with

time. Time-series graphs for porewater parameters and constituents are presented in Appendix F.2. Examples of parameters showing temporal variability are presented in Figure 4-22 and Figure 4-23. In these figures, variability may be preliminarily attributed to one or more of several factors including (i) seasonal changes (e.g., temperature, redox conditions as seen by pH+pE; Figure 4-22), (ii) groundwater level changes due to infiltration and river intrusion (e.g., porewater level, decrease in pH of VB-2 and VB-3 during late summer 2019; Figure 4-22), and (iii) changing conditions shortly after closure of the impoundment (e.g., variability in cobalt, copper, iron, nickel, and zinc in VB-3 porewater during the summer of 2018; Appendix F.2). In comparison, many parameters remain relatively constant throughout this brief monitoring period (e.g., As, B, and Mo; Figure 4-23).

Concentrations from a PAP were deemed higher than other PAPs if consistently higher by a factor of 3 to 5 or more during all sample events. Overall, there was no pattern to spatial variability that applied to all monitored constituents, and concentrations between PAPs were usually within a factor of 10. However, there were patterns that were evident by element as listed below:

- No variability, all non-detect: Sb, Be, Pb, Se, Tl, V
- Little variability between PAPs: Ba, B, Ca, Cl, Cr, Co, Cu, F^-
- VB-1 and VB-2 consistently higher than VB-3: As, Li
- VB-3 consistently higher than VB-1 and VB-2: Cd, Fe, Mo, Ni, Zn
- VB-2 and VB-3 consistently higher than VB-1: SO_4

Subsurface Gas Monitoring

The O_2, CO_2, CH_4, NH_4, and H_2S concentrations were measured in the three GAPs as presented in Figure 4-24 and Figure 4-25. Full tabular data for subsurface monitoring are presented along with graphical comparisons in Appendix F.3. Oxygen levels in the closed impoundment have been typically much less than in air, while CO_2 and CH_4 concentrations are often greater than the calibration limit of 5%. The concentrations of NH_4 and H_2S are sporadic but indicate elevated

concentrations up to 5 ppm for NH_4 and 30 ppm for H_2S. In general, these subsurface gas measurements imply a significant amount of biological activity that results in a stronger chemical reducing environment than indicated by the DO and ORP of the porewater samples.

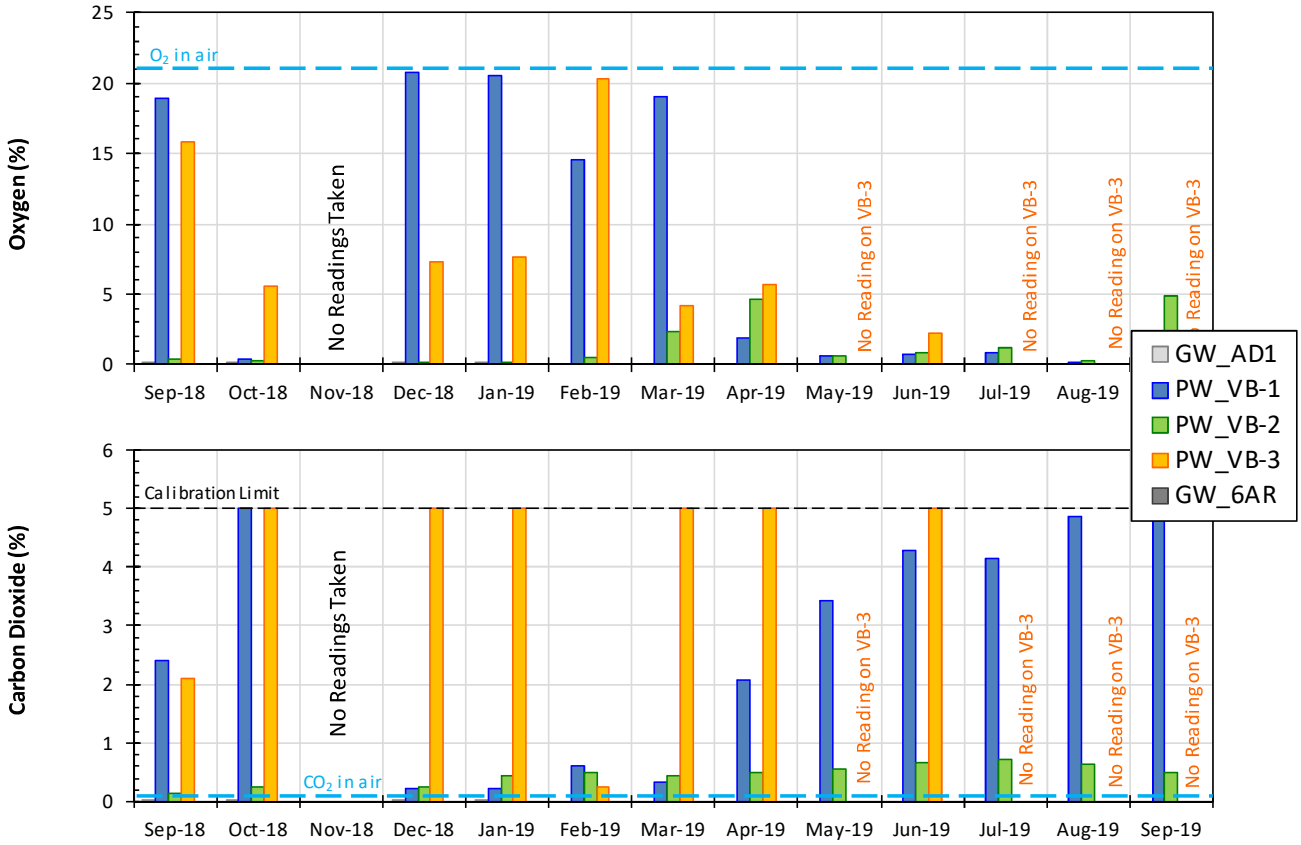

Figure 4-24
Concentration (%) of oxygen (O_2) and carbon dioxide (CO_2) from GAPs (VB-1, VB-2, and VB-3) in the subsurface of the closed ash impoundment

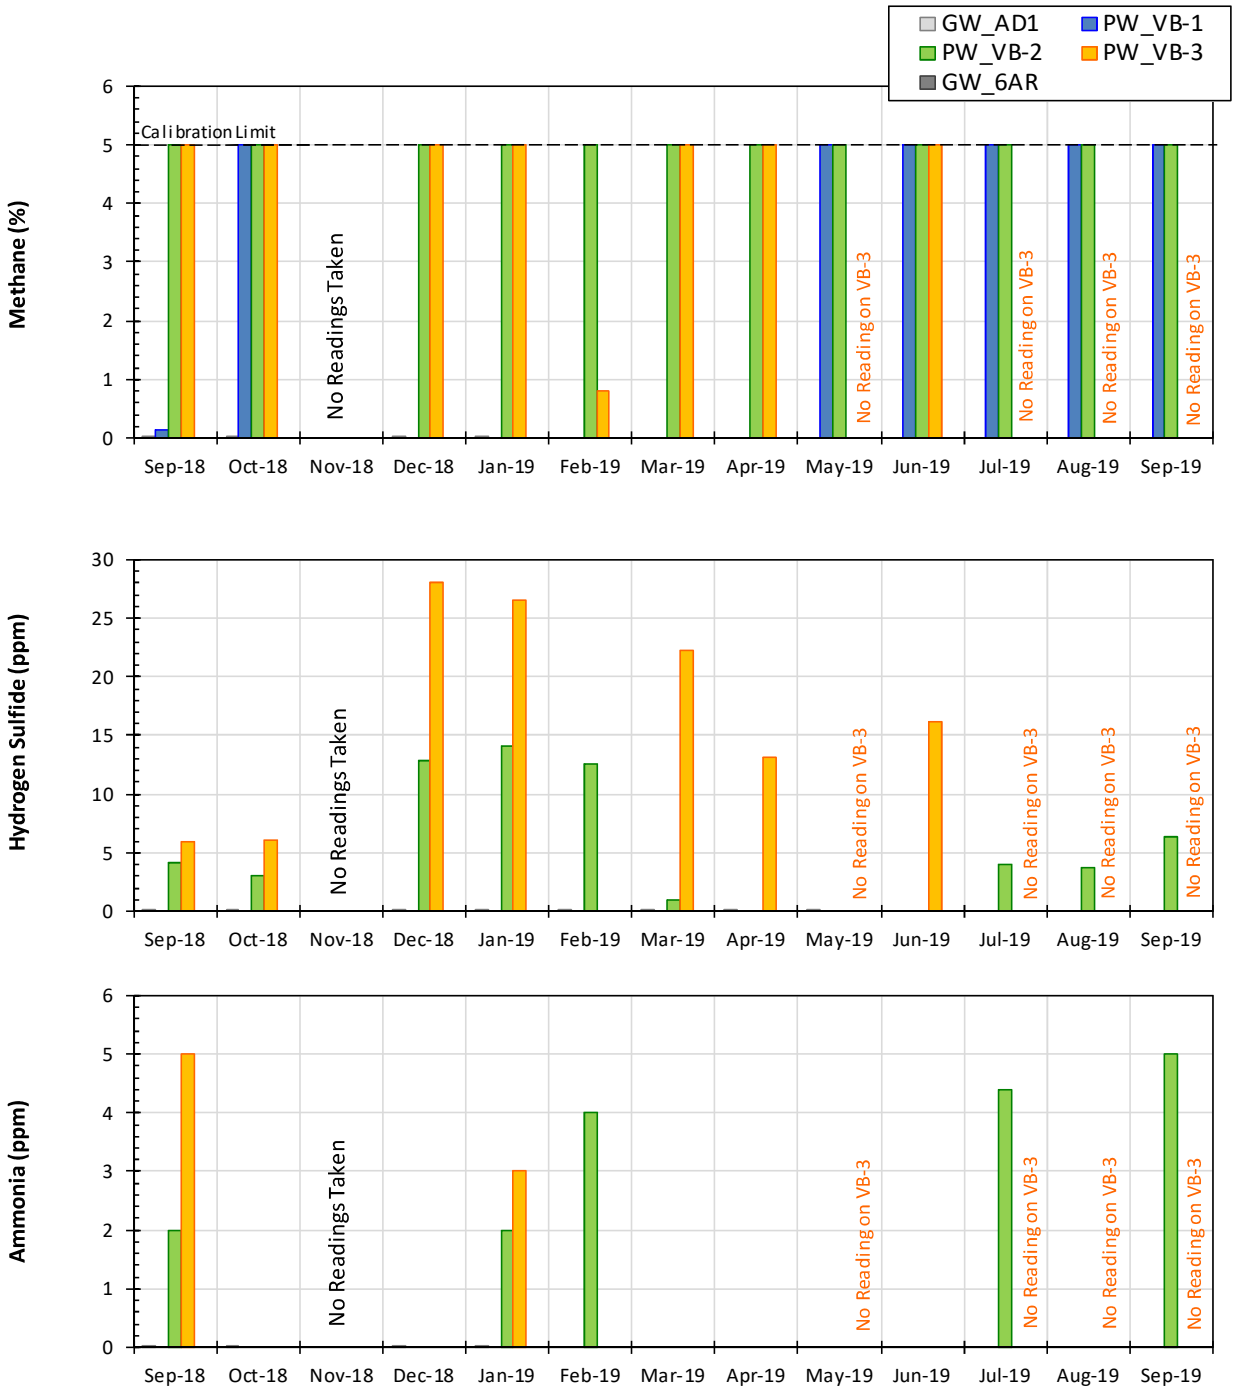

Figure 4-25
Concentrations of methane (CH_4), hydrogen sulfide (H_2S) and ammonia (NH_4) from GAPs (VB-1, VB-2, and VB-3) in the subsurface of the closed ash impoundment

Speciation of Arsenic, Iron, and Selenium Under Low Redox Conditions

At moderately low redox conditions, arsenic release can be associated with loss of HFO sorption sites as Fe(III) is reduced to Fe(II) at a pH+pE value of approximately 7 to 8. At these conditions, there would be a corresponding increase in the concentration of iron (Fe^{2+}) in solution. At lower values of pH+pE, sulfate is reduced to sulfide, and arsenic may be precipitated with sulfidic minerals. At these same redox conditions, biological activity would convert carbon dioxide to methane as observed for VB-2 and VB-3 (see top of Figure 4-25). These processes are consistent with the temporal dissolved arsenic and iron concentrations observed for VB-1, VB-2, and VB-3 (Figure 4-26), where increased dissolved iron in VB-3 was also accompanied with much lower dissolved arsenic concentration (ca. 3.5 vs. 1.0 mg/L) compared to VB-1 and VB-2. Considering the presence of methane, iron reduction appears to have been an intermediary step concurrent with sulfate reduction and methanogenesis, resulting in arsenic precipitation and lower solubility.

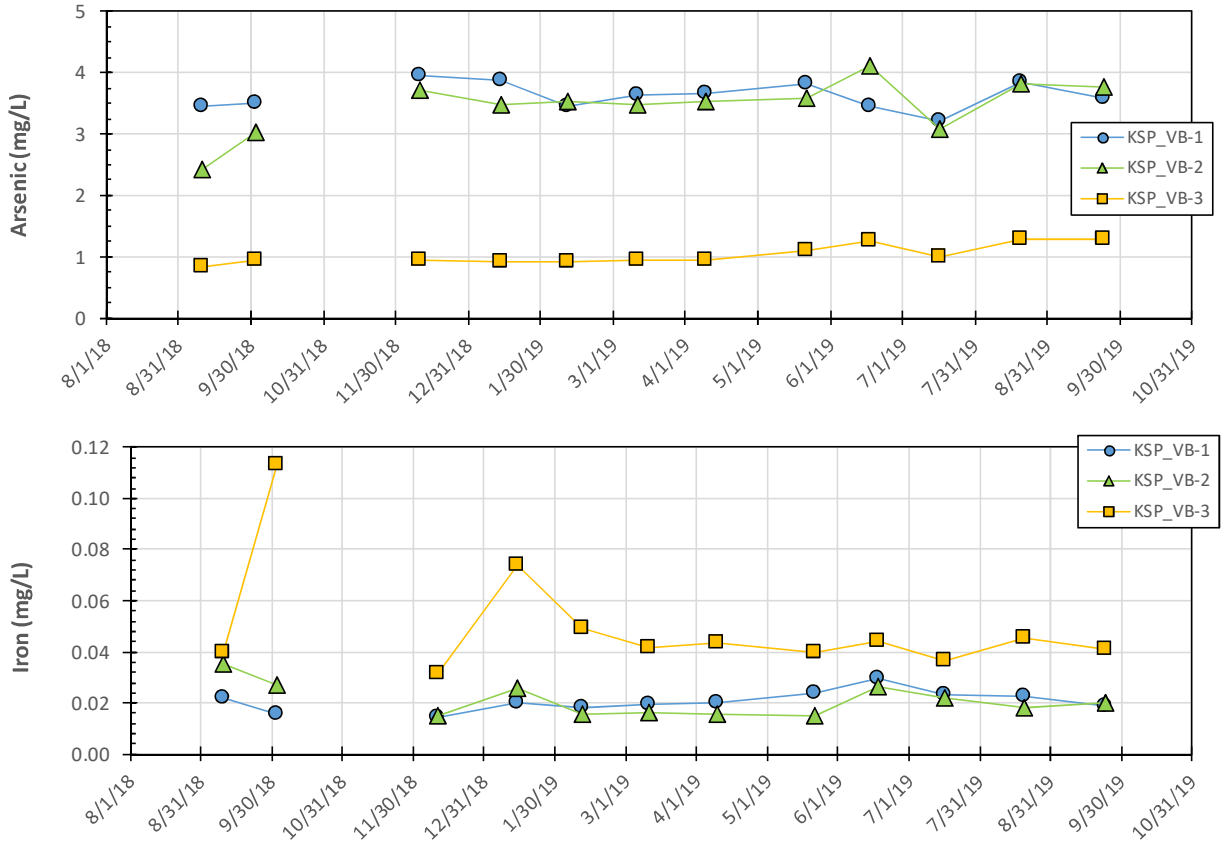

Figure 4-26
Temporal porewater data for arsenic and iron collected at boreholes VB-1, VB-2, and VB-3

Uncertainties in Redox Analysis and Impacts on Porewater Concentrations

Figure 4-27 presents a typical redox ladder for electron donors (e.g., O_2, $Fe(OH)_{3(am,\ s)}$, SO_4^{2-}, $CO_{2(g)}$) and products of biochemical reduction (e.g., CO_2, Fe^{2+}, HS^-, $CH_{4(g)}$).

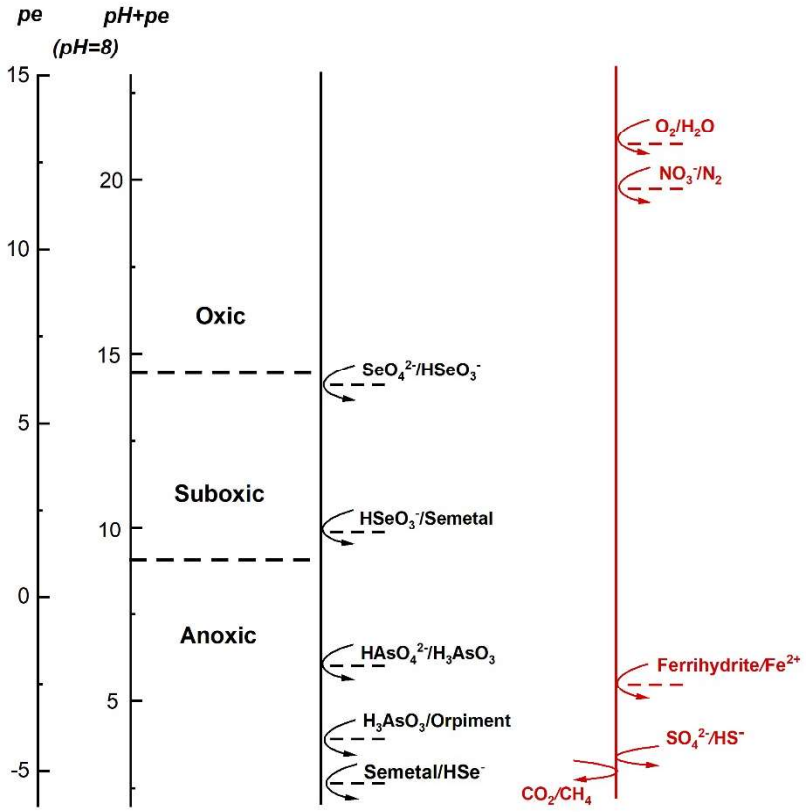

Figure 4-27
Redox ladder for relevant redox reactions (after Borch et al., 2010)

Porewater ORP measurements indicated suboxic to anoxic conditions, while subsurface gas measurements and porewater measurements of pH and dissolved constituents indicated mildly anoxic ($Fe(OH)_{3(am,\ s)}$ conversion to Fe^{2+}) to strongly anoxic and reducing (HS^- and robust CH_4 formation)[3] conditions in the ash deposit. Furthermore, porewater measured redox trended toward less reducing/more oxidizing conditions during warmer months, which is contrary to increased microbial activity, inducing more reducing conditions, at warmer temperatures. There is no clear explanation for the observed discrepancy between field-measured ORP and the redox state as deduced from gas measurements and porewater concentration data; however, the latter are generally considered more reliable indicators of redox conditions. There are several possible causes for the observed inconsistency:

- Integration Areas – Porewater reflects leaching in response to infiltration and possibly mixing with groundwater influx in response to changes in hydraulic heads (e.g., groundwater responses to changes in river elevation are evident in VB-3). In contrast, subsurface gas

[3] Hydrosulfide ion (HS^-) is a weak acid (pKa ≈6.9) resulting in a solution equilibrium with hydrogen sulfide (H_2S) gas, which was detected intermittently during subsurface gas analysis.

measurements integrate over a much larger area by diffusion and convection driven by barometric pressure changes. Gases released from the saturated zone in the coal ash can also be reflected in the gas monitoring. It is well established that the localized zones of microbially active/induced aerobic, suboxic, and highly reduced anoxic conditions can co-exist in close physical proximity (e.g., in biofilms).

- Sampling Effects – Porewater samples reflect integration over the zone of influence around the porewater access point during pumping for sampling.[4] Porewater sampling requires low-flow pumping of the porewater monitoring points, while the monitoring well remains uncapped and in exchange with the atmosphere. During initial monitoring point purging, porewater in the monitoring point can partially aerate and oxidize by oxygen exchange at the air-porewater interface within the monitoring point and the sand packing around the well screen if it is partially unsaturated.
- ORP Readings – Field monitoring instrumentation and the process of data documentation normally do not measure extremely low reducing conditions and, therefore, some negative instrument readings may have been misrepresented as positive readings. In order to examine this possibility, ORP based on sonde measurements (mV) at boreholes VB-1, VB-2, and VB-3 and resultant pH+pE values (Figure 4-28) are compared with the bounding case results if some sonde ORP measurements were actually negative values with the same absolute value (Figure 4-29). This figure indicates more reducing conditions during the warmer months and redox conditions (pH+pE) consistent with the subsurface gas measurements.

[4] For this project, porewater and groundwater sampling was conducted using low-flow sampling techniques that result in negligible drawdown.

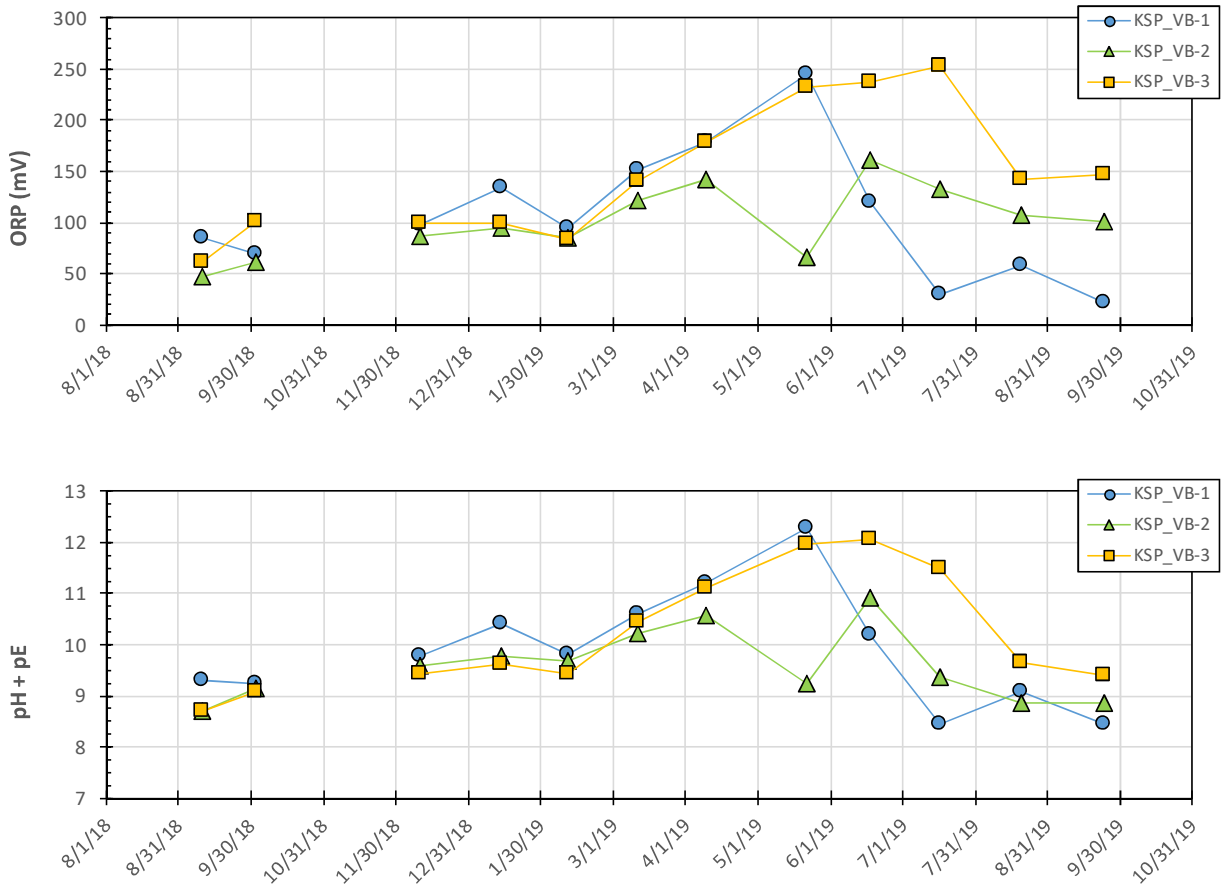

Figure 4-28
Oxidization reduction potential based on sonde measurements at boreholes VB-1, VB-2, and VB-3 and resultant pH+pE values

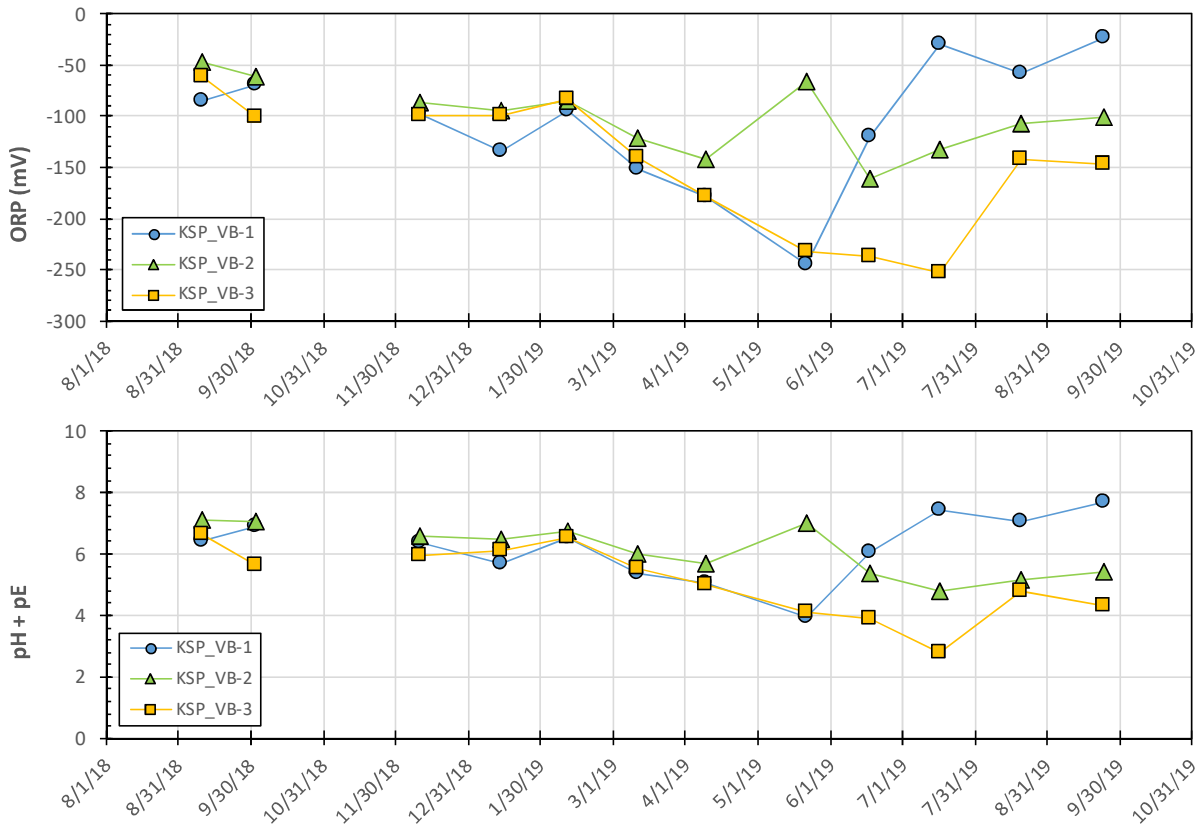

Figure 4-29
Oxidization reduction potential and resultant pH+pE values if recorded ORP measurements were negative for boreholes VB-1, VB-2, and VB-3

Comparison of Leaching Tests to Monthly Porewater Samples

The results of LEAF leaching tests and traditional tests (TCLP, SPLP, and ASTM) were plotted as a function of pH along with the porewater concentrations measured at the corresponding borehole (VB-1, VB-2, or VB-3). Examples of these comparisons are shown in Figure 4-30 through Figure 4-32, while a full set of results is presented in Appendix G. In the pH-dependence graphs, monitored porewater data are presented both as data points representing monthly measured porewater concentrations and as dashed lines representing the mean pH and mean concentration of all measured values.

To the right of each pH-dependence graph, bar charts show the ratio of the leaching test concentration to the mean porewater concentration. The seven ratios are shown in increasing order of L/S, including:

- The 1st eluate from EPA 1314 at L/S=0.2 mL/g-dry,
- The 2nd eluate from 1314 at L/S=0.3 mL/g-dry (cumulative L/S=0.5 mL/g-dry),
- The 1313_L/S=1 concentration at own pH at L/S=1 mL/g-dry,
- The 1313 concentration at natural pH at L/S=10 mL/g-dry,
- TCLP conducted at an average L/S of 23 mL/g-dry,
- SPLP conducted at an average L/S of 22 mL/g-dry, and
- ASTM at an average L/S of 27 mL/g-dry.

The eluate-to-porewater-concentration ratios indicate how closely leaching test concentrations can predict measured field concentrations. For example, Figure 4-30 shows that B porewater concentrations are reasonably predicted by low L/S leaching test data (EPA 1314 and 1313_L/S=1) while being under-predicted by at least an order-of-magnitude at higher L/S ratios. This is consistent with available content-limited LSP where eluate concentration is a strong function of L/S. However, arsenic is under-predicted in all leaching test approximations at VB-1 and VB-2 (Figure 4-31), most likely because of oxidation of solid materials with experiments conducted under laboratory conditions. This observation is consistent with the reducing conditions observed through subsurface gas monitoring and explains why arsenic concentrations are different in the field than in laboratory samples, possibly due to the loss of HFO as adsorption sites and precipitation as arsenic sulfides. Due to the effects of oxidation of laboratory samples, the leaching tests tend to over-predict the porewater concentrations of other oxyanions including Sb (Figure 4-32), Se, and V.

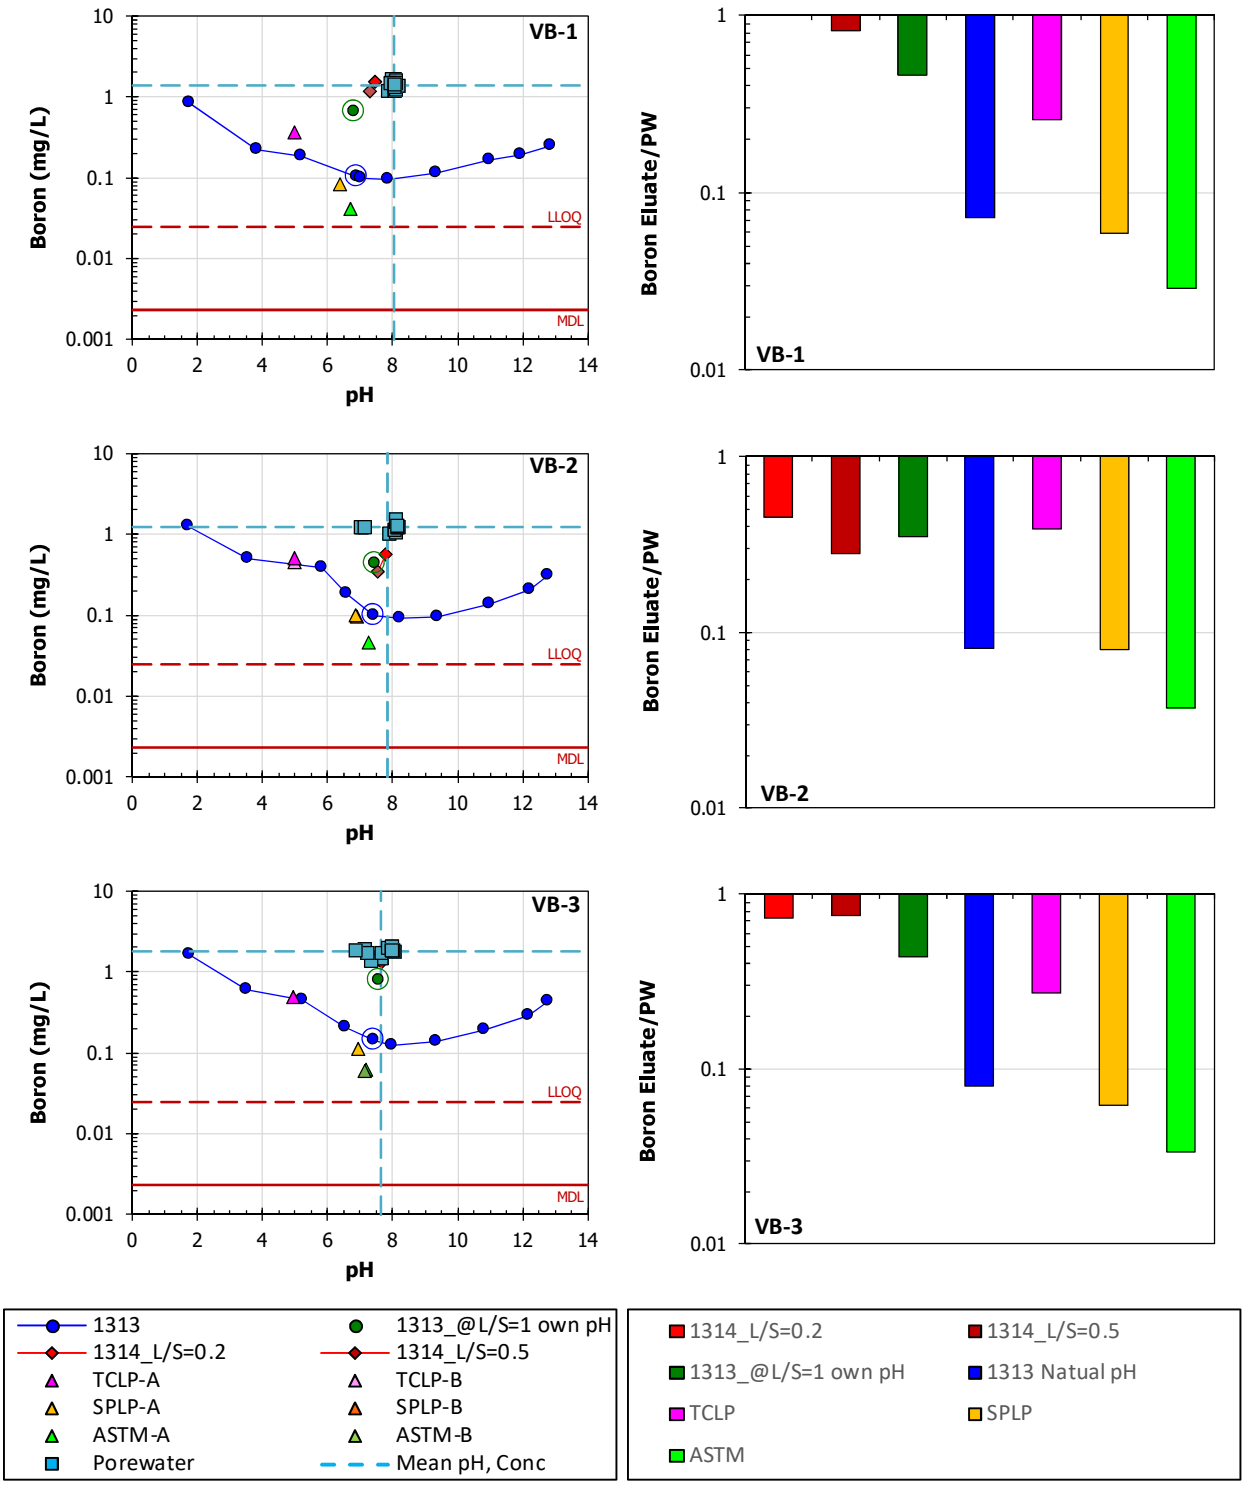

Figure 4-30
Boron concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right)

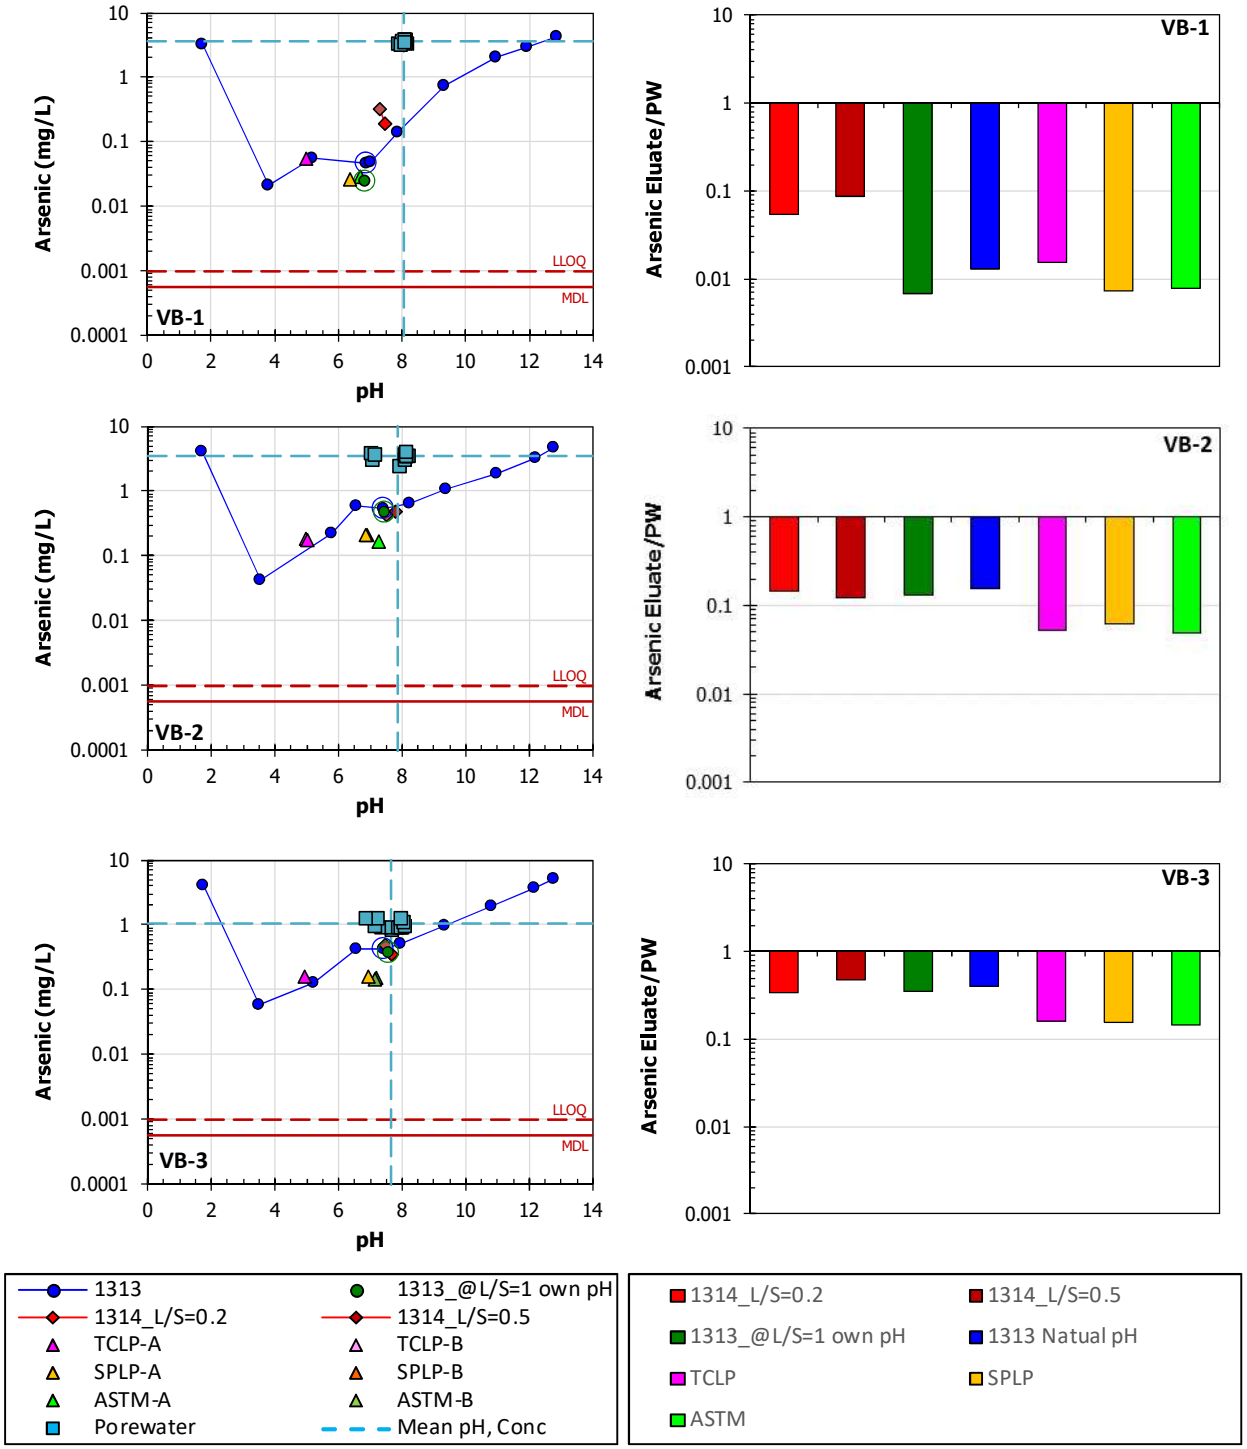

Figure 4-31
Arsenic concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right)

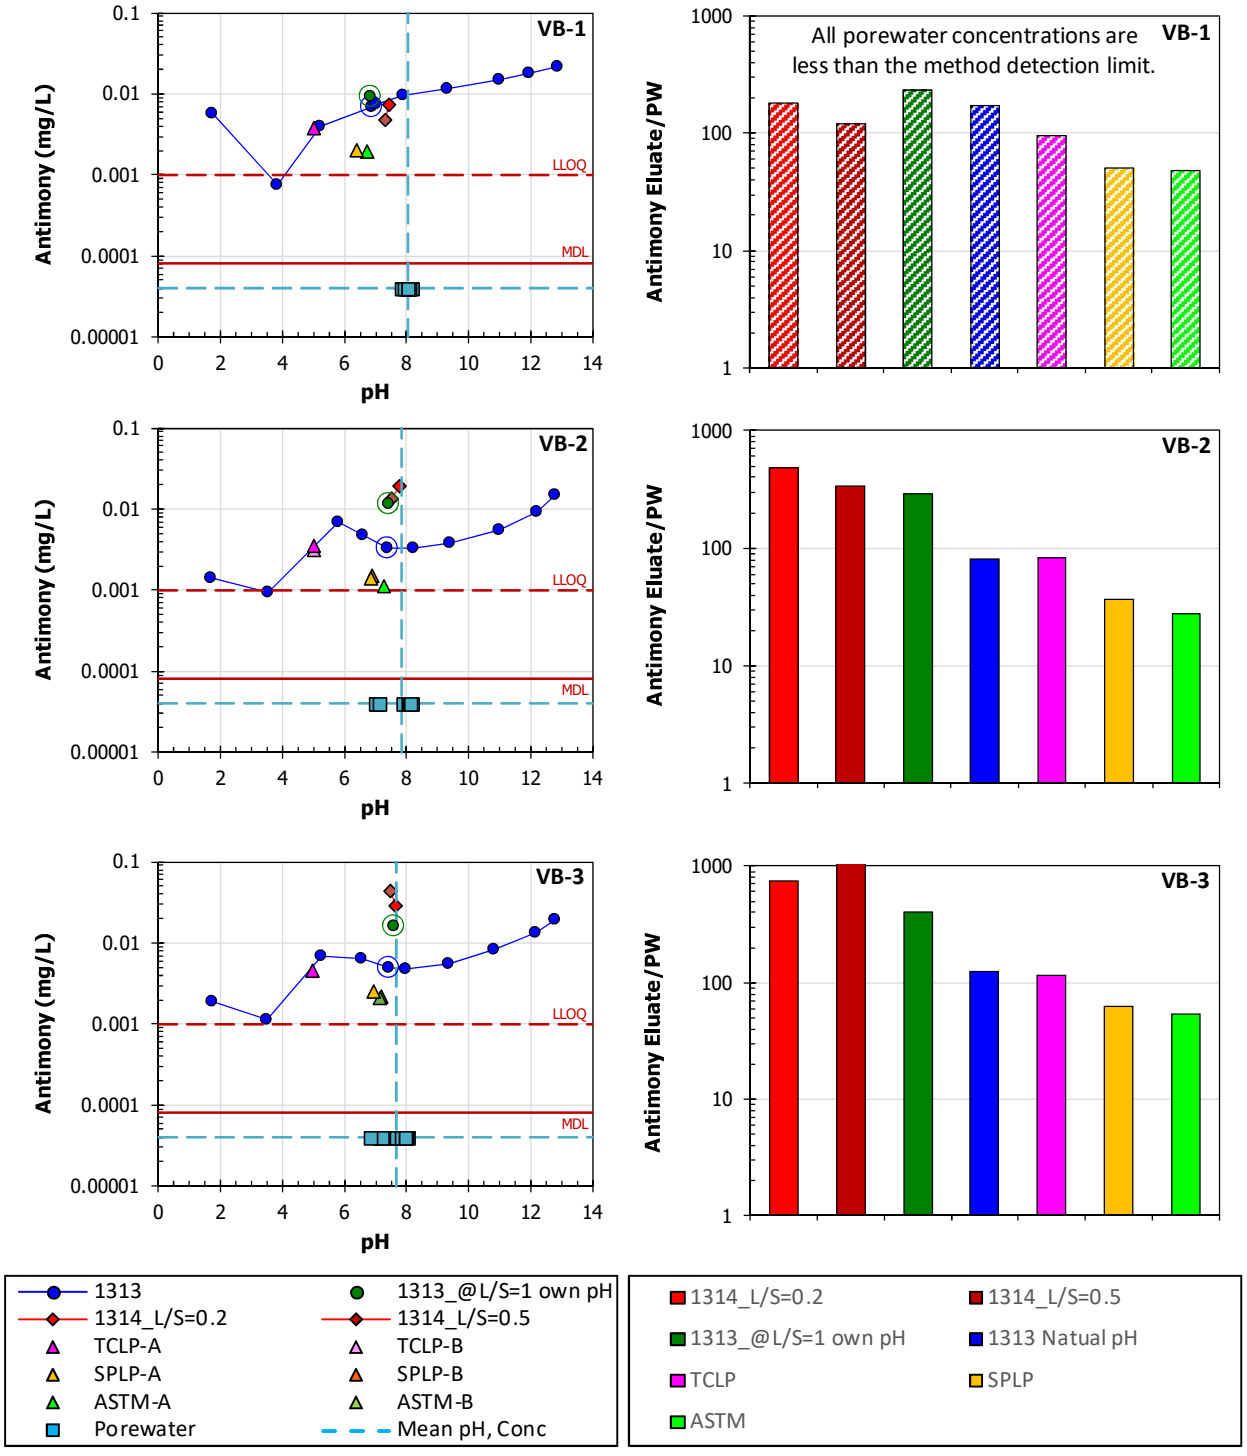

Figure 4-32
Antimony concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right); crosshatched ratio results indicate estimates based on at least one MDL value

A qualitative summary of the ability of different leaching tests to estimate the measured porewater concentrations at each of the PAPs is shown in Table 4-14 for constituents with solubility-controlled LSP, Table 4-15 for constituents with available content-limited LSP, and Table 4-16 for constituents where the LSP could not be determined. In those tables, shading is used to indicate if the leaching test estimate is within 25% of the mean groundwater concentration (green), within an order-of-magnitude of the mean porewater concentration (orange), or greater than an order-of-magnitude from the mean porewater concentration (red). When "GW <MDL" appears in the Notes column, the mean porewater concentration was less than the analytical MDL. Within the field of the table, an asterisk is used to indicate that the leaching test results were less than the MDL.

Table 4-14, Table 4-15, and Table 4-16 provide an overview of the ability of leaching tests, conducted on materials collected from a highly reducing environment and tests at mildly oxidizing conditions in a laboratory setting, to estimate porewater concentrations. The results of this qualitative summary should not be used without consideration of the redox conditions of the field and should always be shown along with the graphical data (e.g., Figure 4-30 through Figure 4-32) that preserve the pH result for the tests. For example, the table indicates that TCLP would provide a good estimate of porewater concentration for Ca; however, this is somewhat of a coincidence because the pH of TCLP is more than two pH units less than the natural pH of the ash.

Table 4-14

[5] Although the liquid-solid partitioning (LSP) for arsenic appears to be solubility-controlled, arsenic LSP is likely a result of adsorption onto hydrous ferric oxides (HFO) and not solubility of arsenic-bearing minerals.

5
SUMMARY OF OBSERVATIONS

The data presented in this report represent the results of geotechnical, hydrologic, and leaching characterization of samples of coal ash collected from the closed and capped impoundment at Plant 42201. The hydraulic conductivity of intact cores from the ash deposit was measured in context of the distribution of particles in the coal ash samples and the overburden pressure associated with disposal at depth within the pond. The leaching test results for LEAF tests (i.e., EPA Methods 1313 and 1314) were compared to those for traditional tests (i.e., ASTM, TCLP, and SPLP). In addition, leaching test results were compared to porewater concentrations determined from field samples, and field-sampled porewater concentrations were compared to groundwater concentrations, to evaluate similarities and dissimilarities between these results.

Based on the presented data and analysis, the following general observations can be made:

- The hydraulic conductivity of intact ash samples is dependent on the fraction of fines in the material. The measured hydraulic conductivity of finer, less permeable coal ash was lower (ranging from approximately $7x10^{-4}$ cm/s to $1x10^{-5}$ cm/s) than the hydraulic conductivity of coarser, more permeable coal ash (approximately $1x10^{-3}$ cm/s). In general, the hydraulic conductivity decreases modestly with increasing effective stress.
- The subsurface within the closed impoundment was more bio-chemically reducing than indicated by porewater analysis. Monitoring of subsurface gas concentrations shows the presence of hydrogen sulfide and methane, indicating strongly reducing conditions. Monthly data indicate that the extent of reducing conditions is spatially variable and may be seasonally dependent. In addition, arsenic concentrations in the porewater are at the high end of previously reported ranges for coal ash (EPRI, 2019) in some areas. At intermediate reducing conditions (e.g., at VB-1), elevated concentrations of arsenic (ca. 3 mg/L) are likely due to loss of HFO when ferric oxides are reduced and solubilized (conversion of insoluble Fe^{3+} to soluble Fe^{2+}). Under very low redox conditions, as observed by subsurface gas monitoring at VB-2 and VB-3 by the presence of methane, arsenic porewater concentrations decrease due to conversion of As(V) to As(III) and likely precipitation as sulfides. Conversely, the porewater concentrations of Sb and Se in the reduced pond environment are suppressed due to formation of reduced species with lower solubility.
- Some constituents in the porewater samples exhibited temporal variability due to factors such as (1) seasonal changes in pH and redox, (2) changes that appeared to be related to seasonal groundwater elevation changes, and (3) changing conditions shortly after closure of the impoundment. However, some constituents such as, B, and Mo remained relatively constant within each porewater access point throughout the 13-month monitoring period.
- The data collected suggest that porewater concentration is an unreliable indicator for which constituents will have elevated groundwater concentrations or for prediction of downgradient concentrations at this site.

- Traditional leaching tests (TCLP, SPLP, and ASTM) are poor indicators of measured porewater concentrations. Low liquid-to-solid ratio (L/S) eluates from EPA Method 1314 are better indicators than the traditional tests for concentrations for available content-limited constituents (B, Ca, Cl, Mo, Tl) because of the strong L/S-dependence. However, additional information (e.g., available content and porewater L/S) is needed to provide a reasonable approximation of porewater concentrations. For constituents with apparent solubility-controlled liquid-solid partitioning (Sb, As, Ba, Cr, F^-, Se, SO_4, V, Zn), pH-dependence tests (e.g., EPA Method 1313) may provide valuable information for geochemical modeling, but, for this site, the natural or own pH responses did not reliably estimate field porewater concentrations, in part due to differences in redox as noted in the next bullet.
- When the field environment is highly reducing, laboratory leaching results for redox sensitive elements (e.g., As, Cr, Sb, Se, and Fe) do not directly reflect the leaching anticipated in porewater. This is, in part, because reduced materials collected in the field are inevitably partially oxidized during sampling, handling, and testing.

Figure C-27
Comparison of standardized mass release profiles (mg/kg) from field extractions (L/S~1) and laboratory extractions (L/S=1): sodium, strontium, and sulfur.

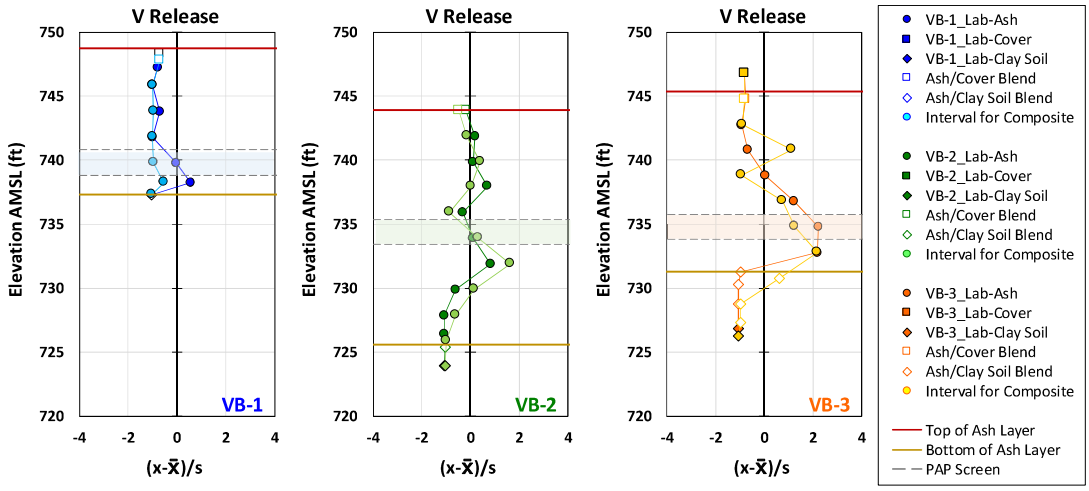

Figure C-28
Comparison of standardized mass release profiles (mg/kg) from field extractions (L/S~1) and laboratory extractions (L/S=1): vanadium.

D
LEAF TEST RESULTS ON COMPOSITE SAMPLES

Table of Appendices

D.1 pH- and L/S-Dependent Test Results

The following graphs present the results of pH-dependent tests (i.e., EPA Method 1313 and the low L/S-modified 1313) and L/S-dependent test (i.e., EPA Method 1314) on composite samples from split spoon samples taken from three boreholes at the closed KSP impoundment. These figures show the following data for three composites of coal ash:

a) eluate concentration in mg/L as a function of pH (top, left),

b) eluate concentration in mg/L as a function of L/S (top, right),

c) mass release in mg/kg-dry as a function of pH (middle, left) including available content, derived from the maximum concentration in the 1313 LSP curve,

d) cumulative mass release in mg/kg-dry as a function of cumulative L/S (middle, right),

e) acid/base neutralization capacity (ANC/BNC) of the composite material as a function of pH, and

f) evolution of eluate pH from the percolation column test.

D.2 Comparison of Individual Split Spoon and Composite Sample Data

D.1 pH- and L/S-Dependent Test Results

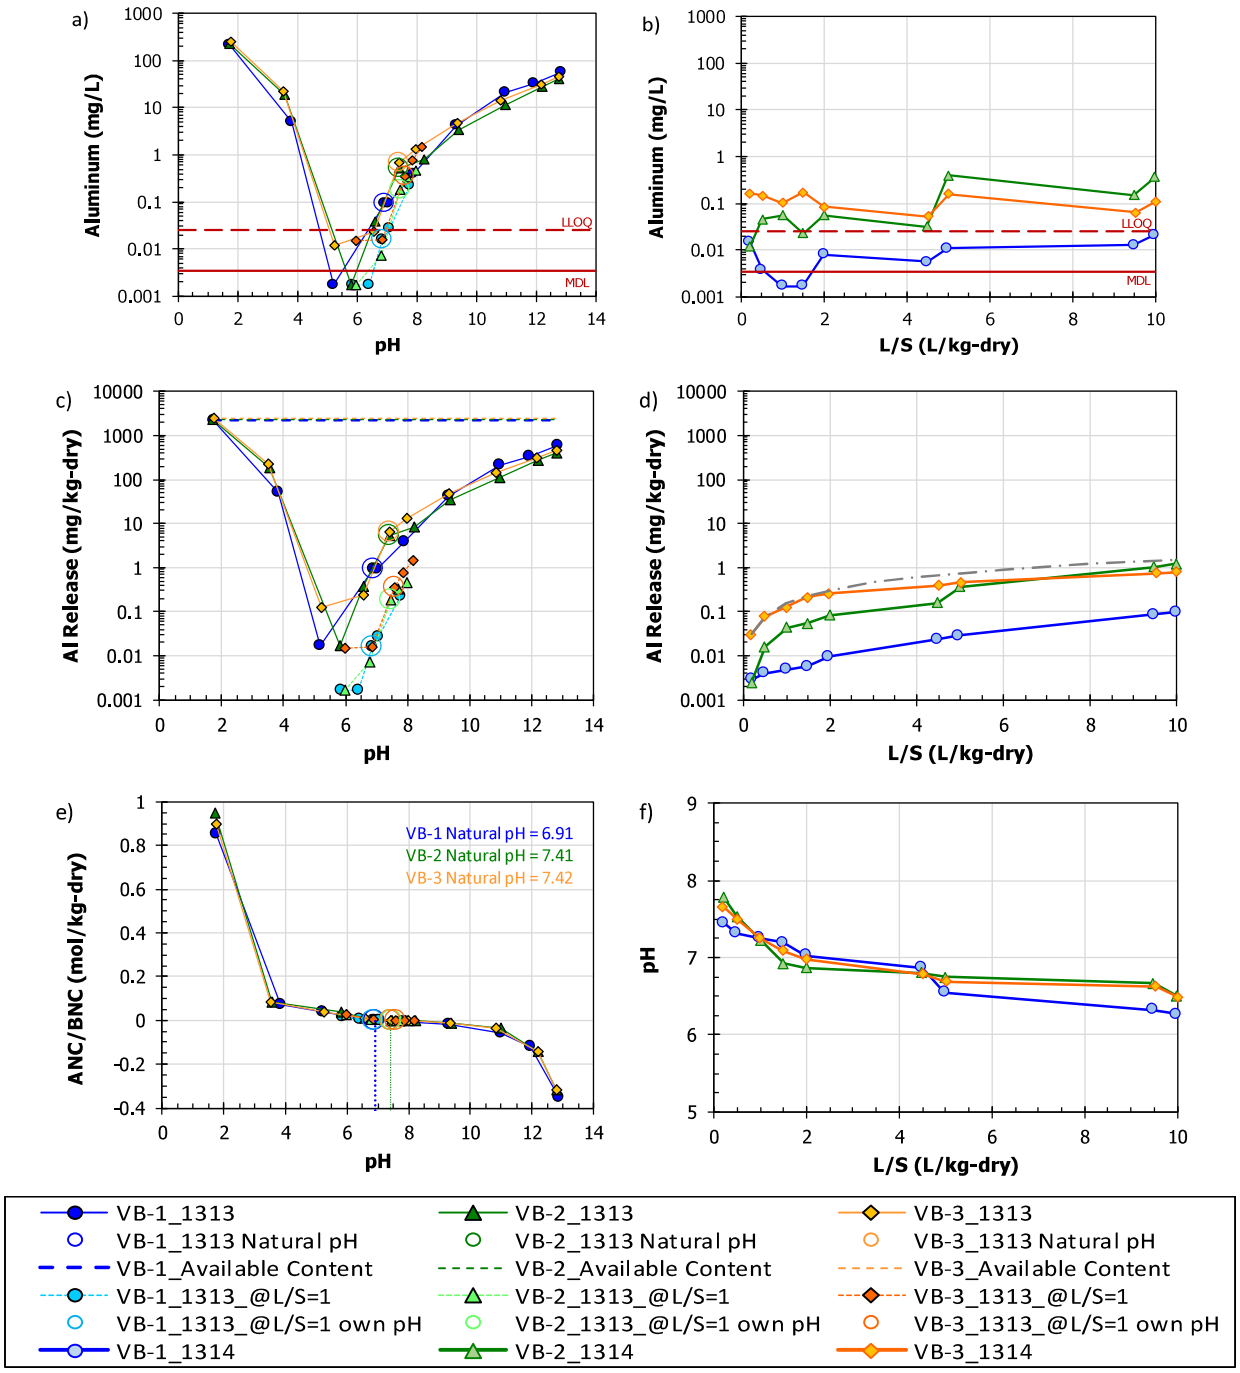

Figure D-1
Aluminum LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

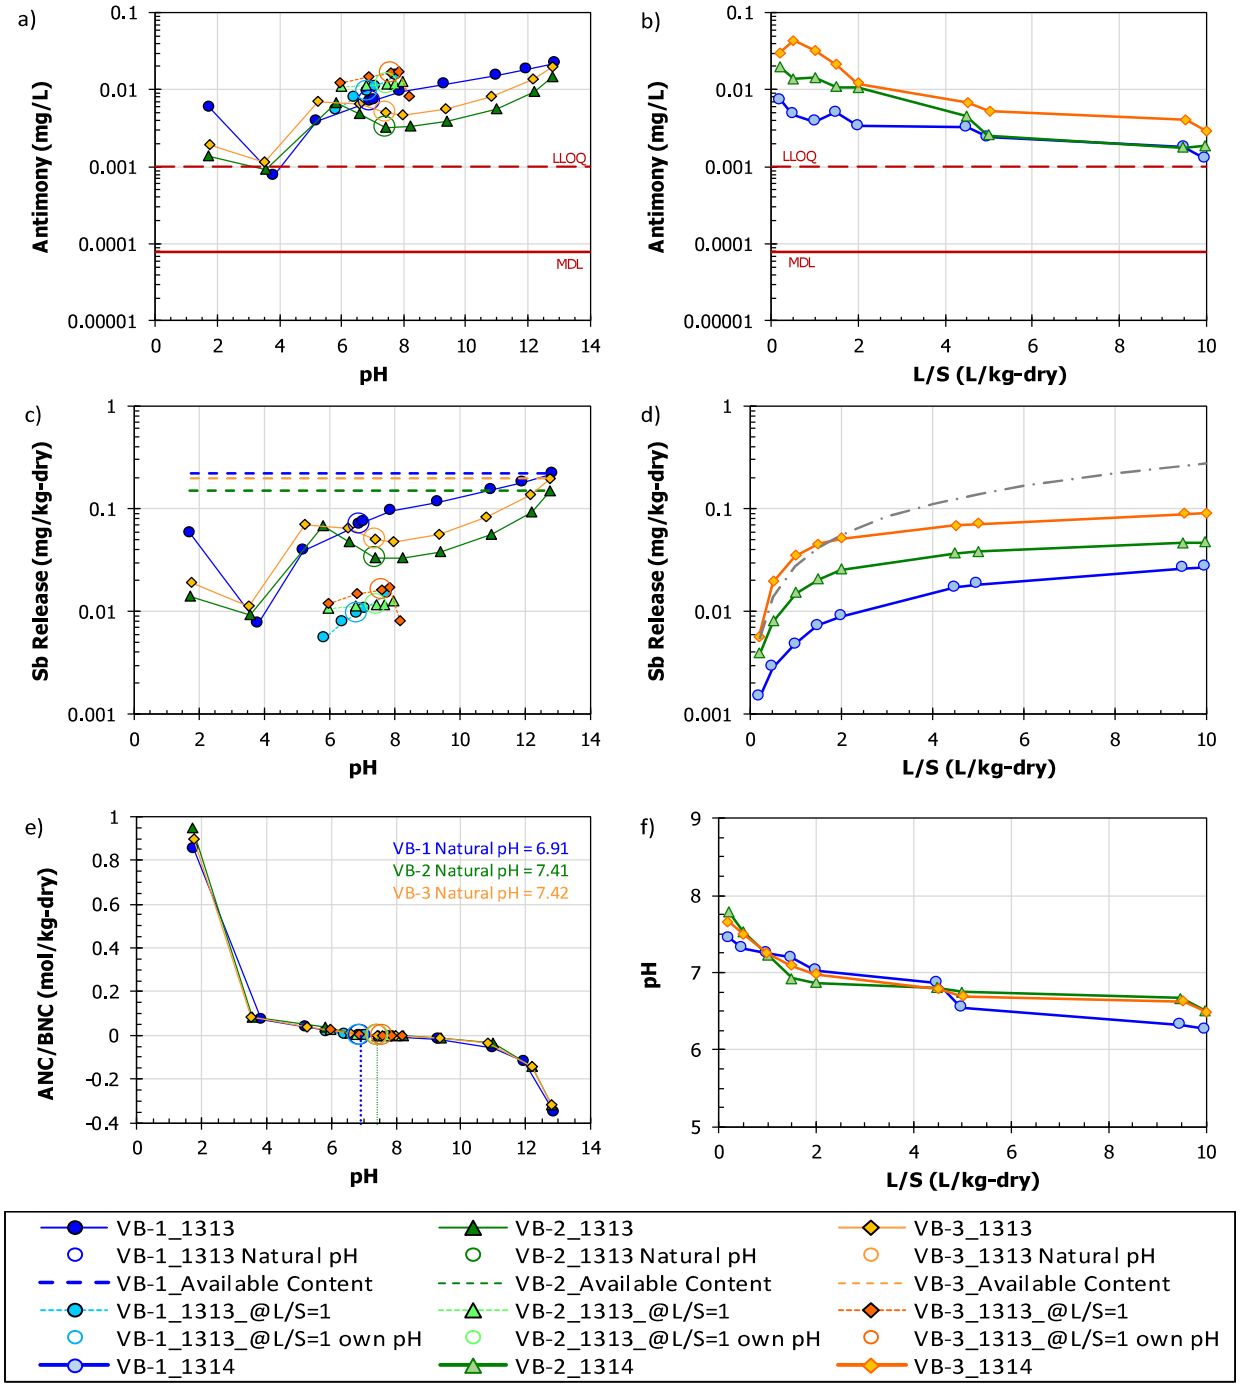

Figure D-2
Antimony LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

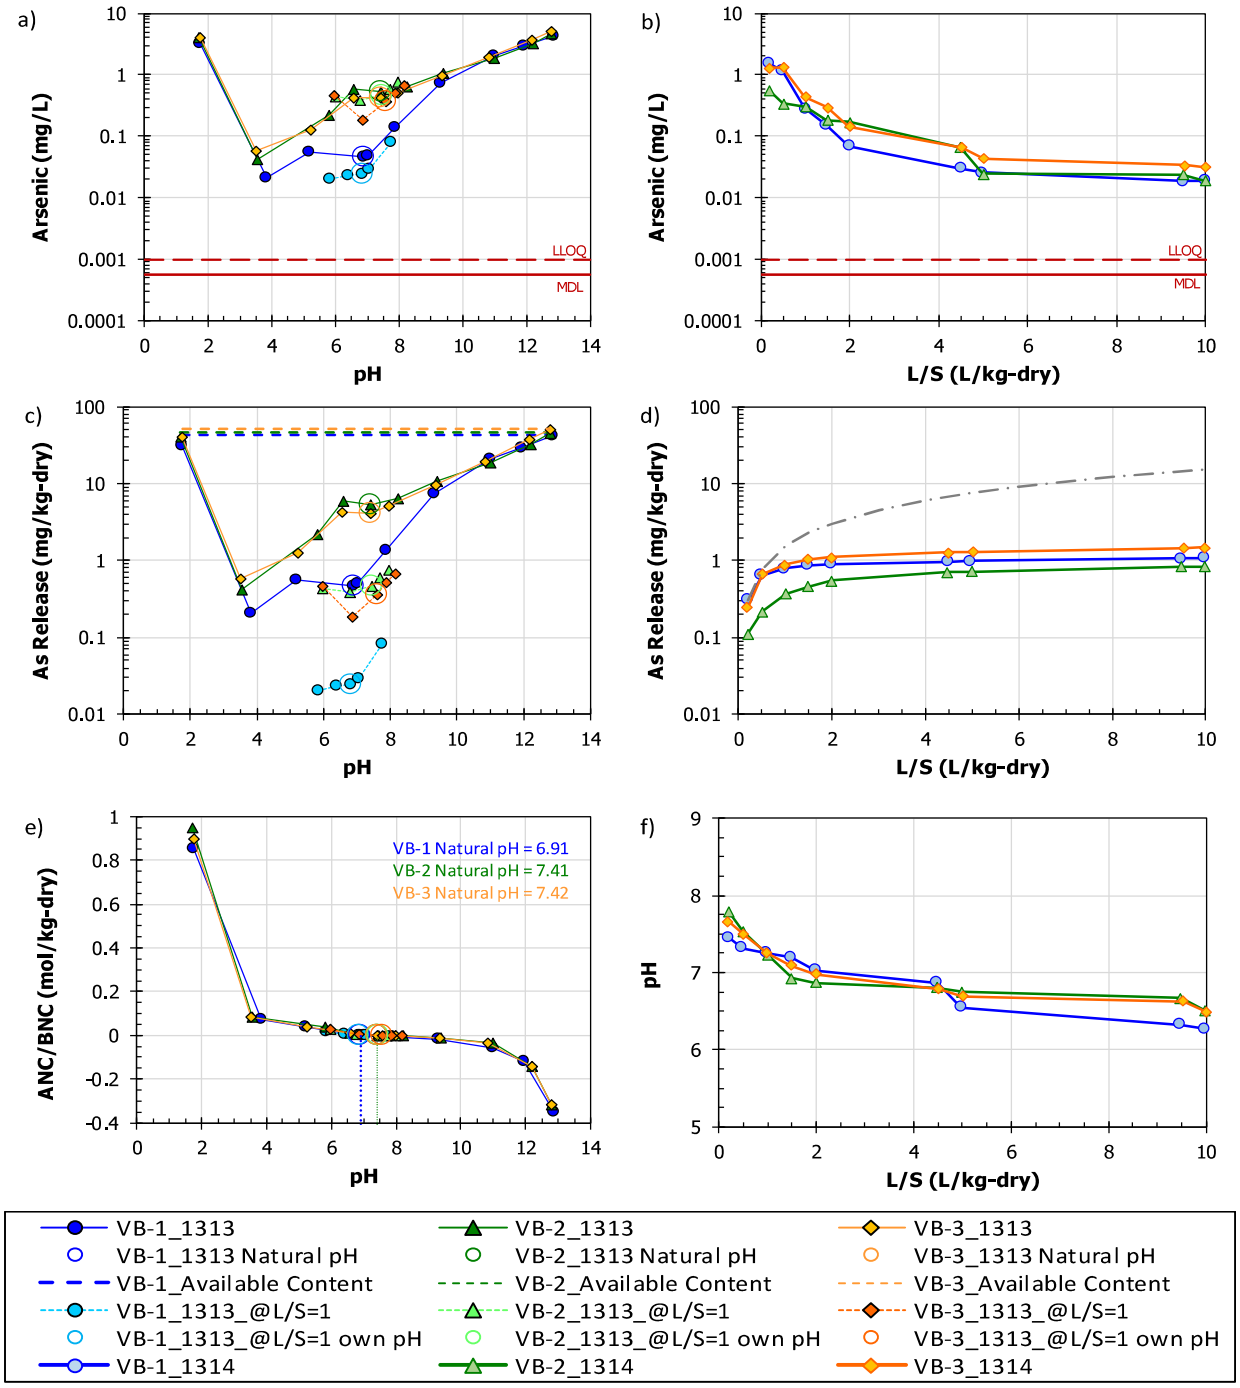

Figure D-3
Arsenic LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

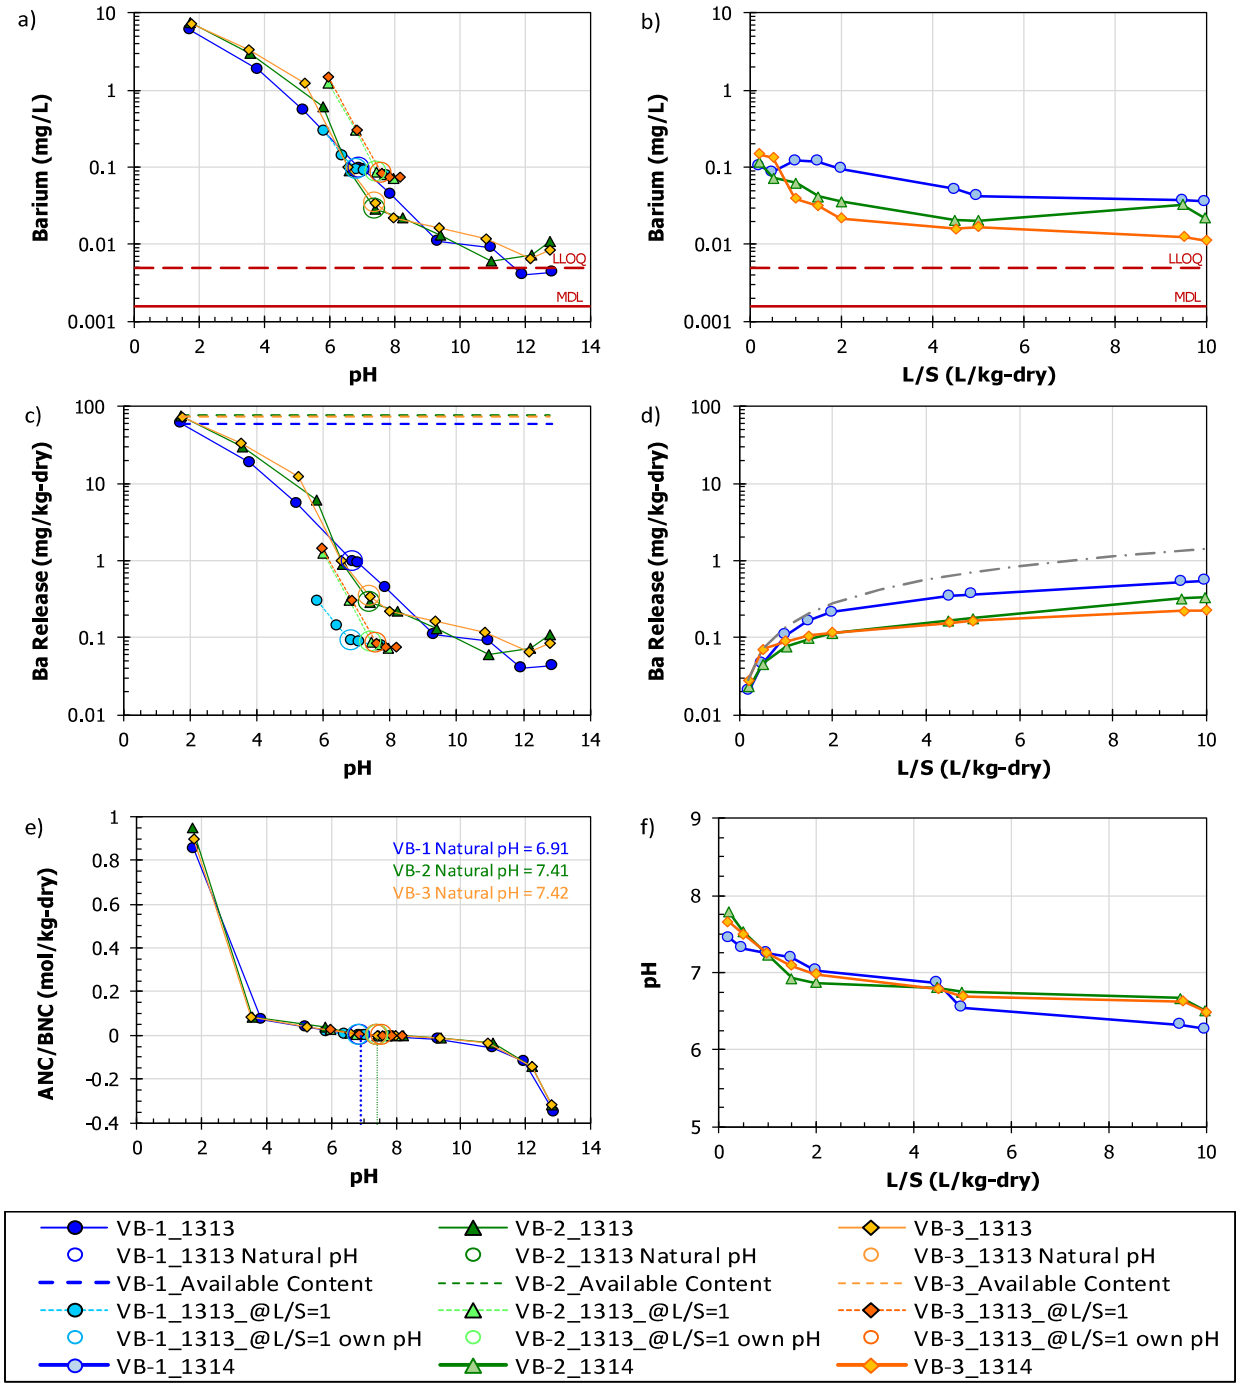

Figure D-4
Barium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

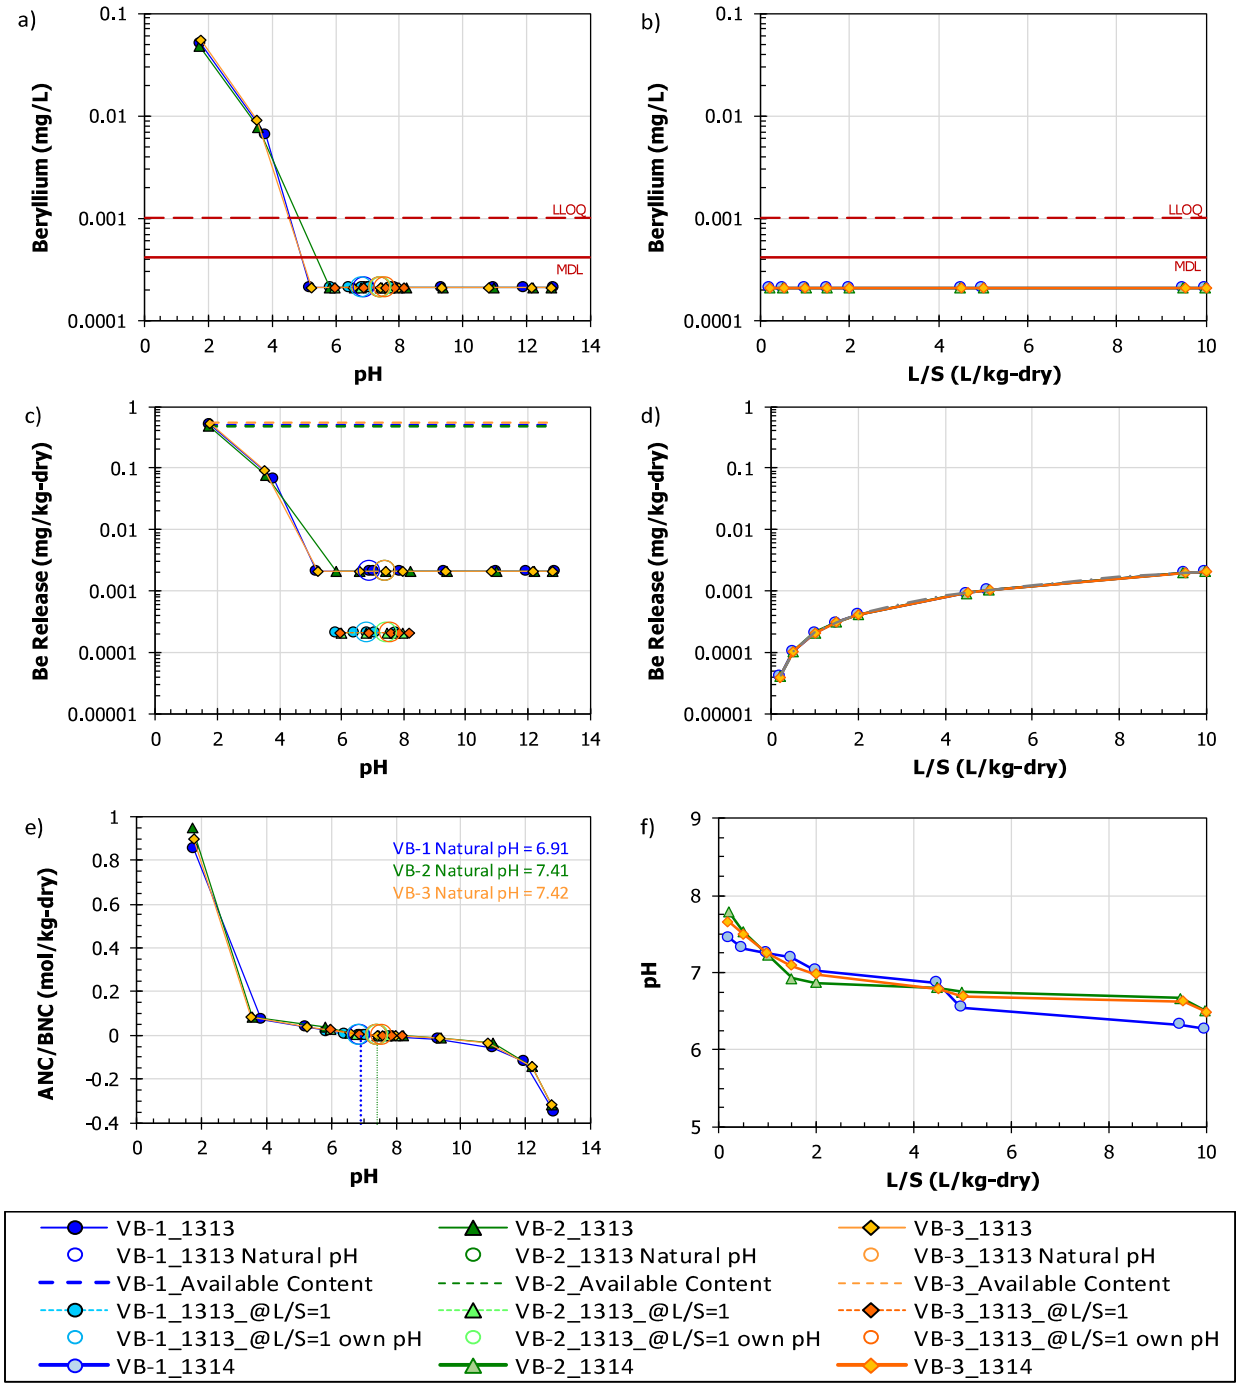

Figure D-5
Beryllium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

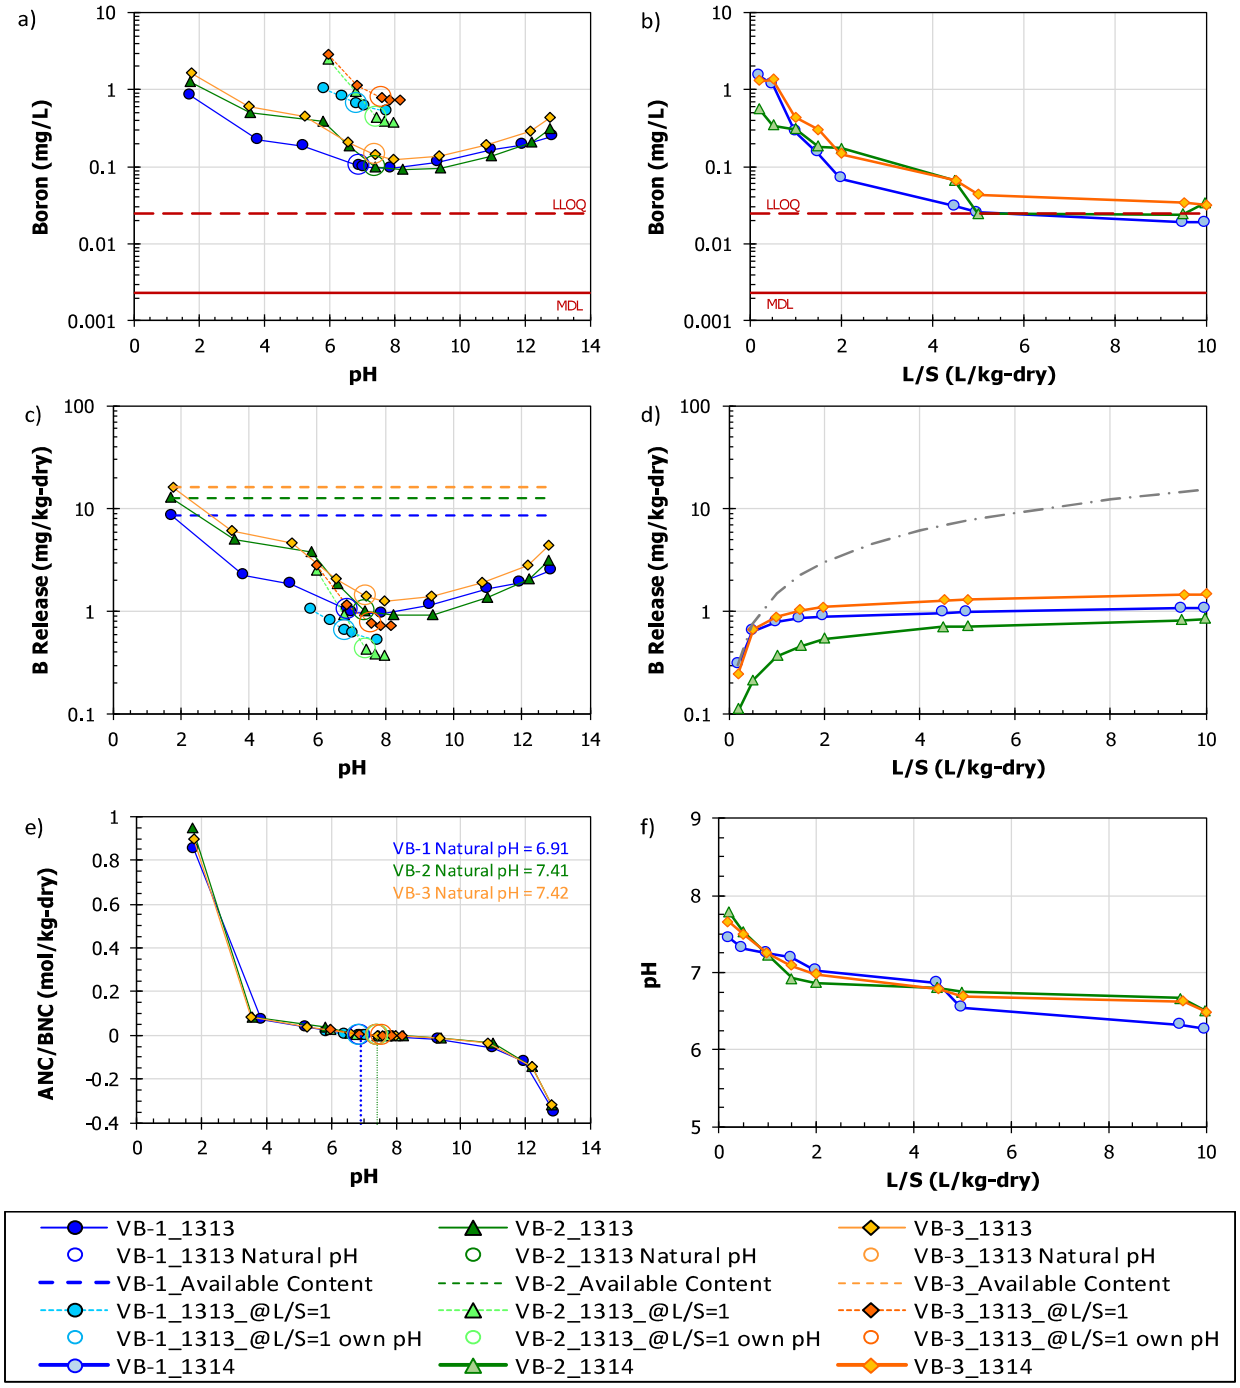

Figure D-6
Boron LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

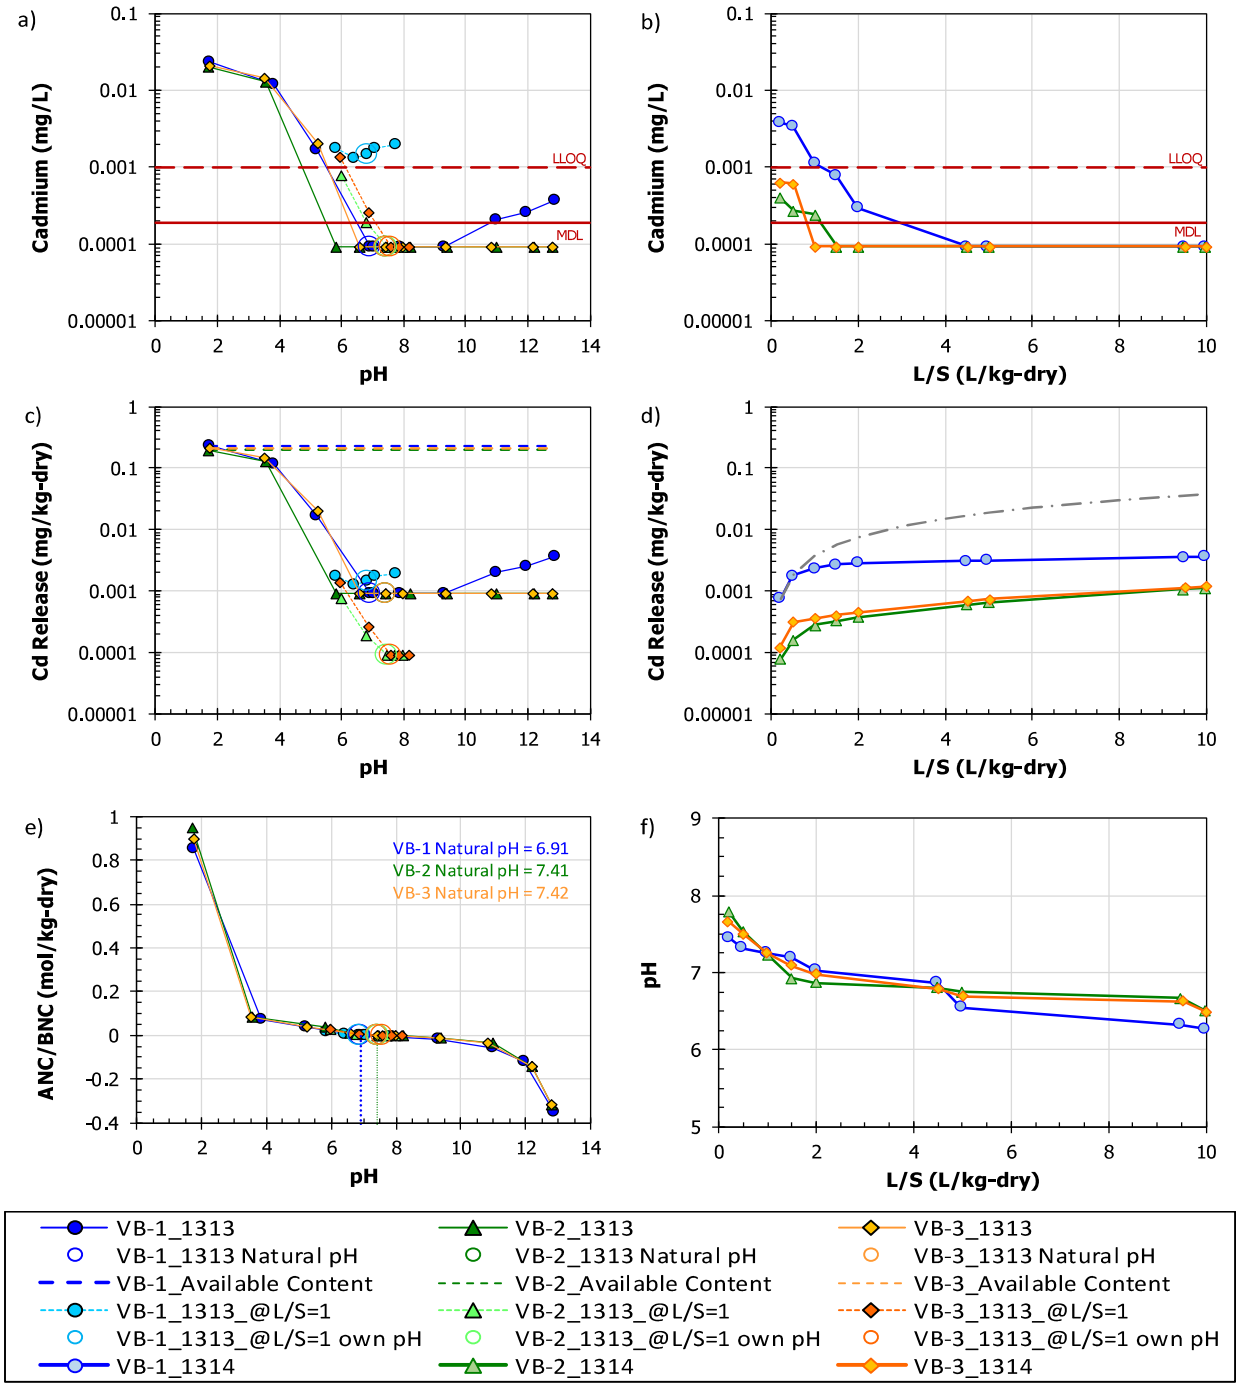

Figure D-7
Cadmium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

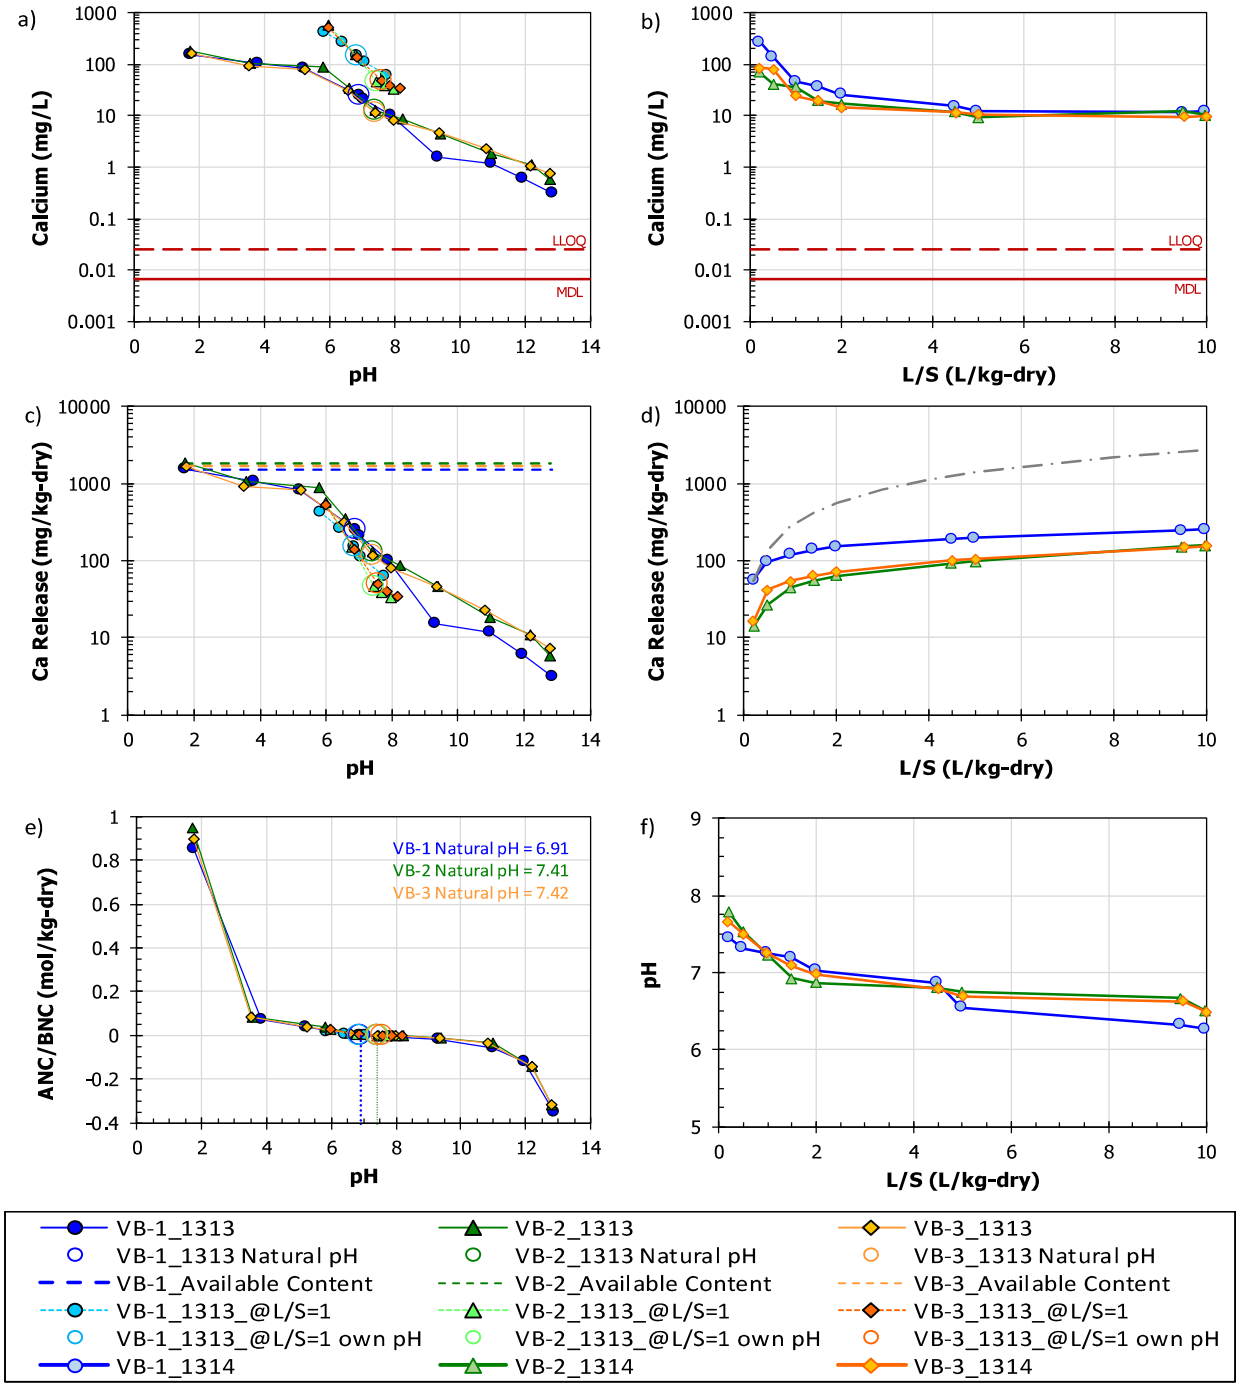

Figure D-8
Calcium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S.

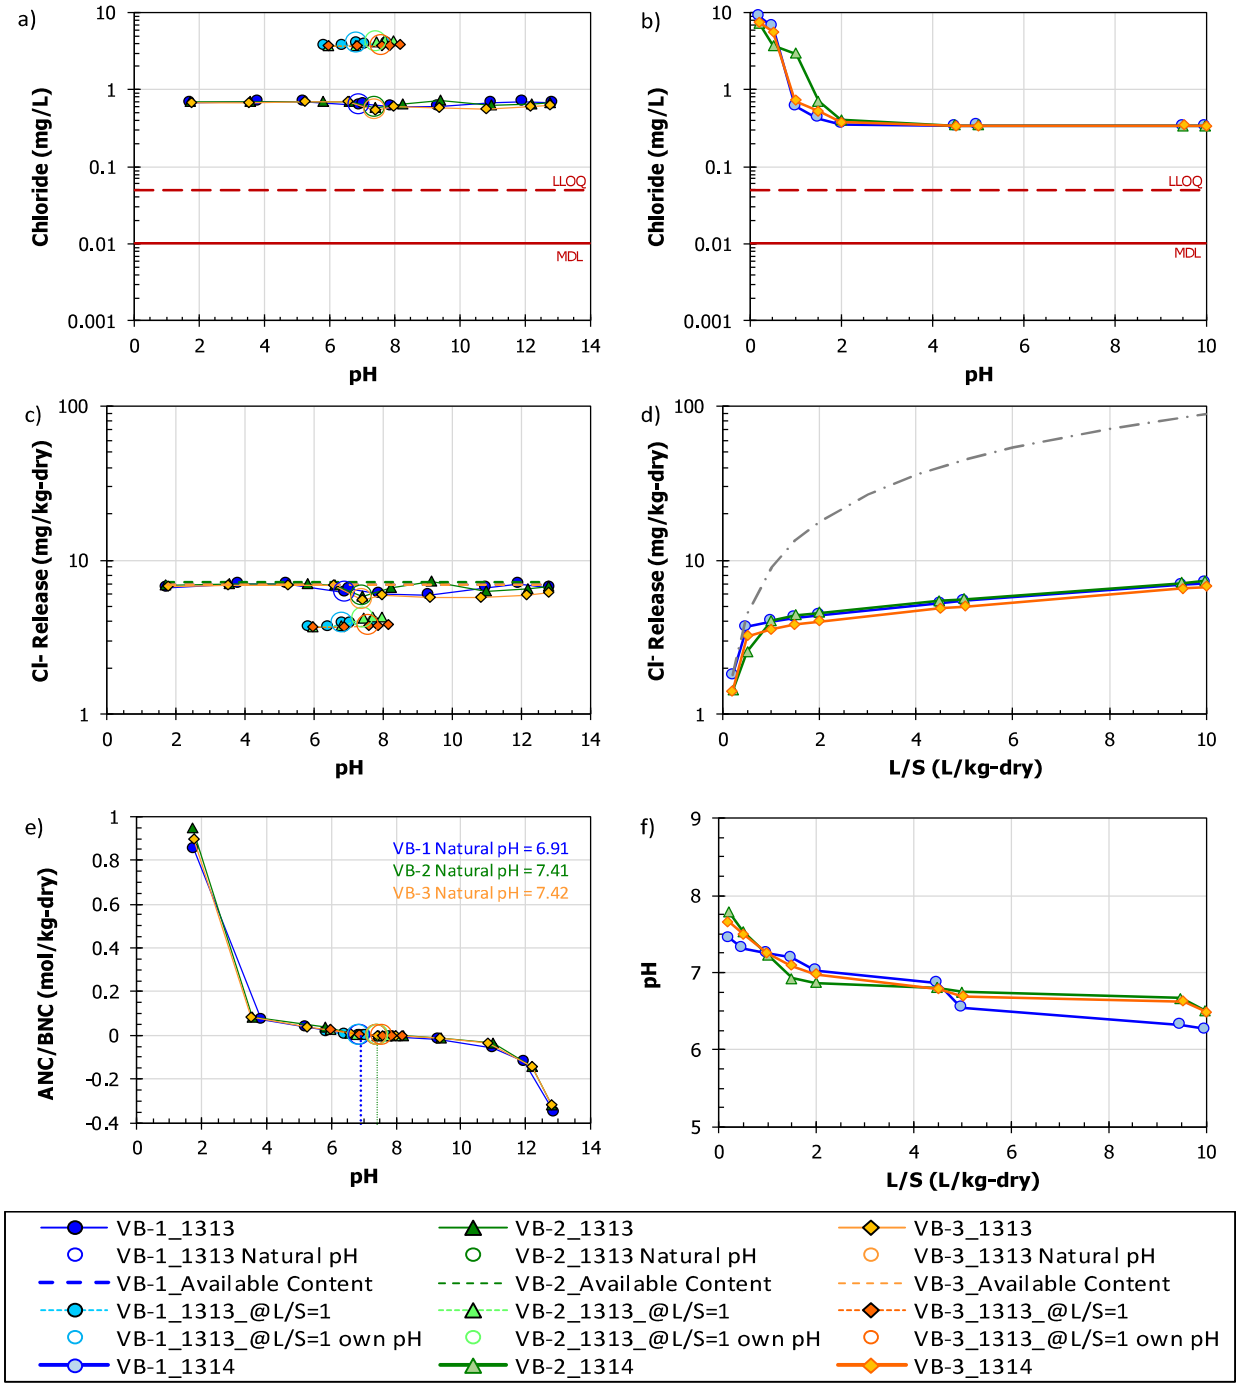

Figure D-9
Chloride LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S.

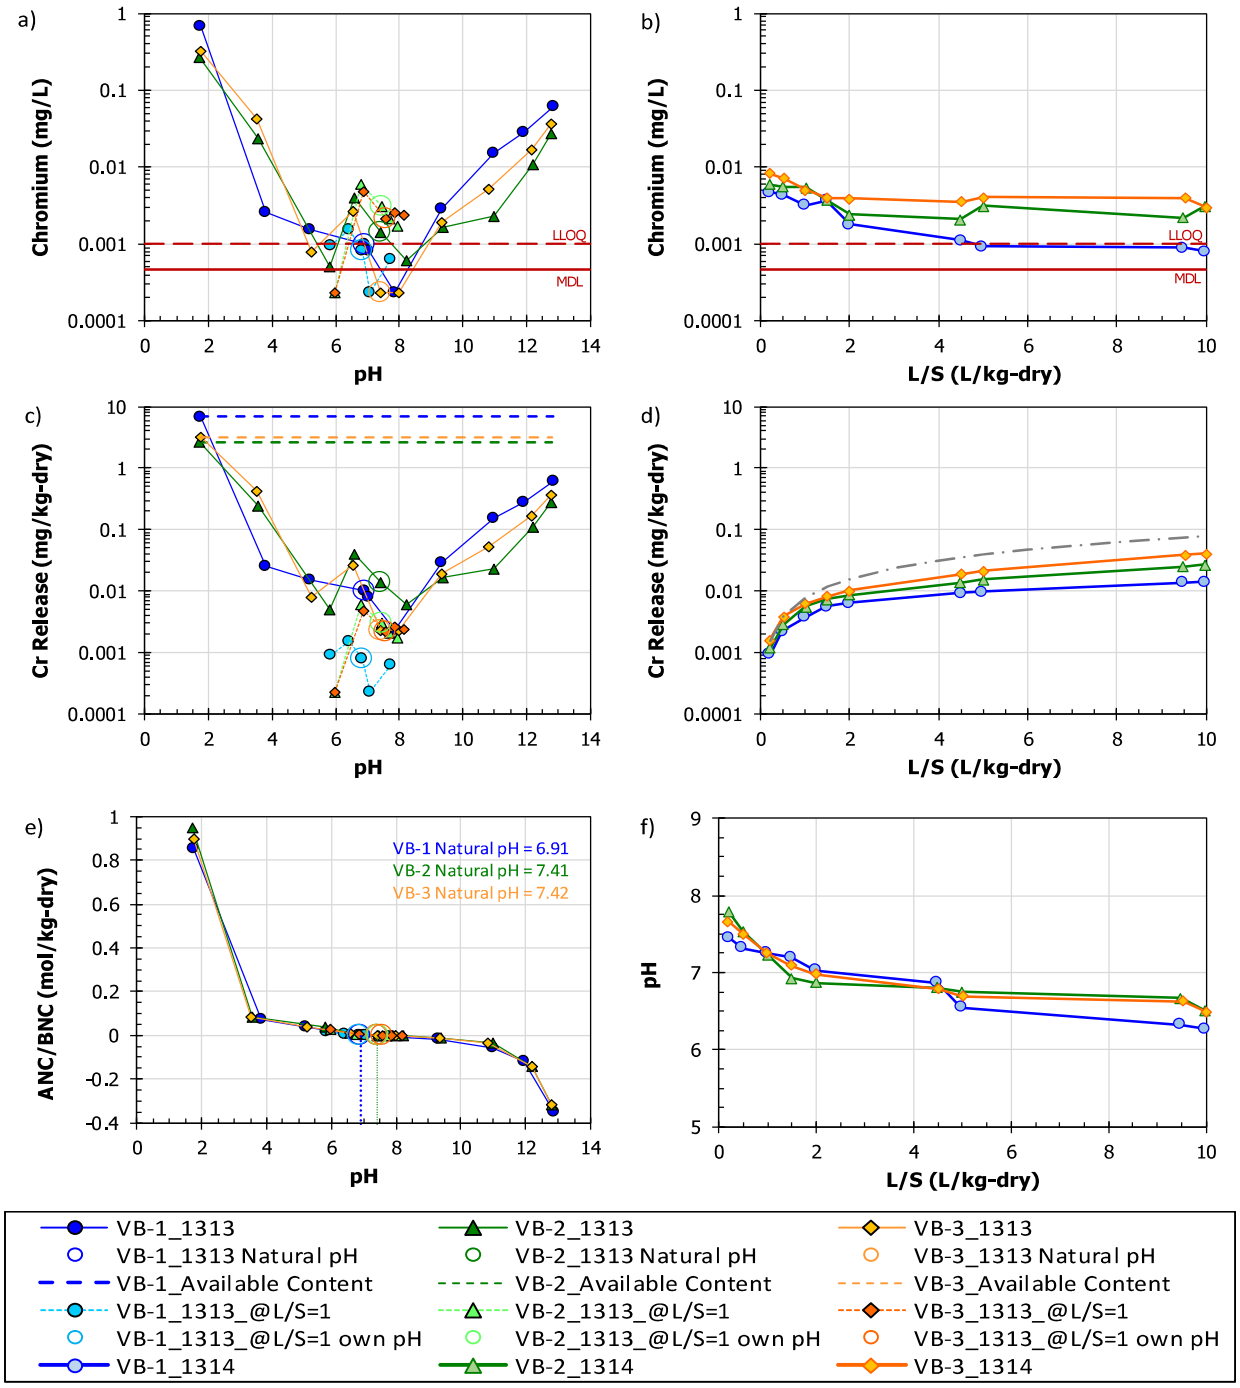

Figure D-10
Chromium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

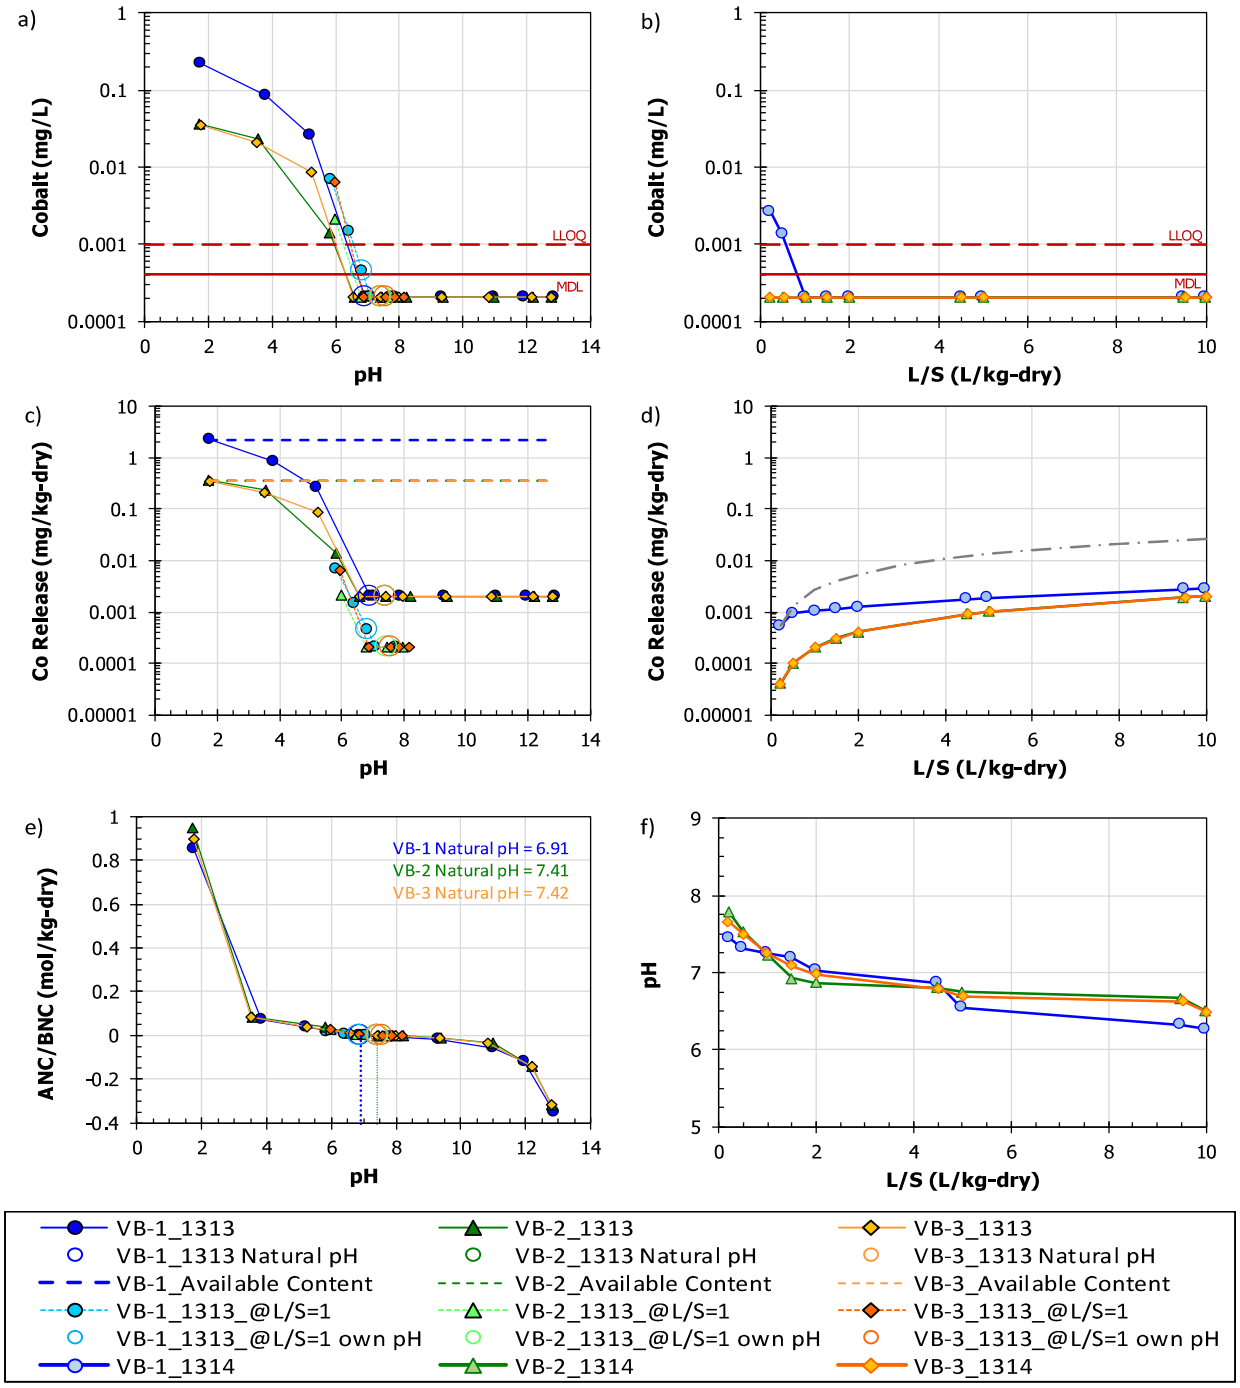

Figure D-11
Cobalt LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S.

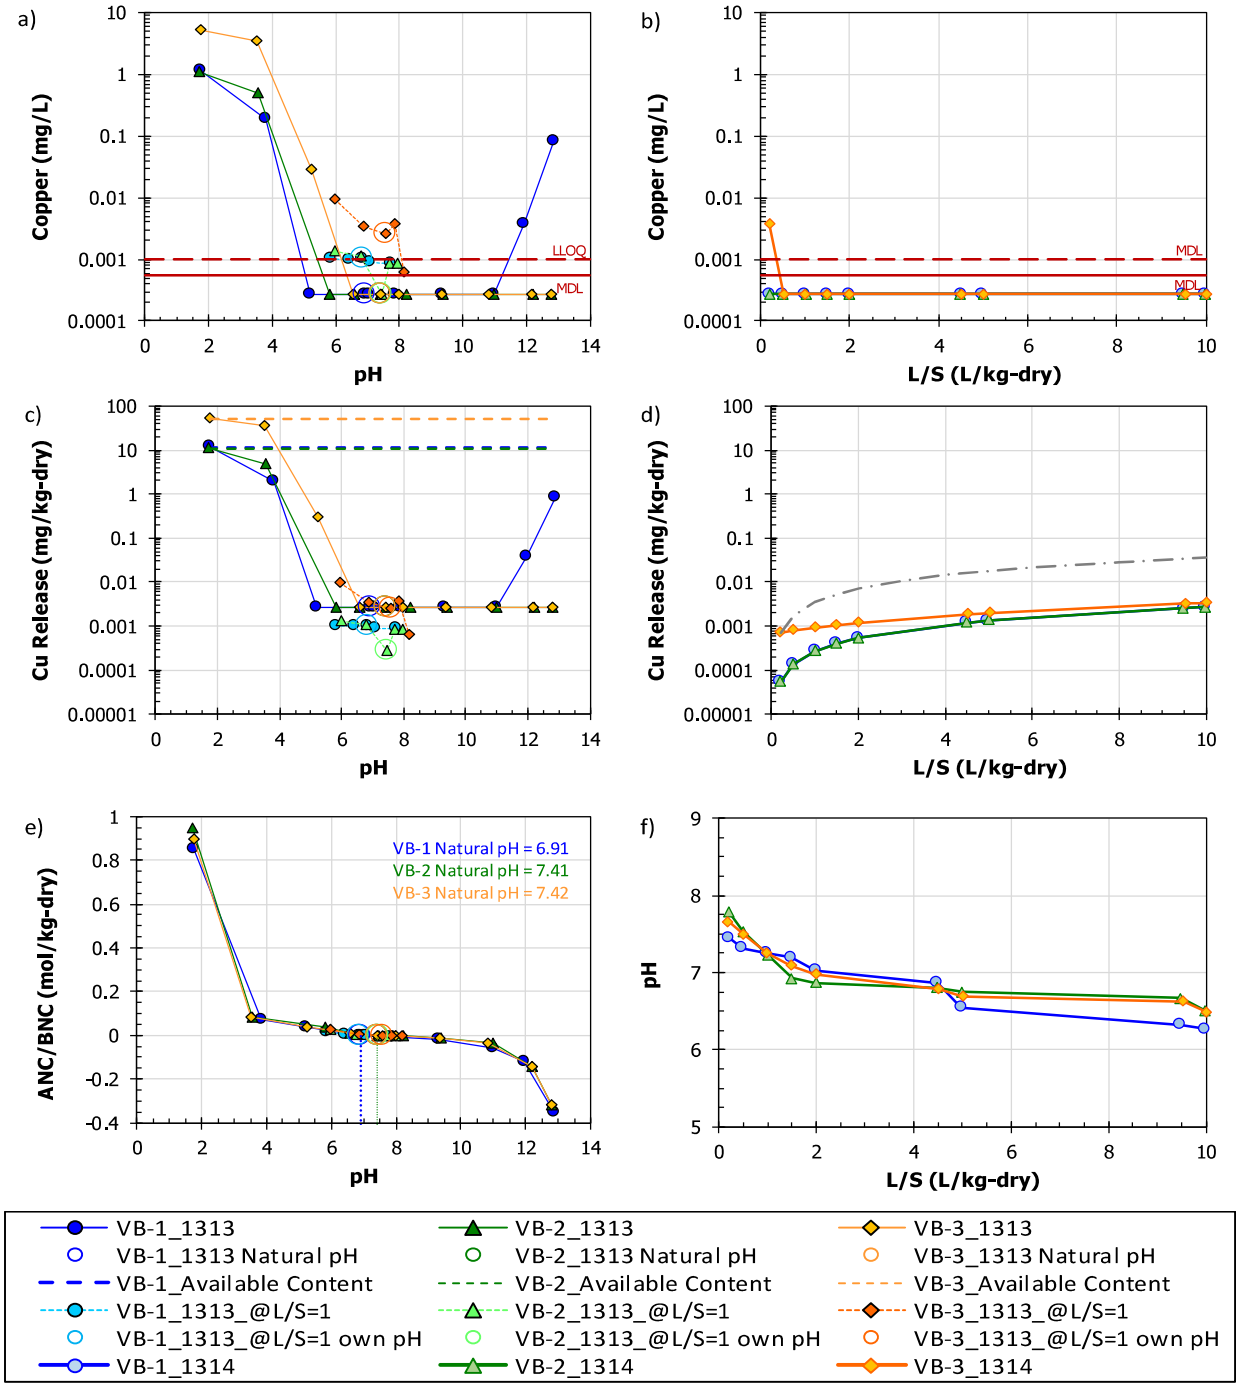

Figure D-12
Copper LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

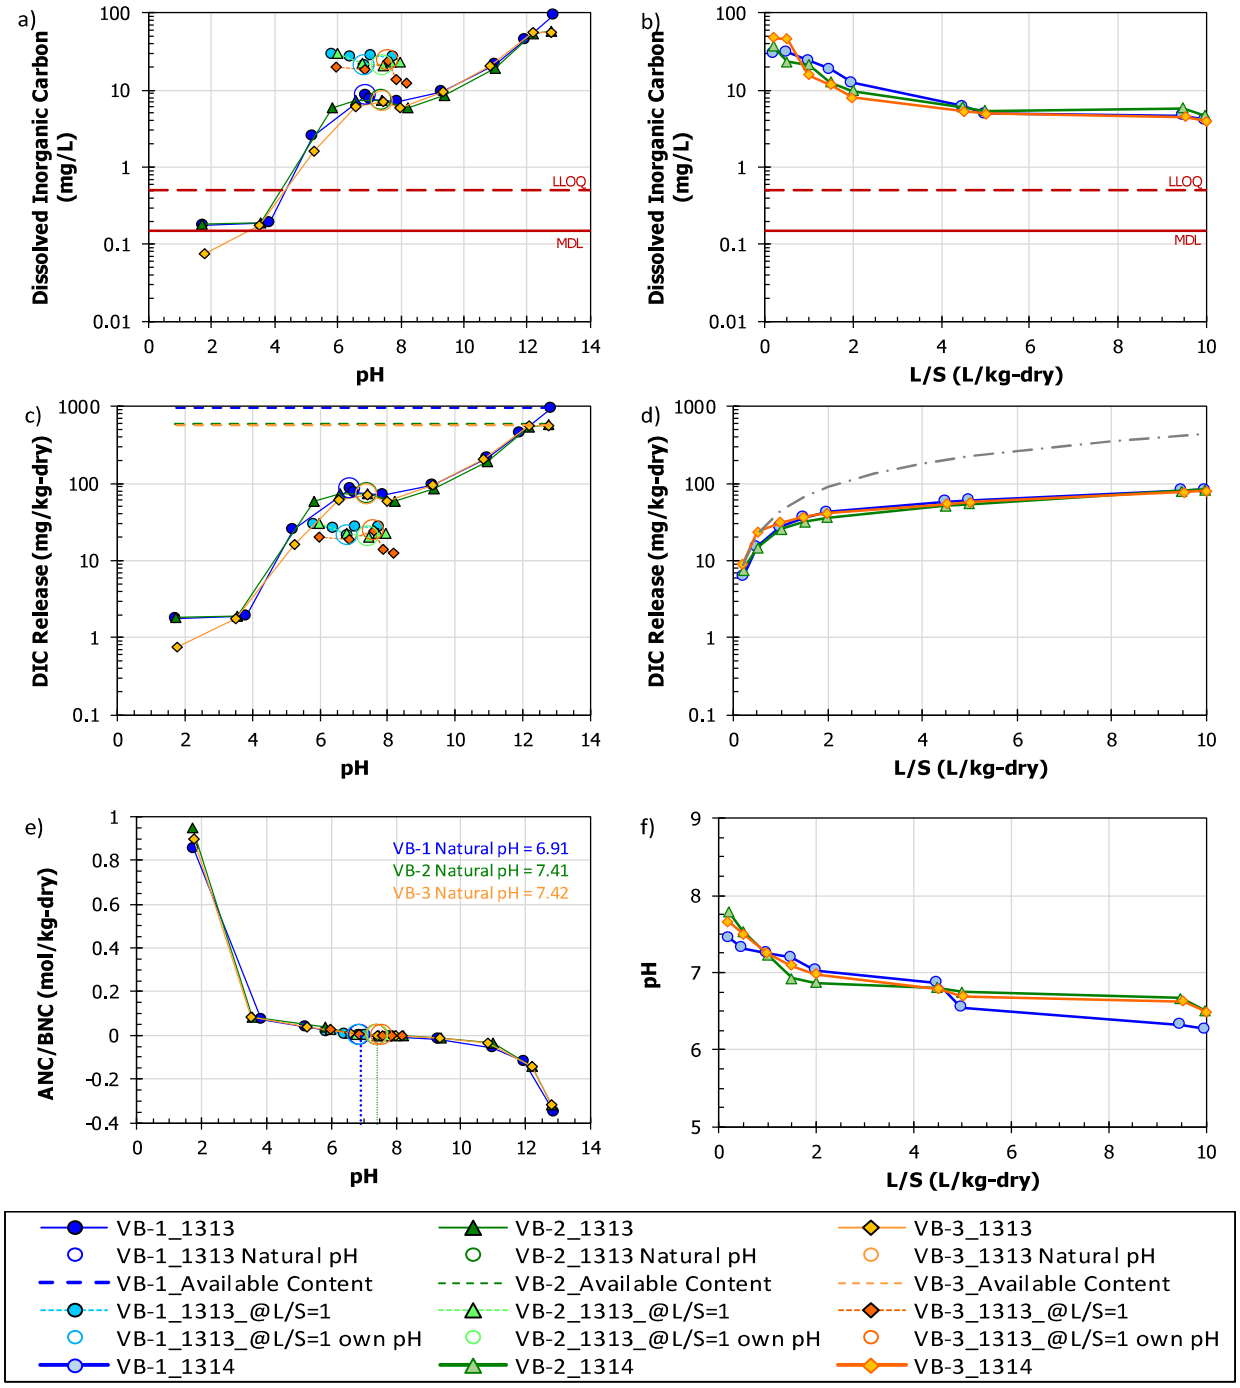

Figure D-13
Dissolved inorganic carbon LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

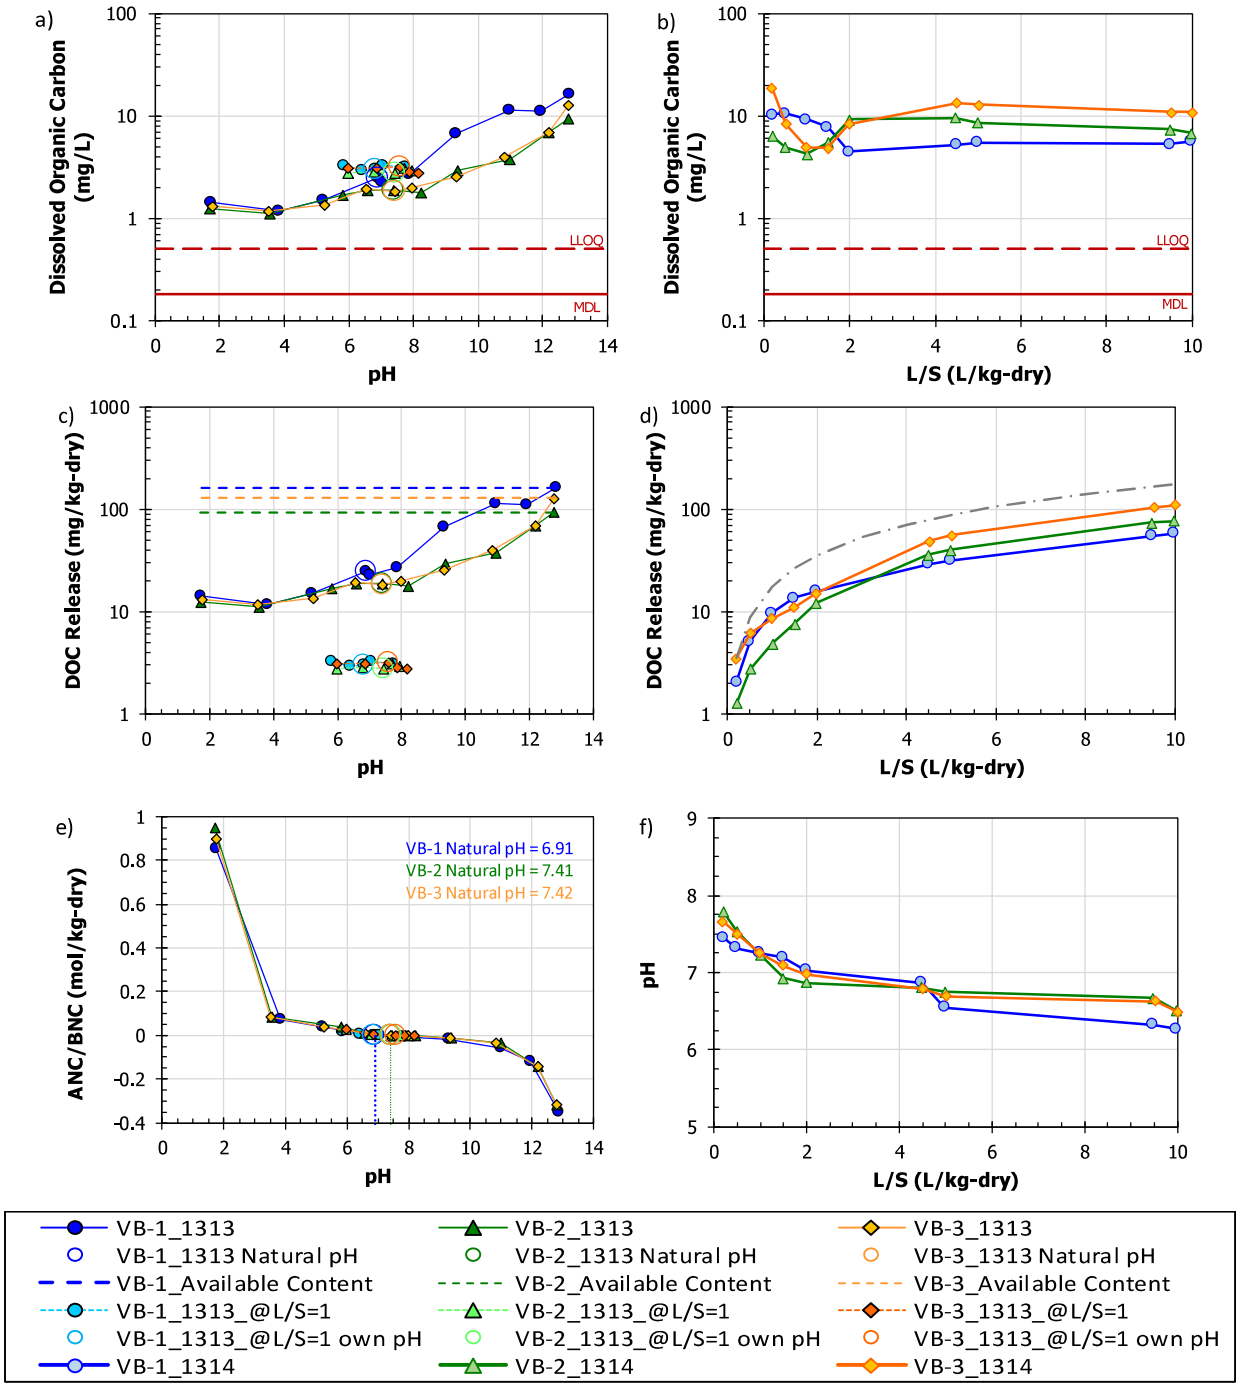

Figure D-14
Dissolved organic carbon LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

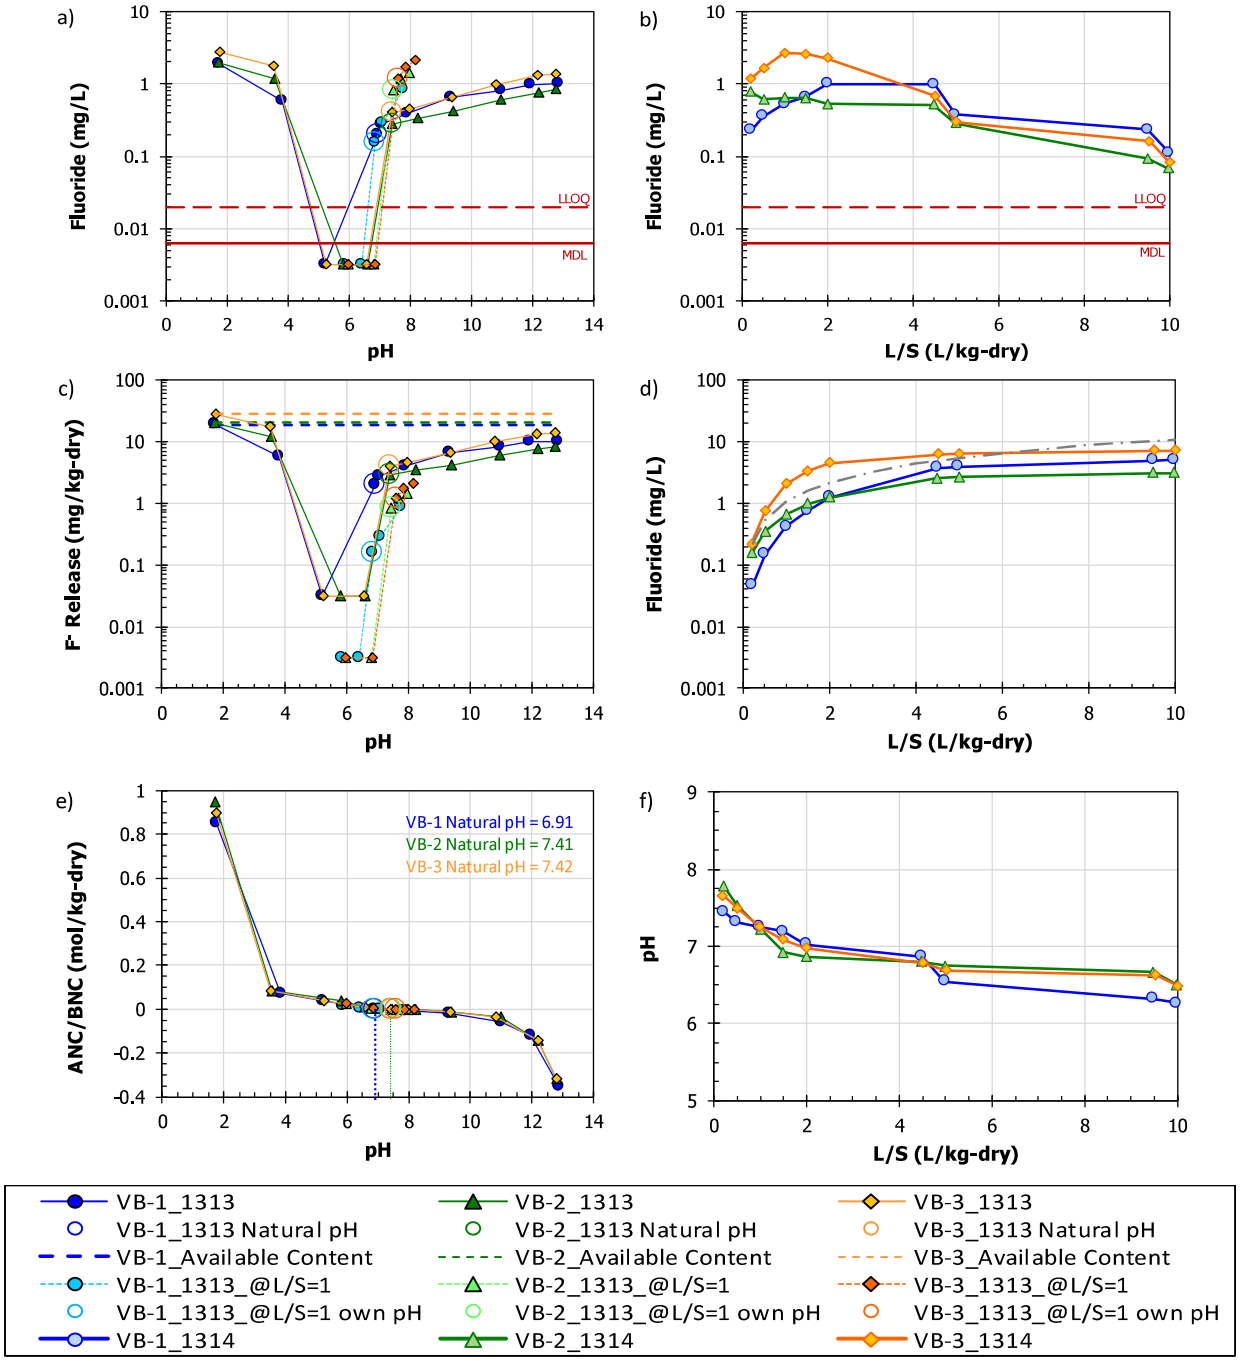

Figure D-15
Fluoride LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

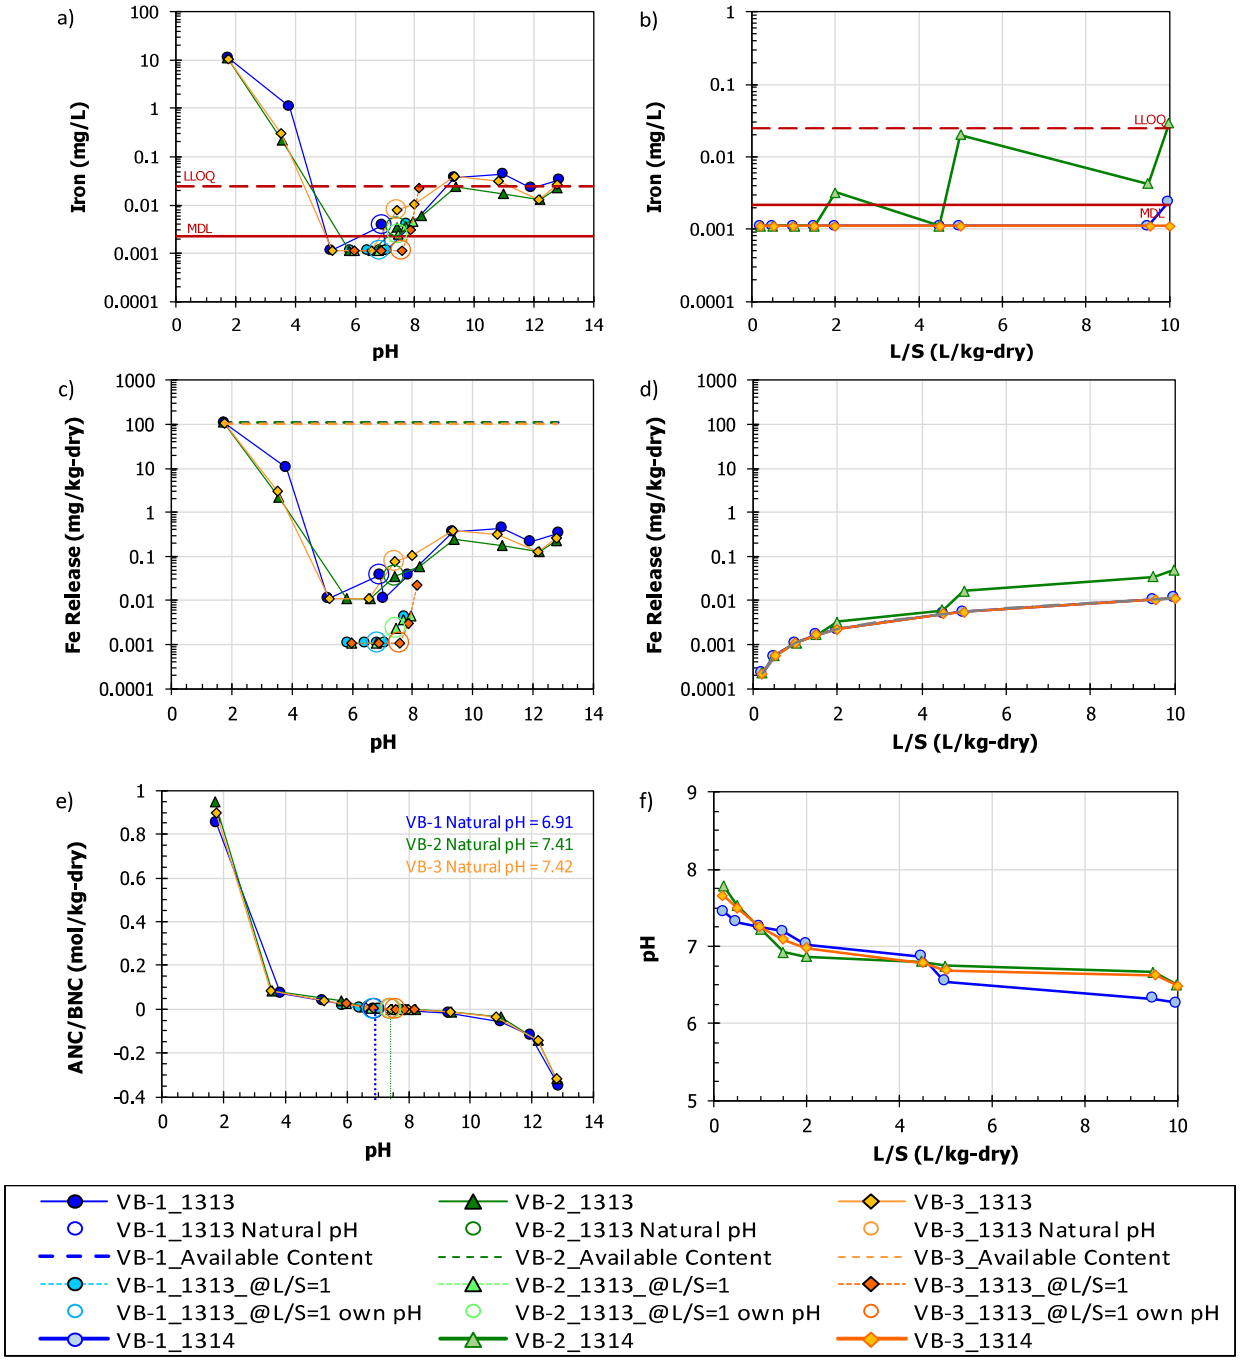

Figure D-16
Iron LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

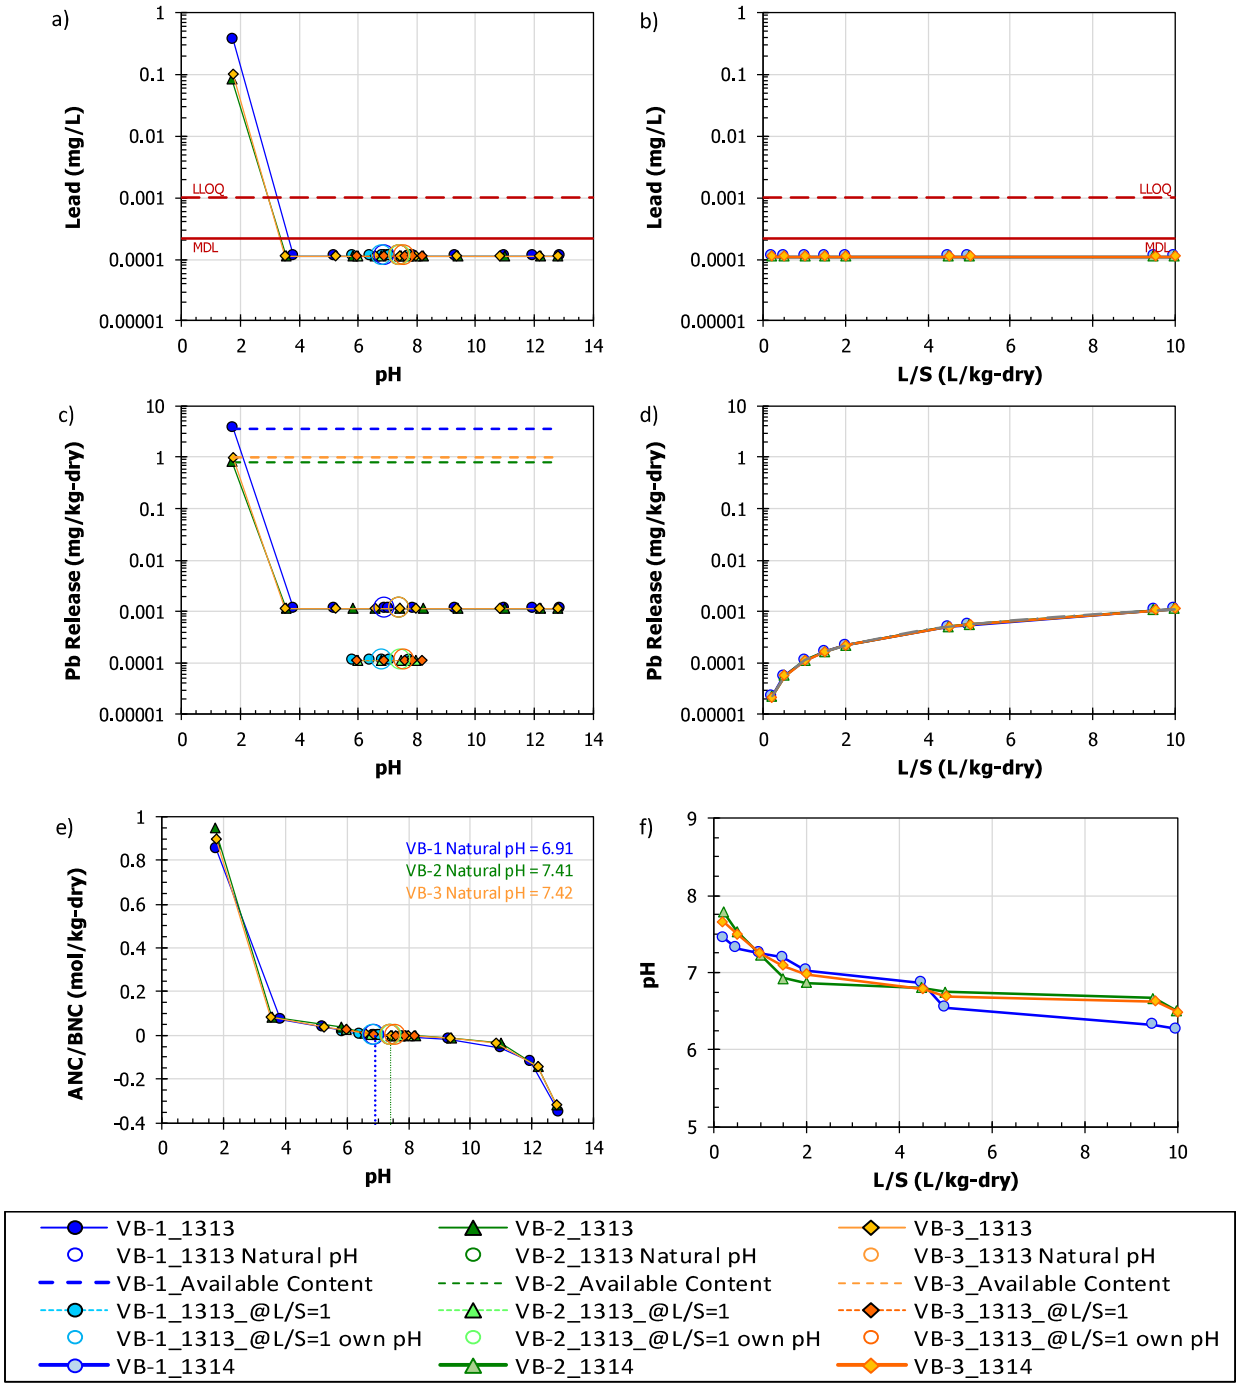

Figure D-17
Lead LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

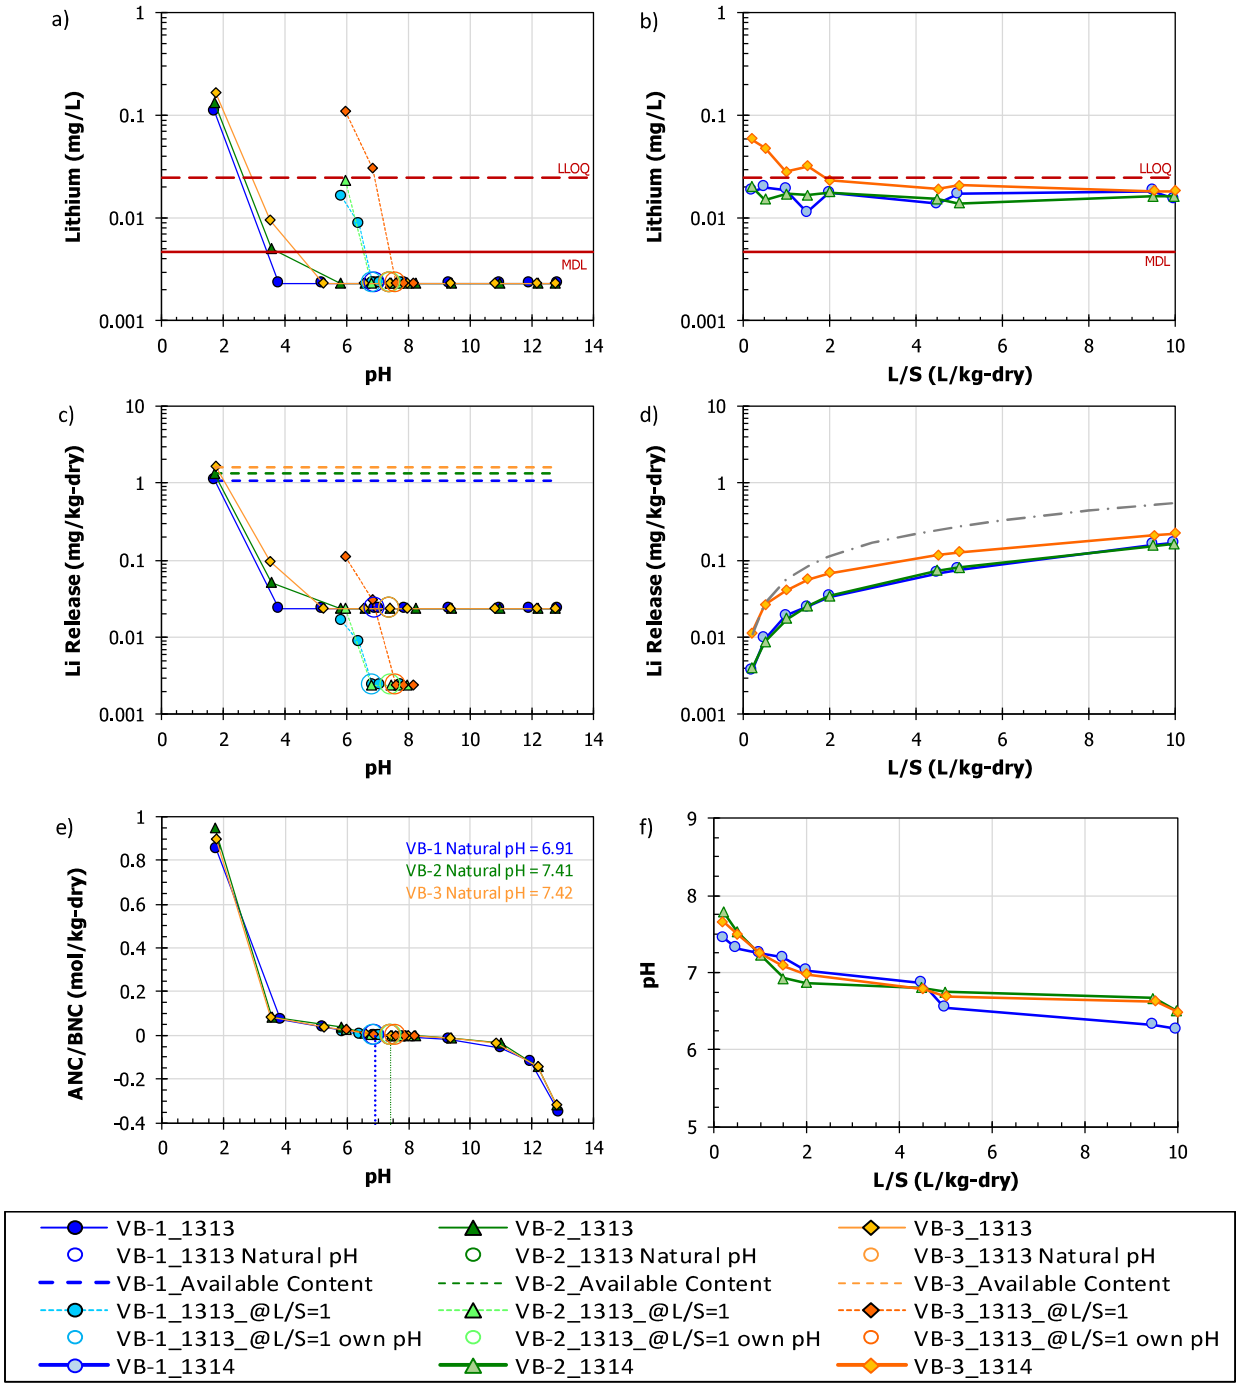

Figure D-18
Lithium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

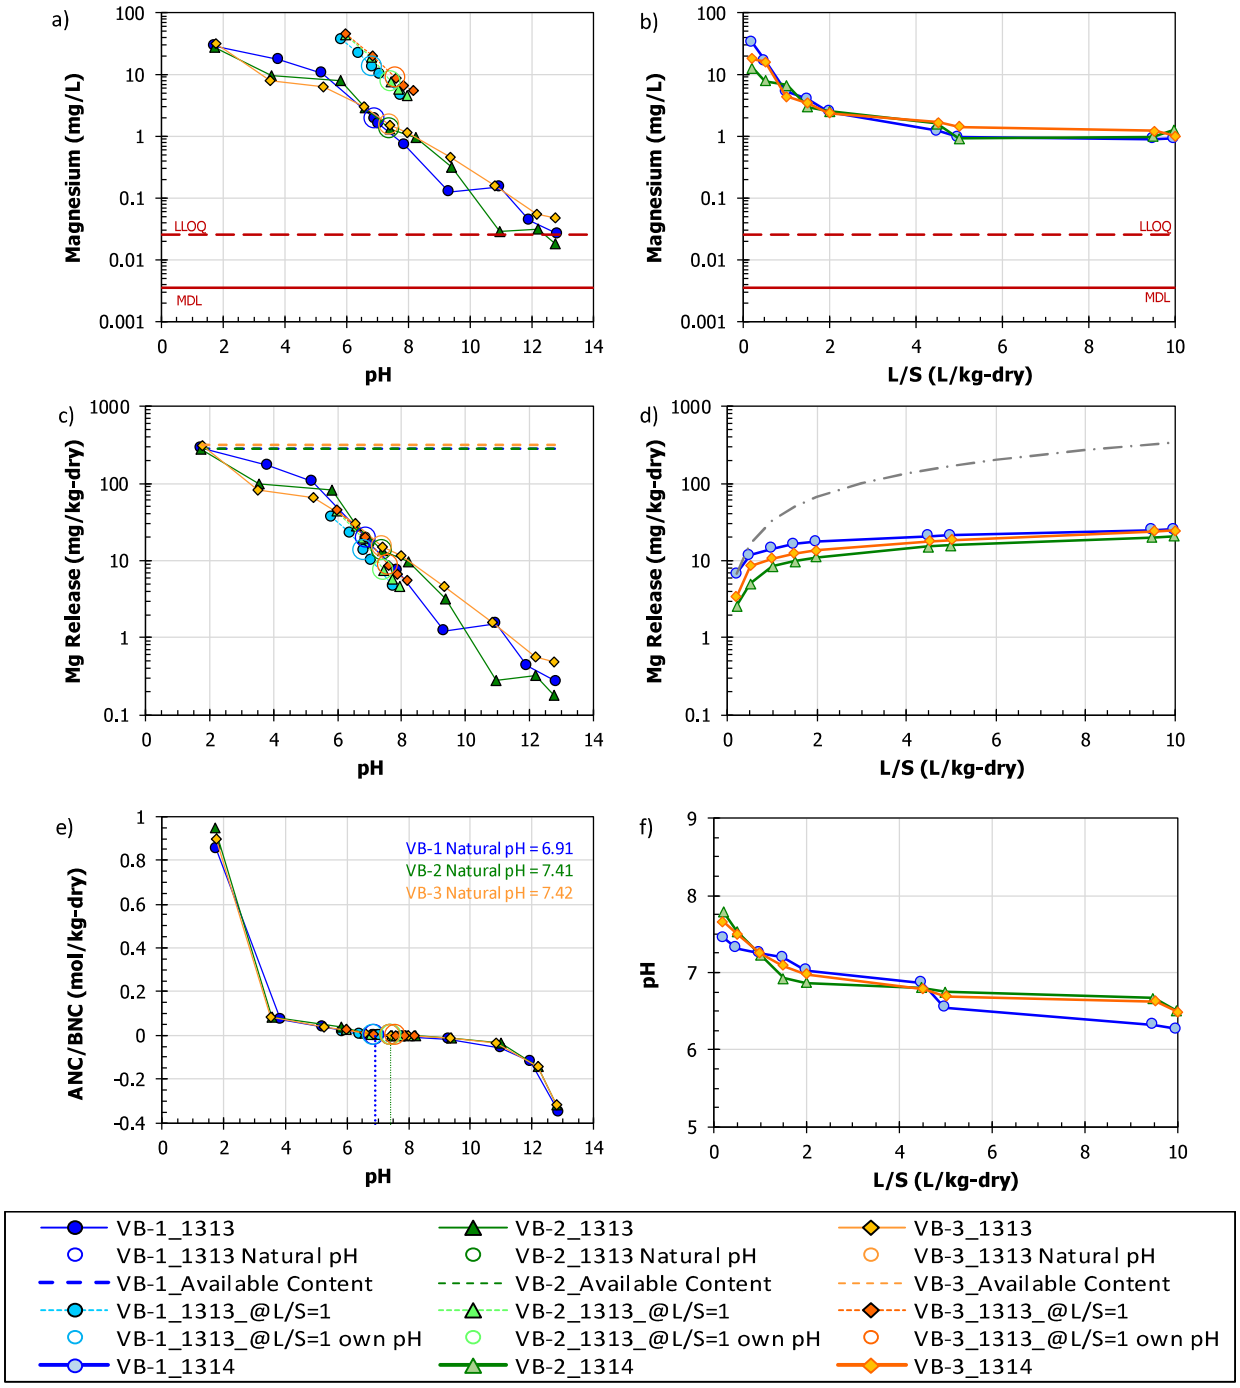

Figure D-19
Magnesium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

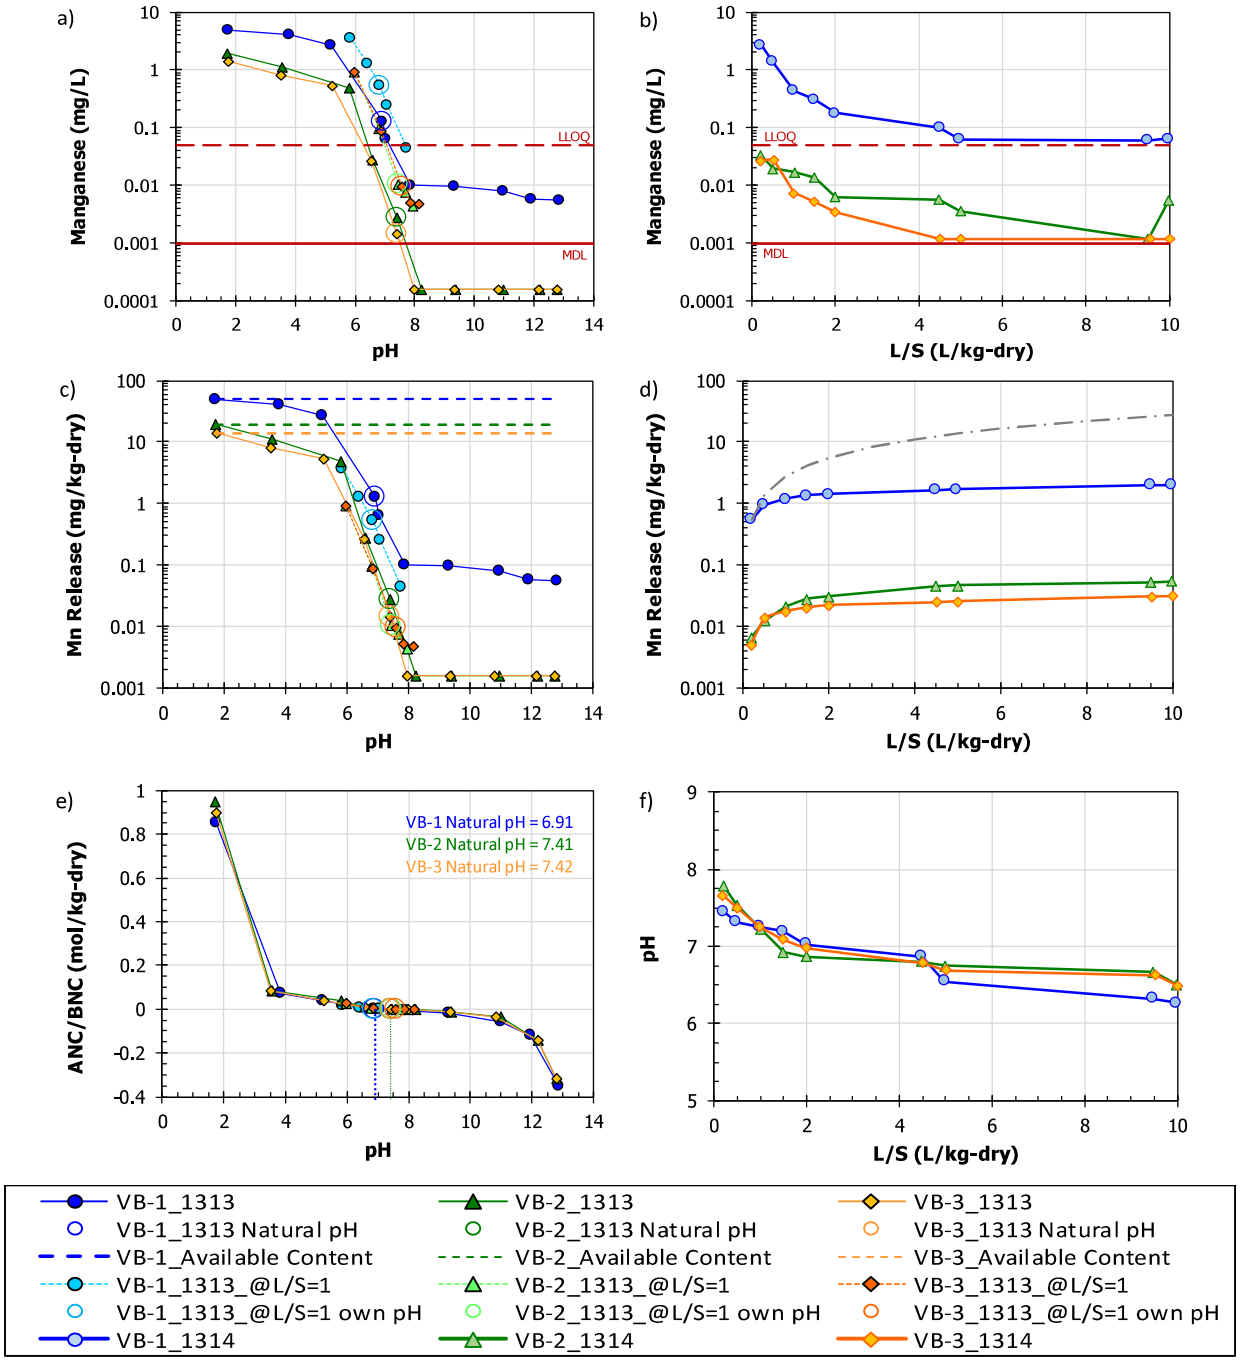

Figure D-20
Manganese LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

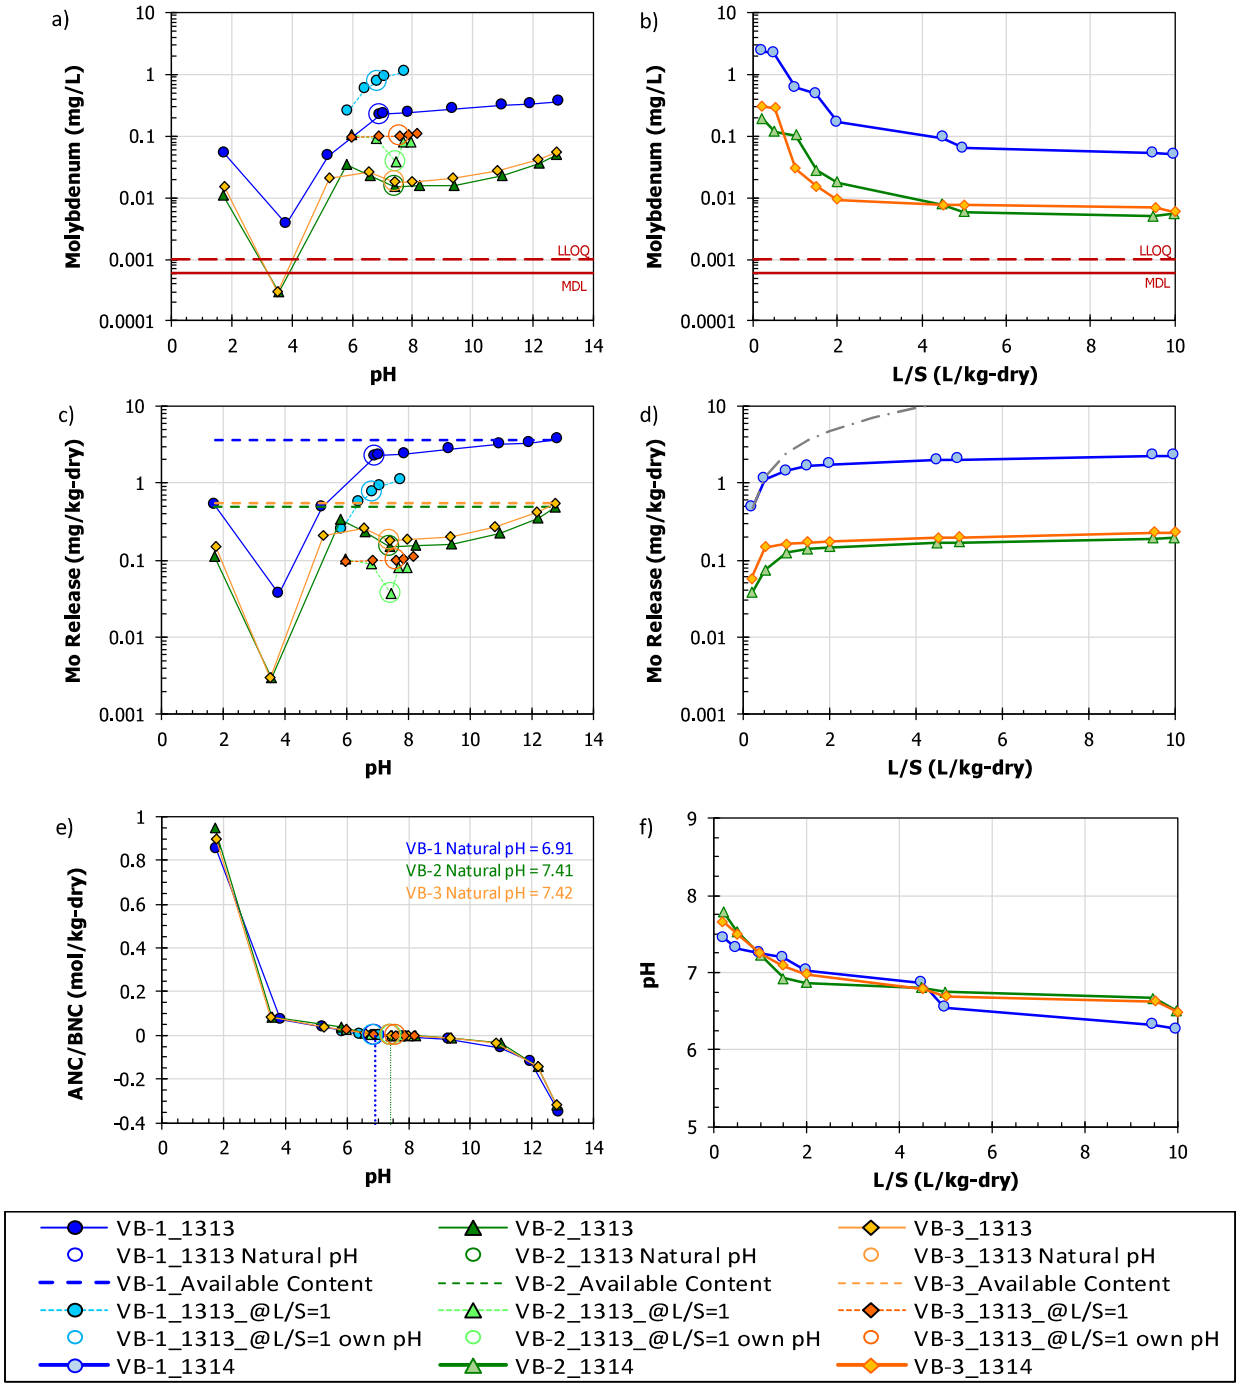

Figure D-21
Molybdenum LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

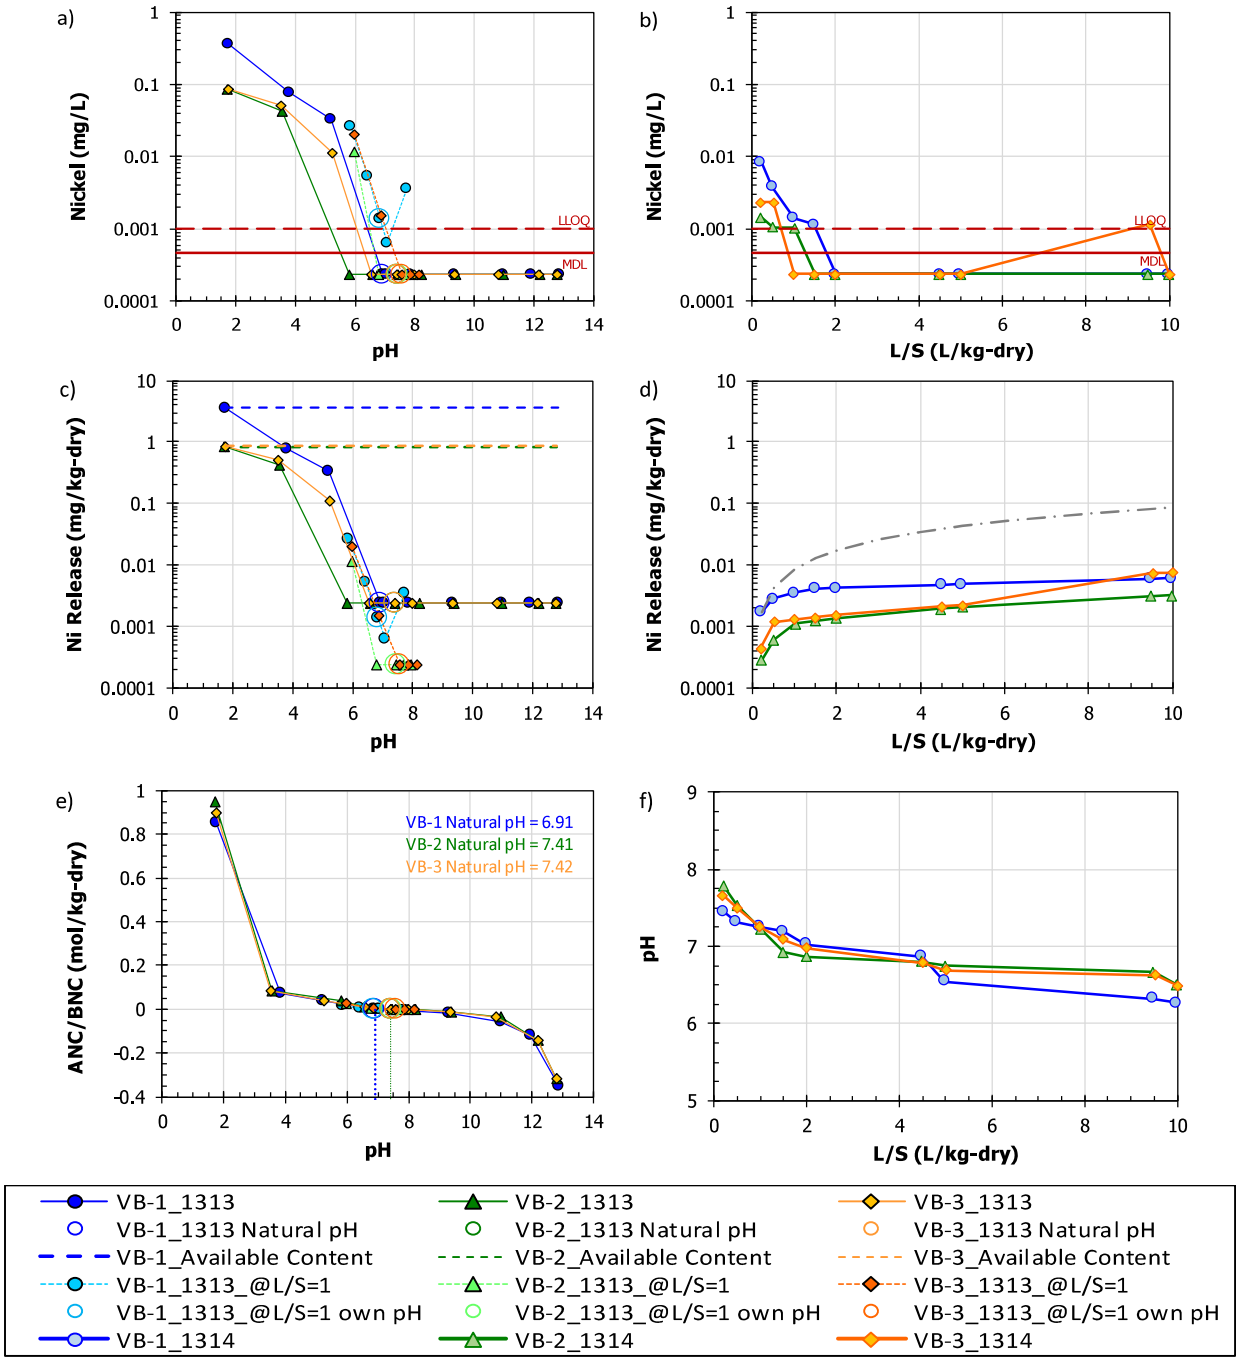

Figure D-22
Nickel LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

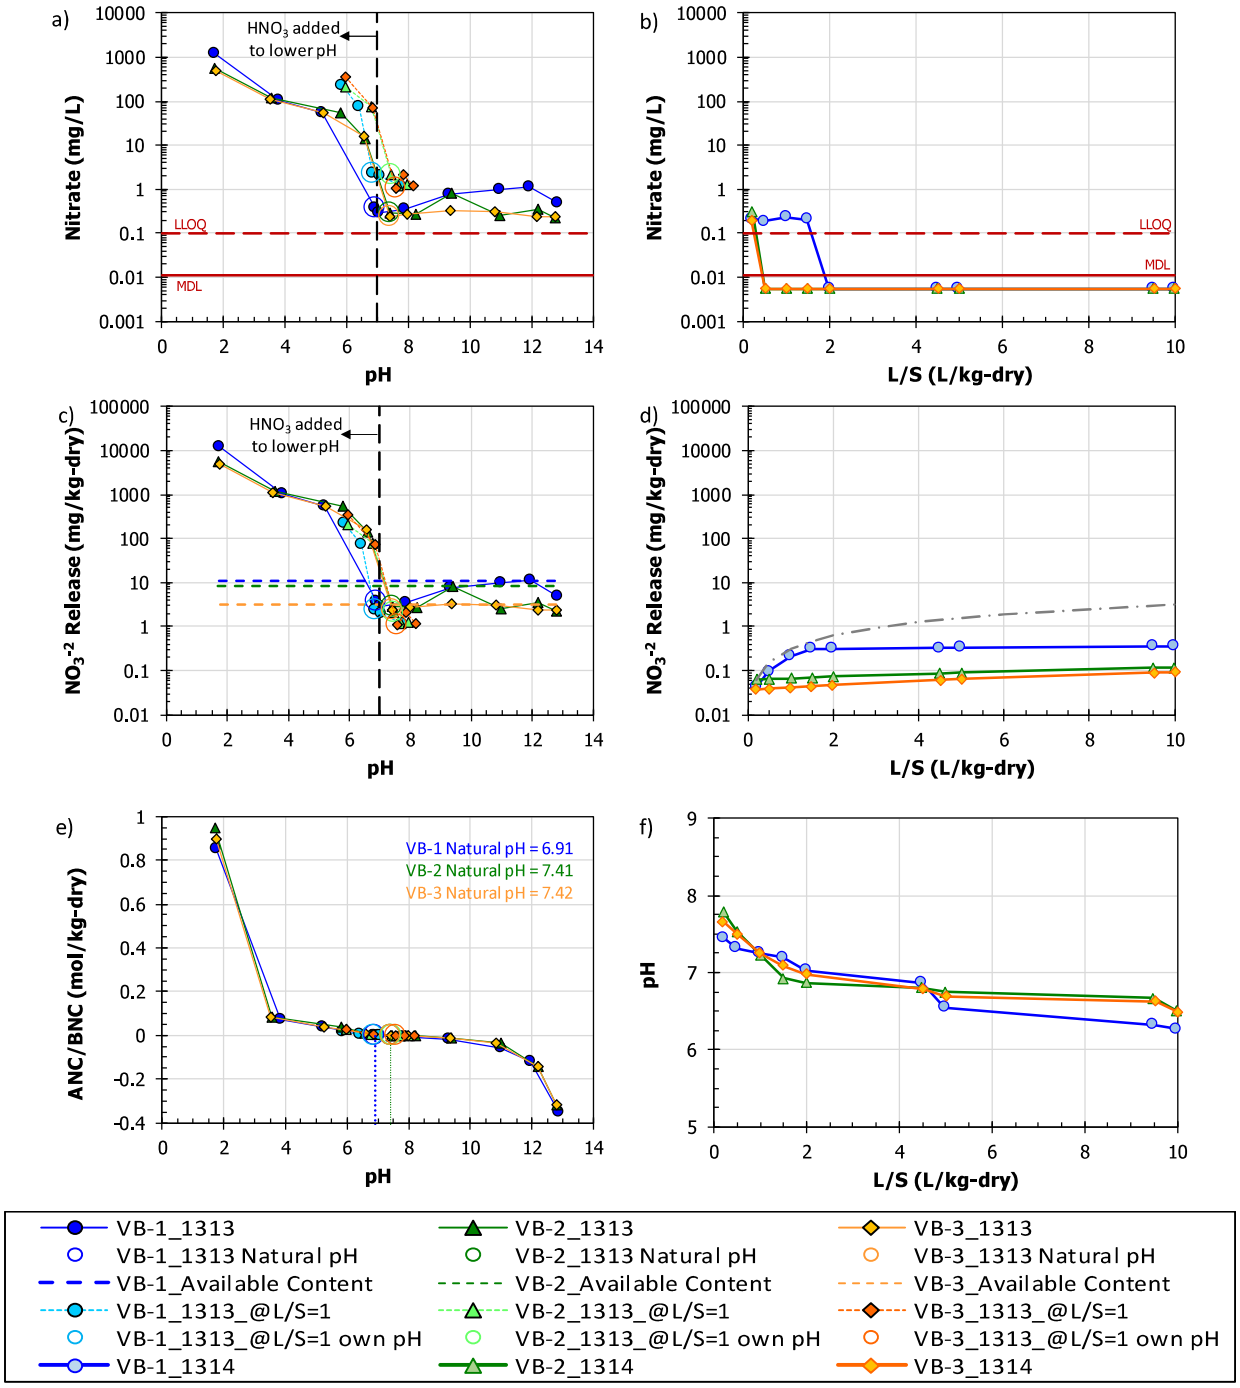

Figure D-23
Nitrate LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

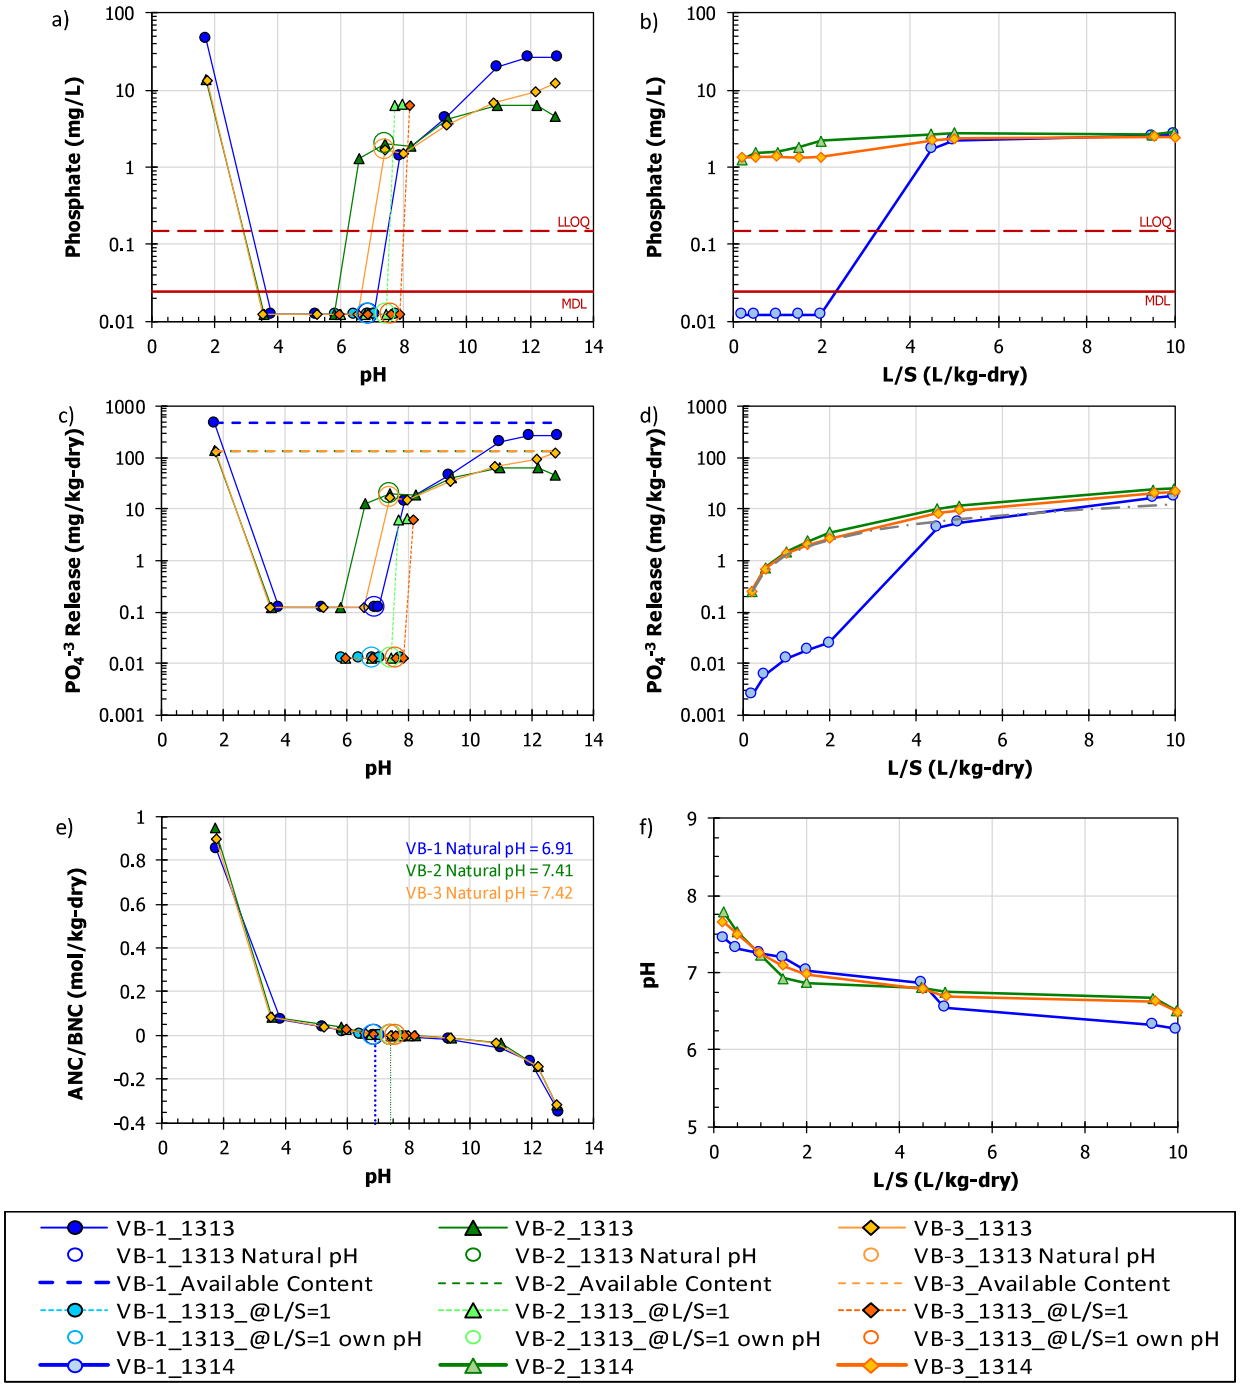

Figure D-24
Phosphate LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

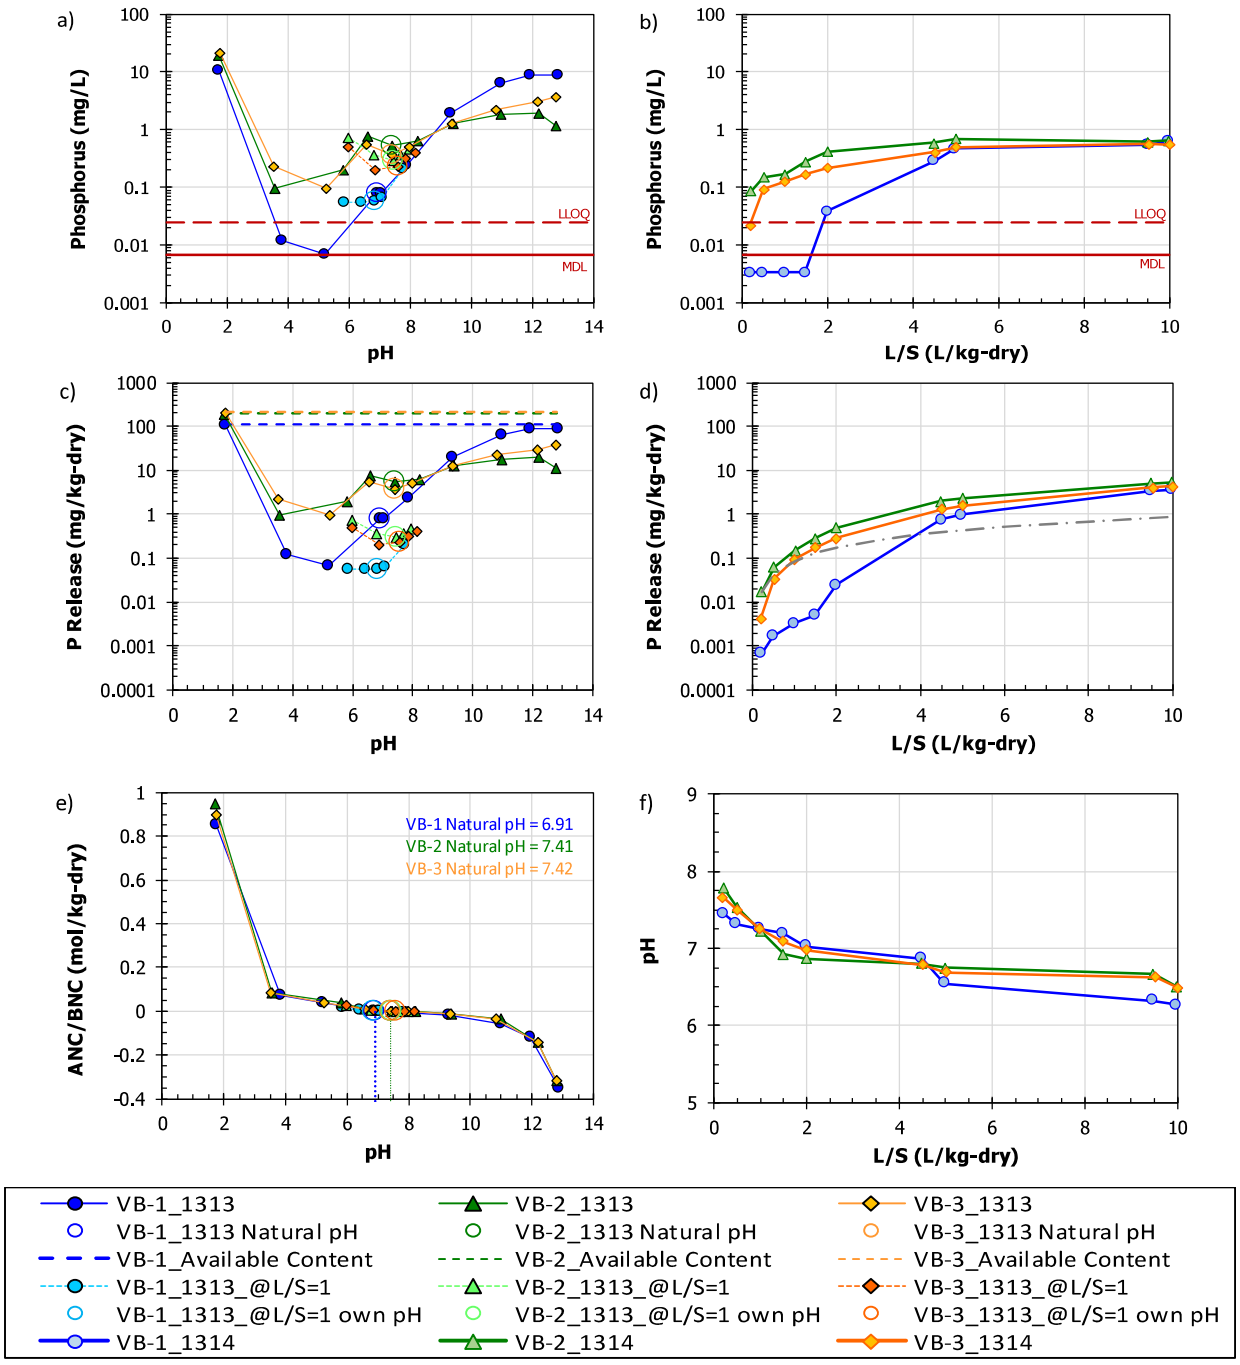

Figure D-25
Phosphorus LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

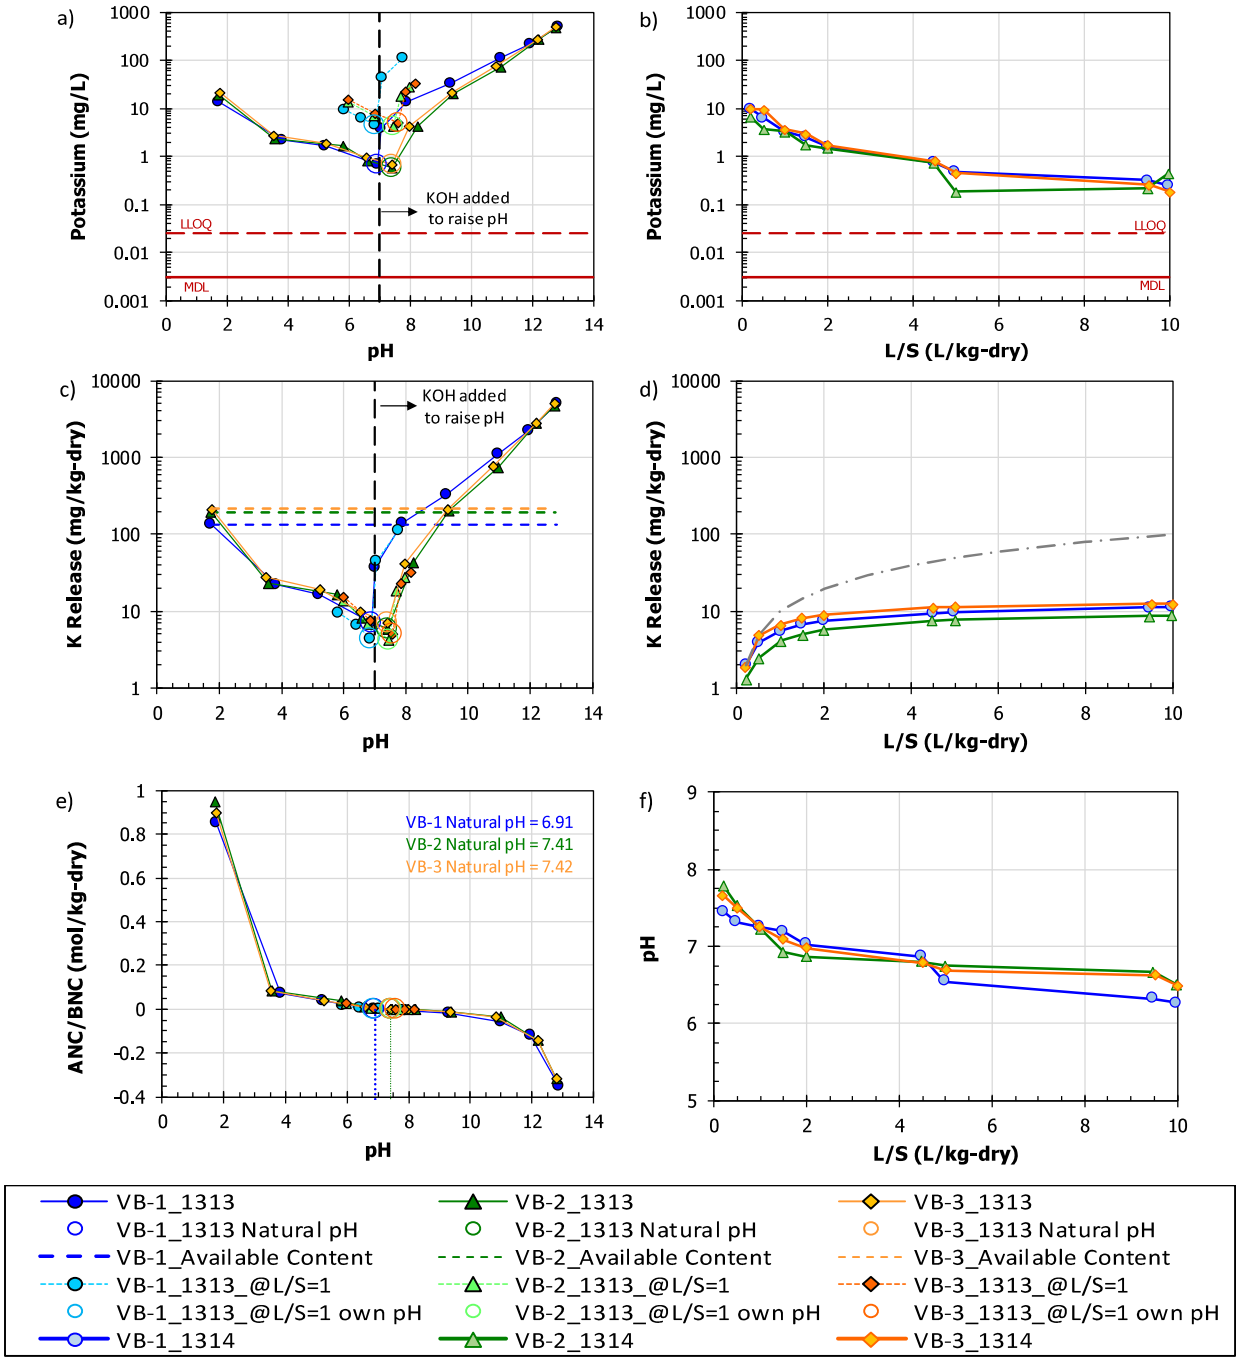

Figure D-26
Potassium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

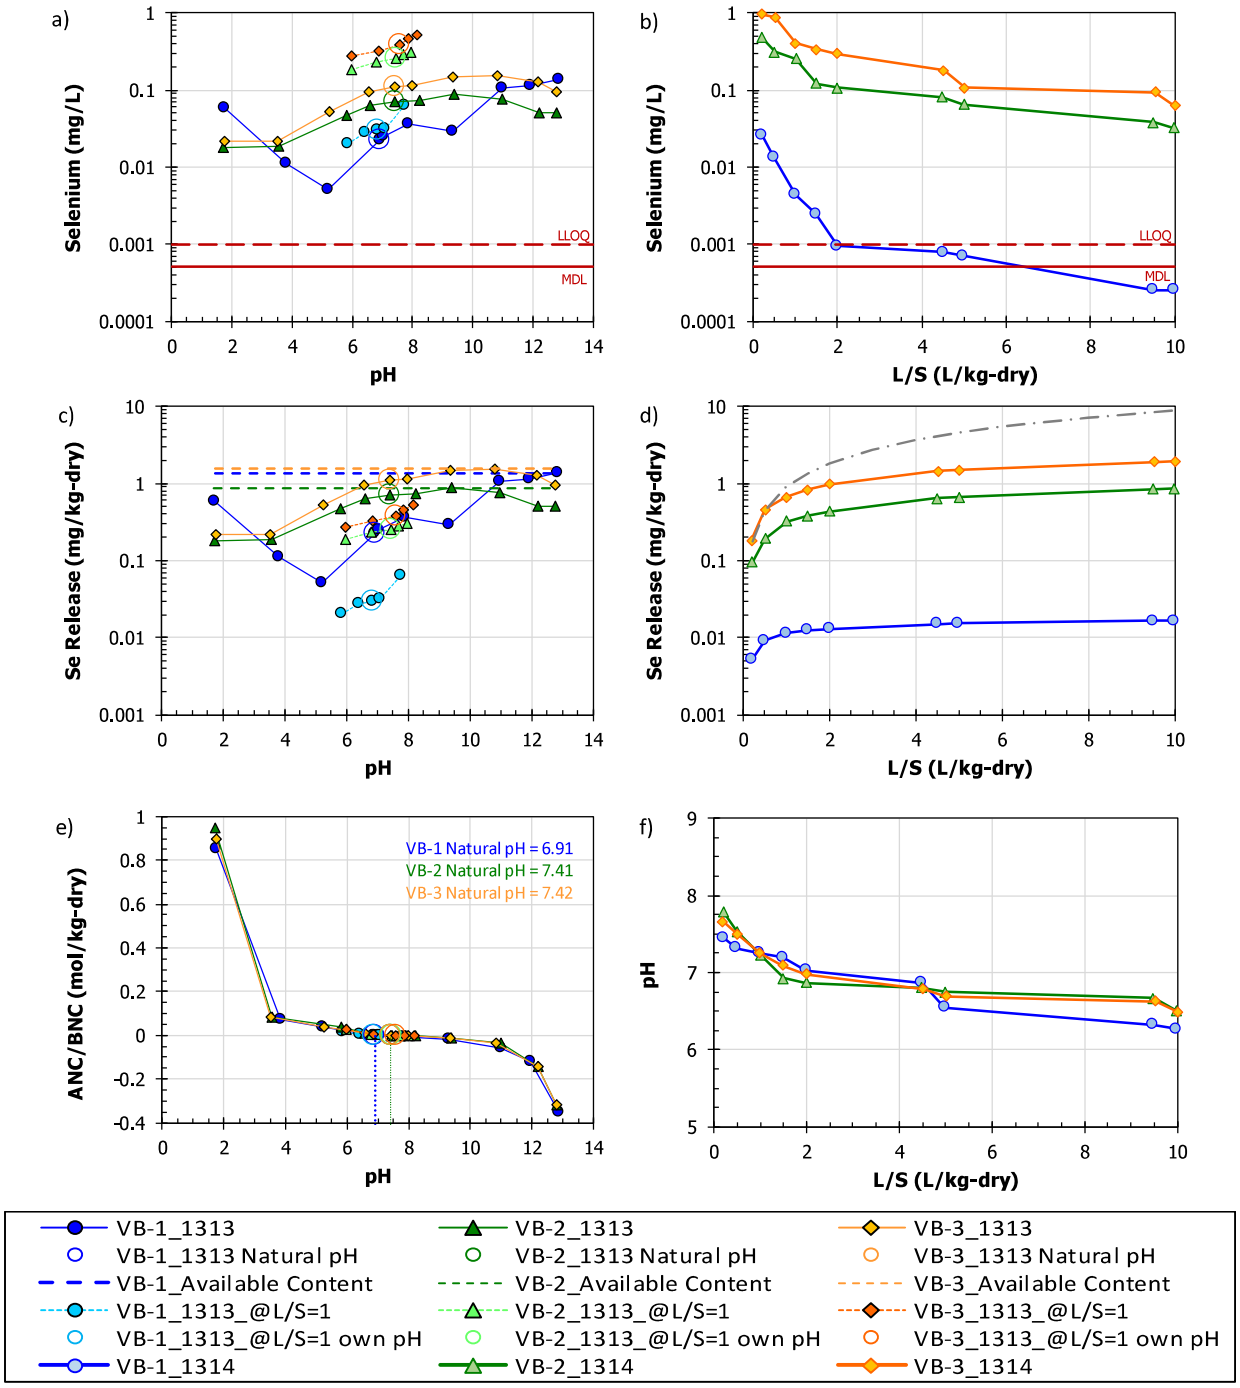

Figure D-27
Selenium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

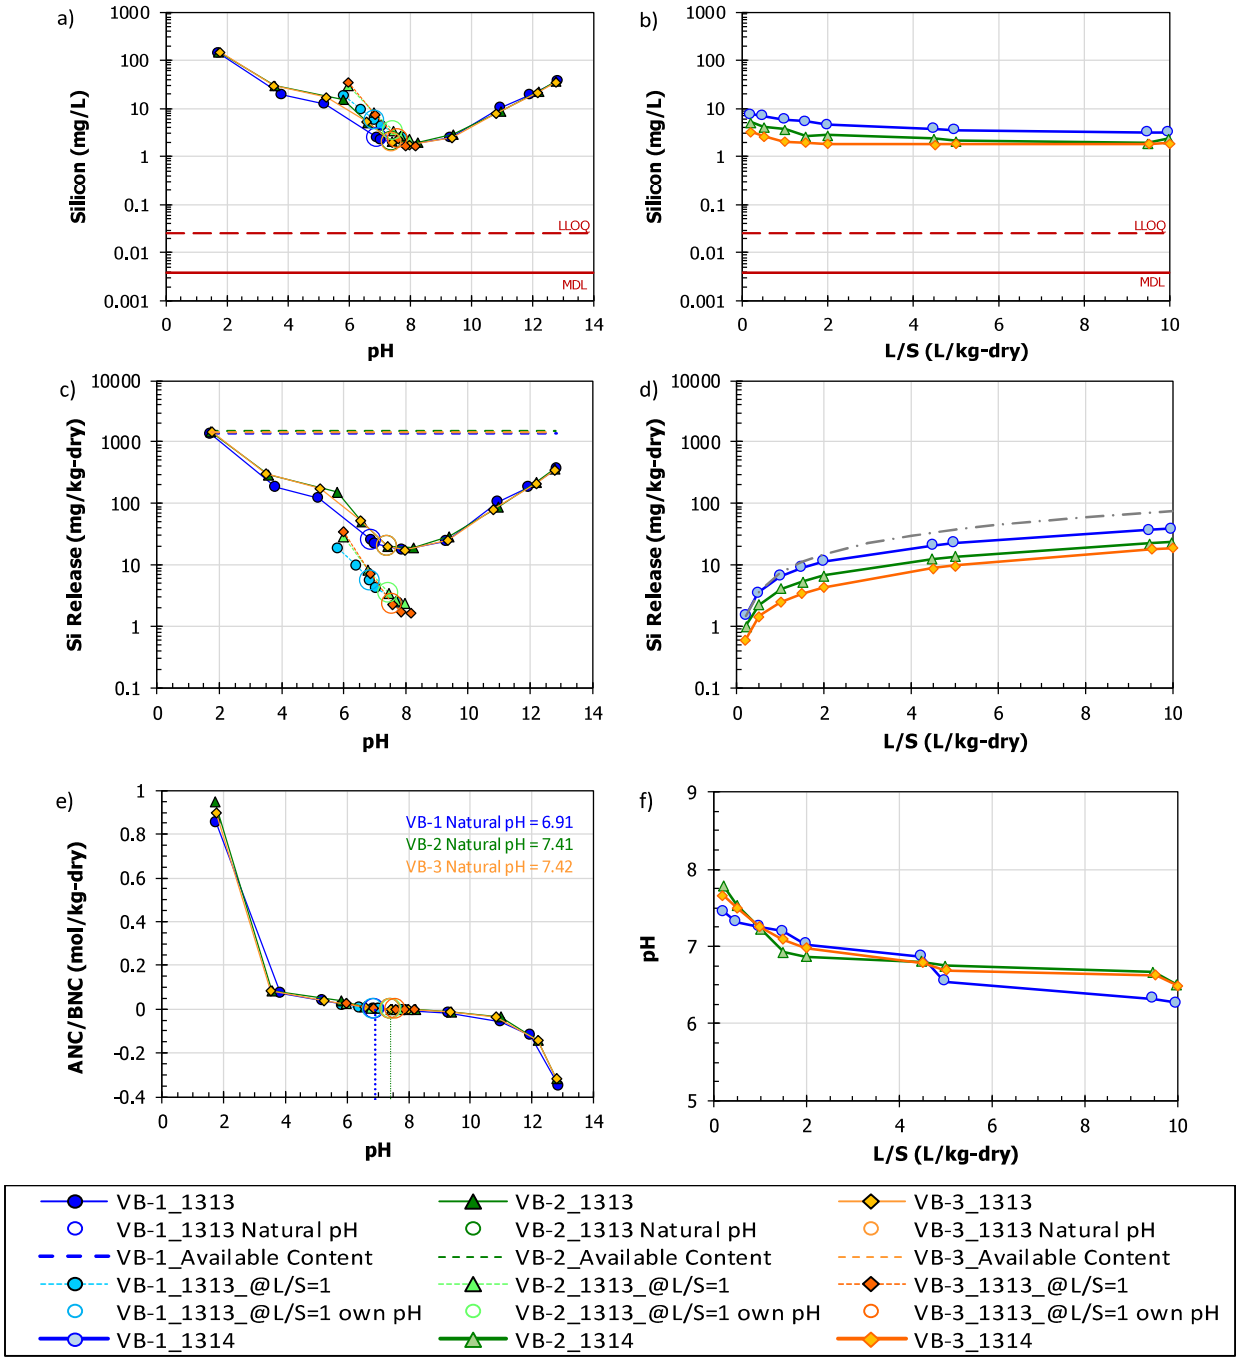

Figure D-28
Silicon LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

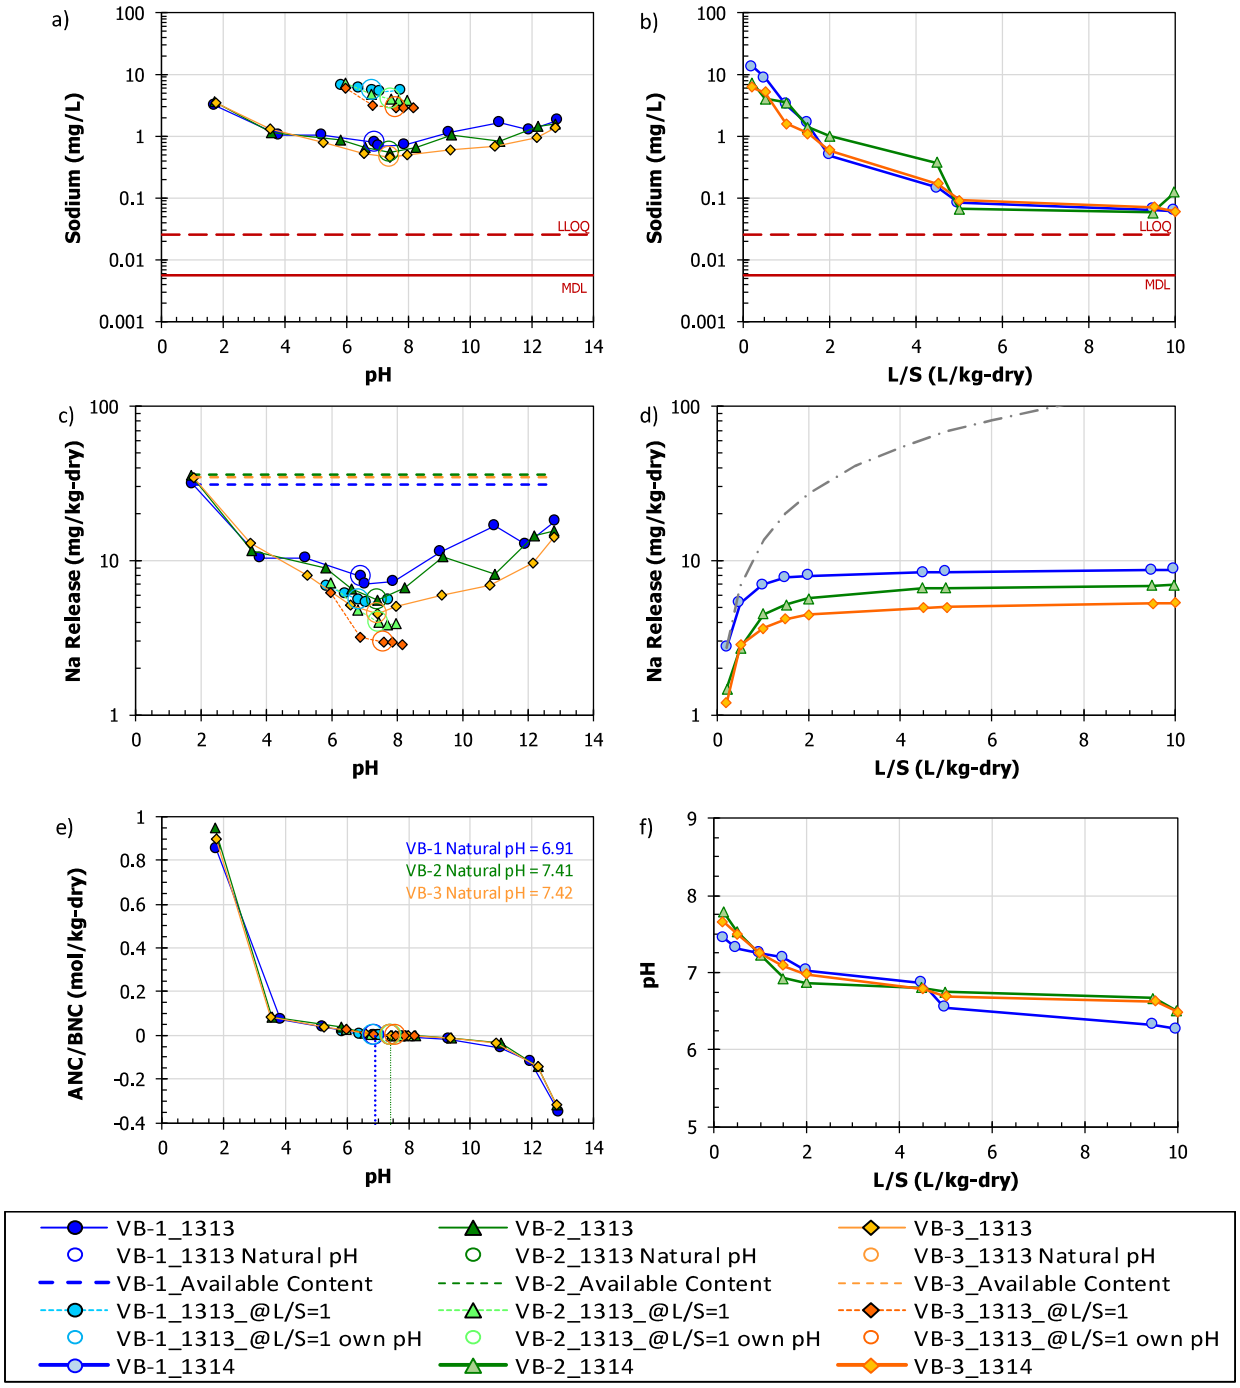

Figure D-29
Sodium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

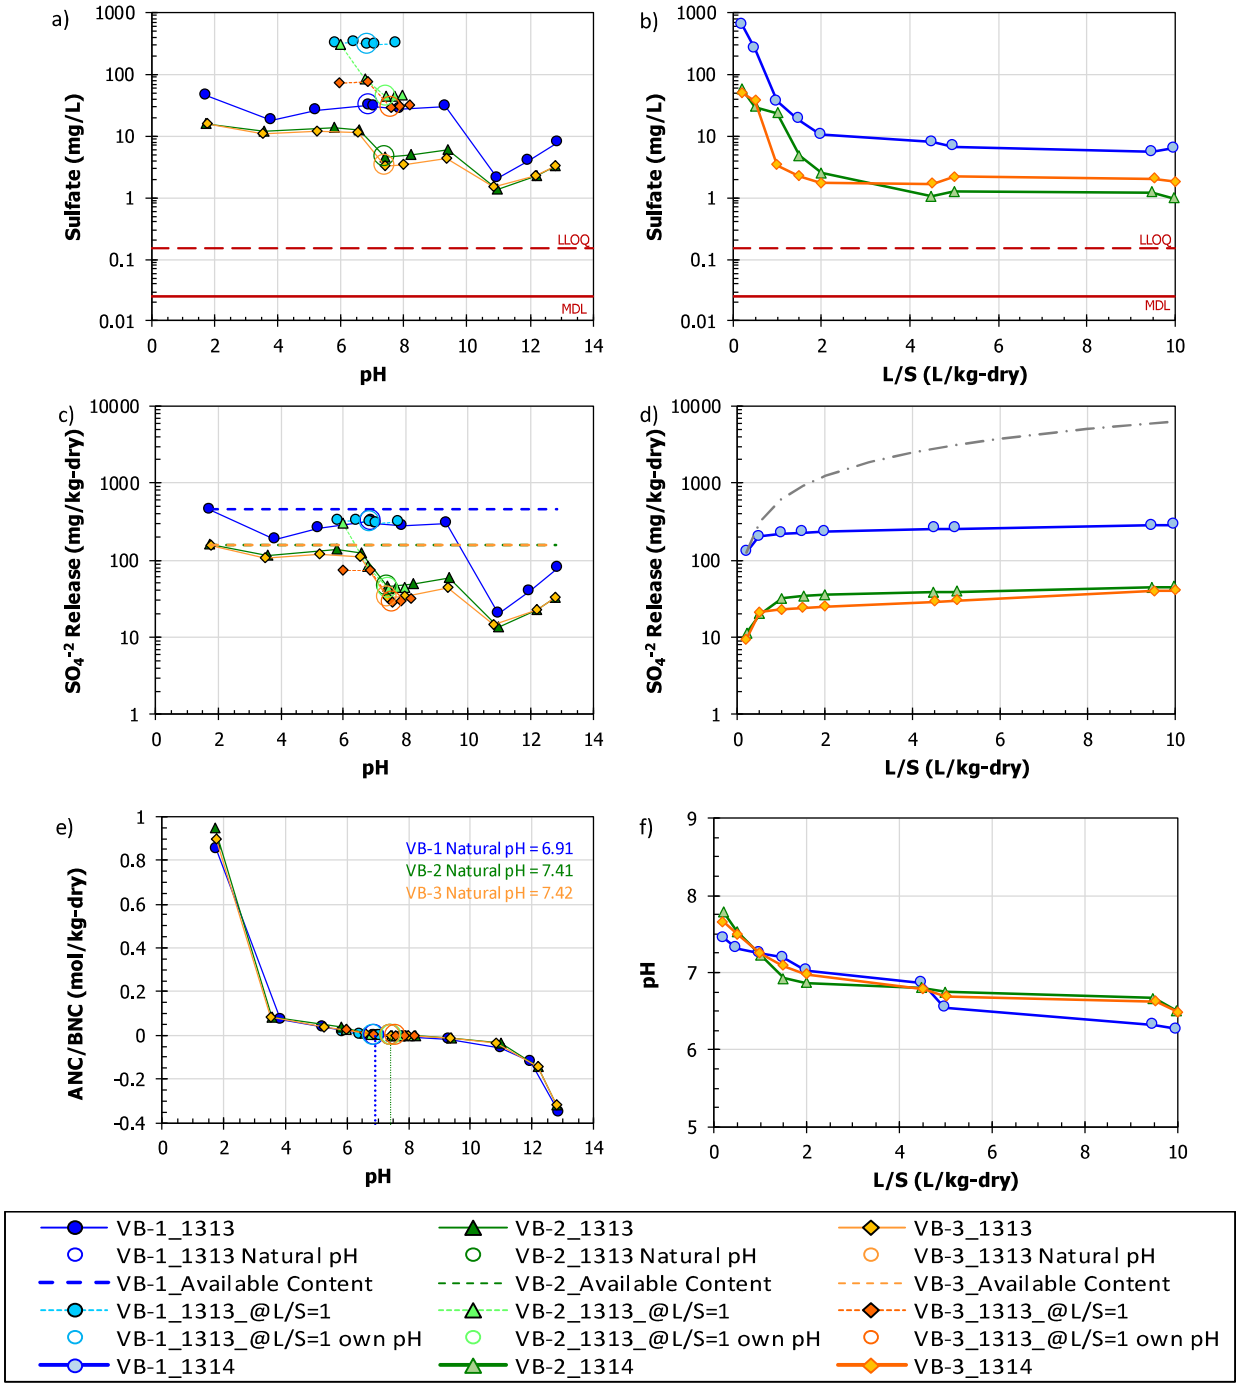

Figure D-30
Sulfate LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

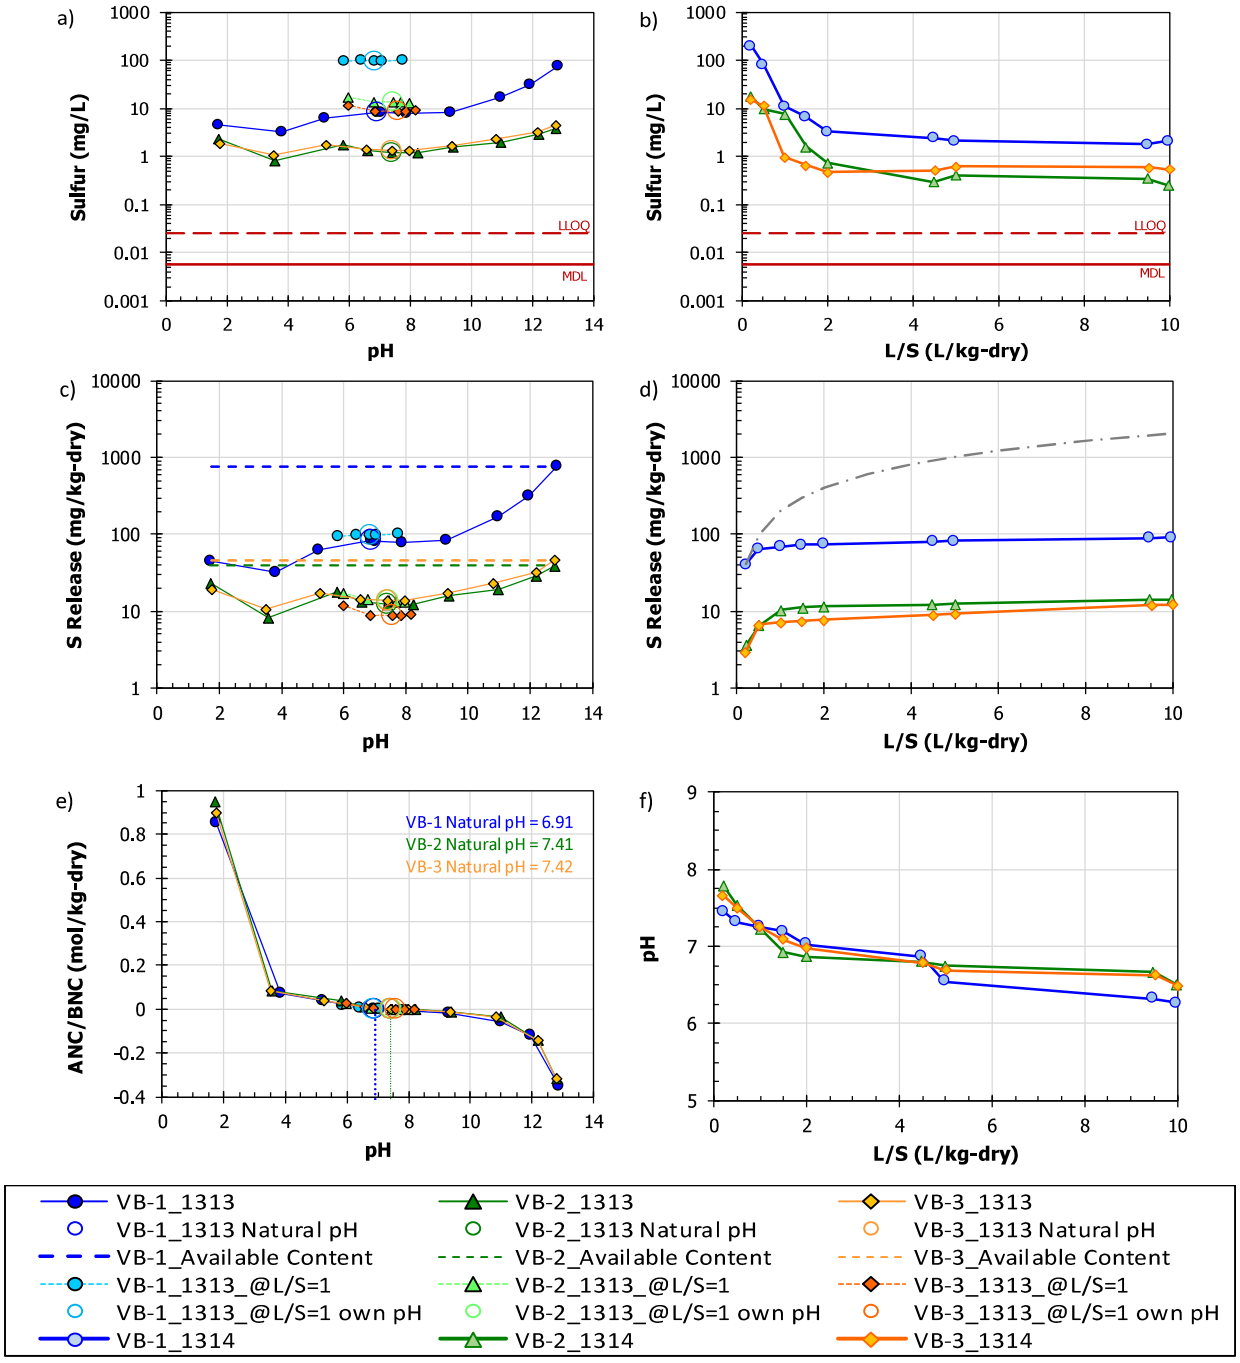

Figure D-31
Sulfur LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

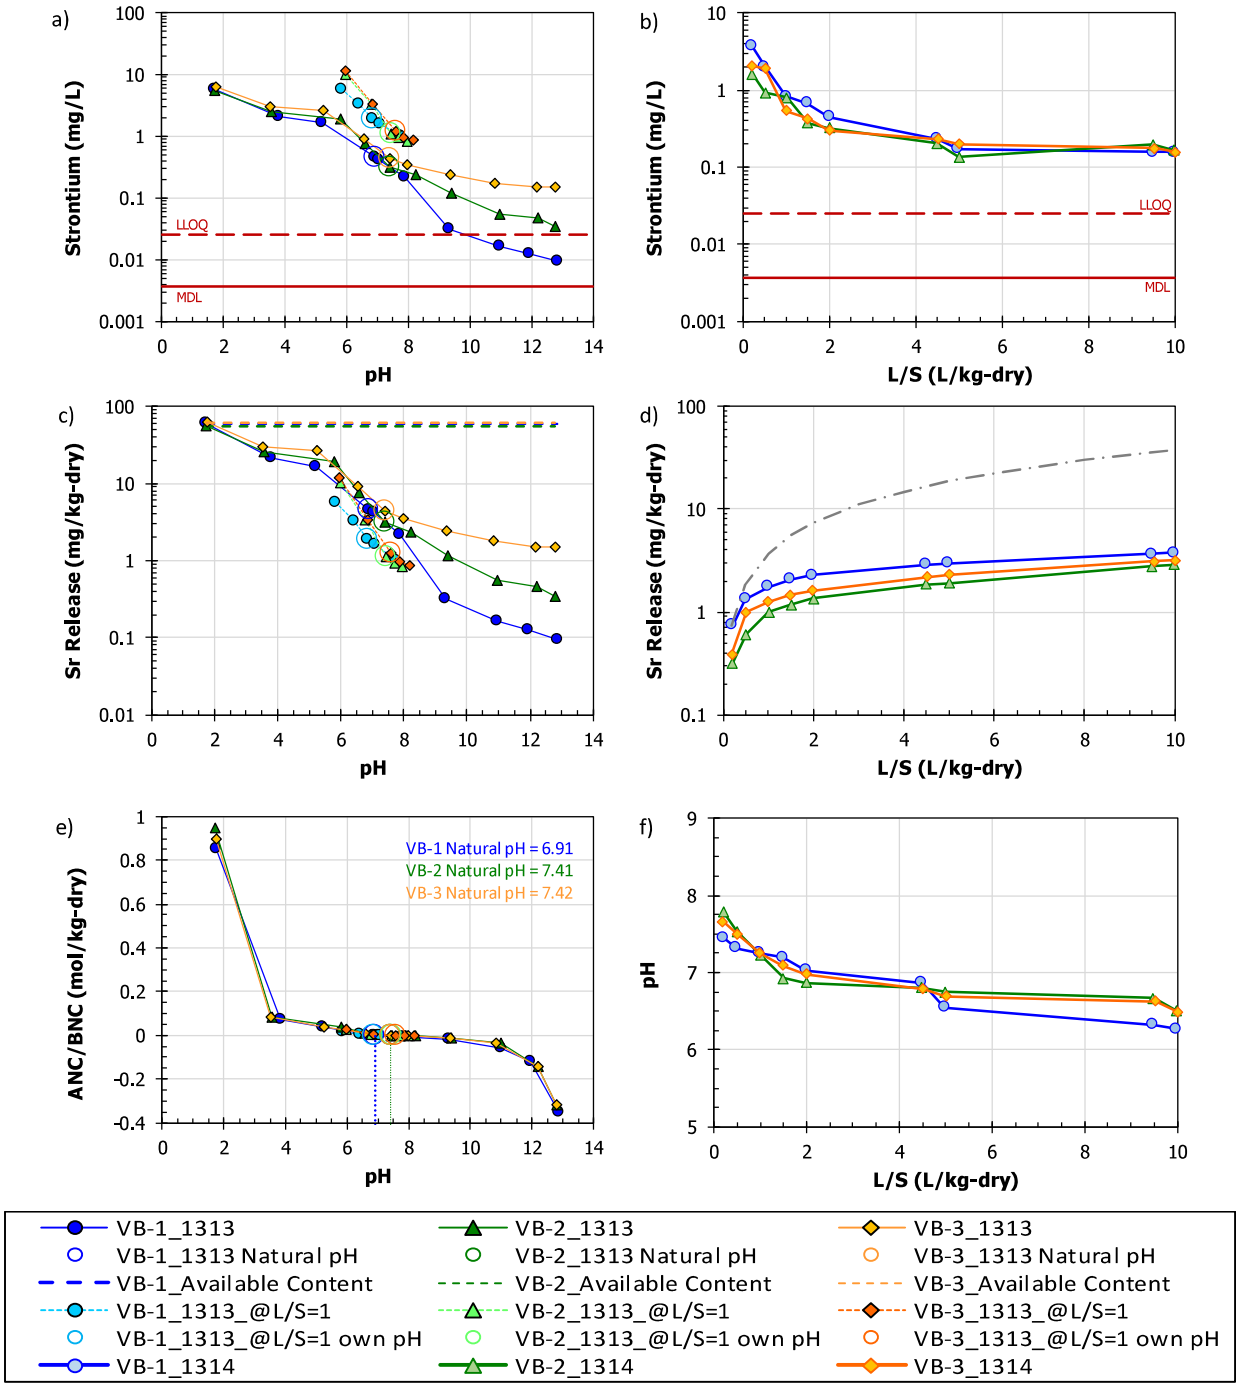

Figure D-32
Strontium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

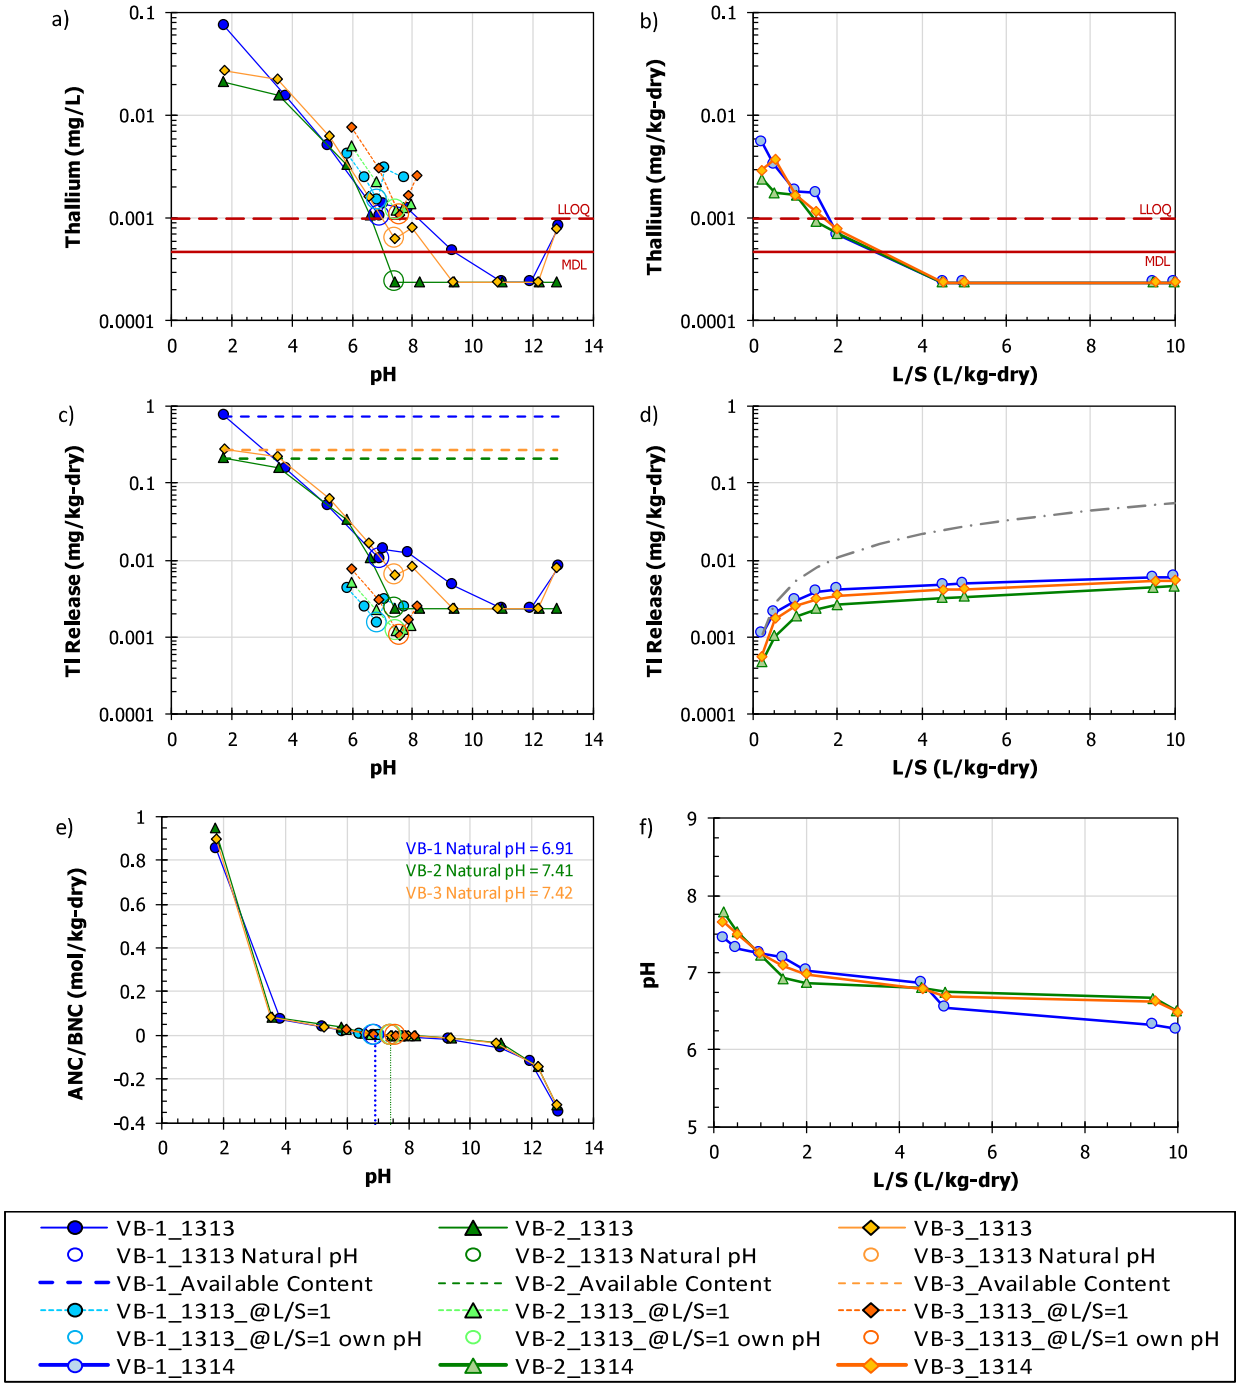

Figure D-33
Thallium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

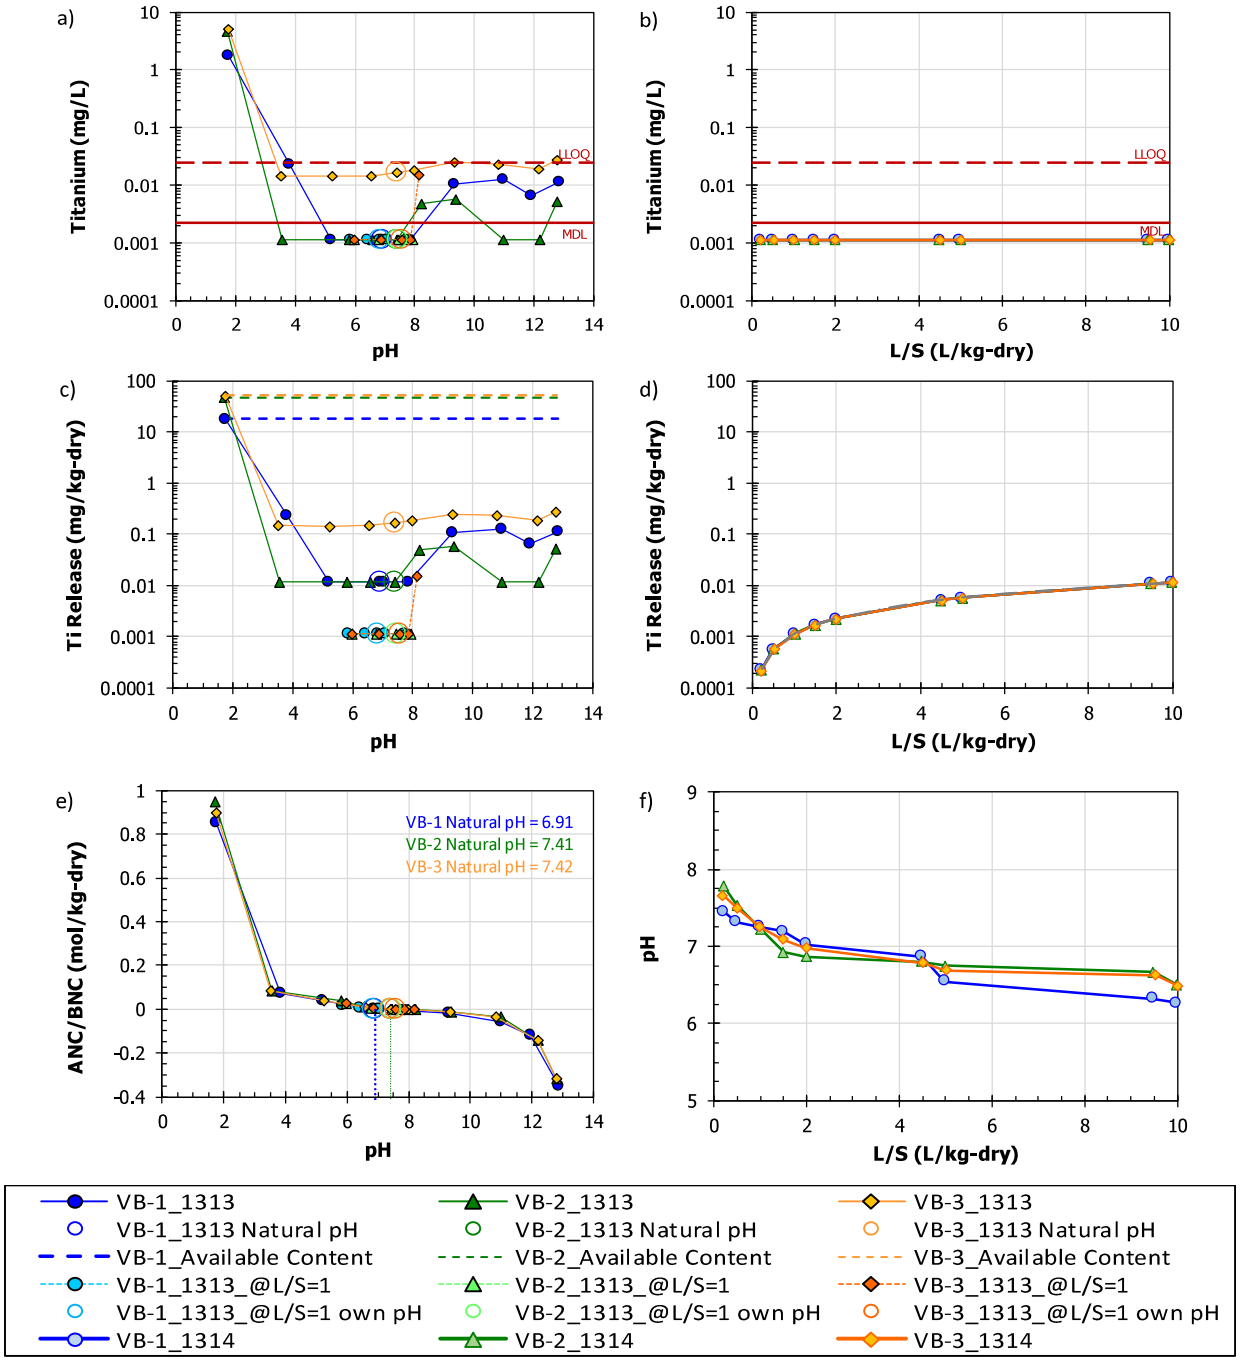

Figure D-34
Titanium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

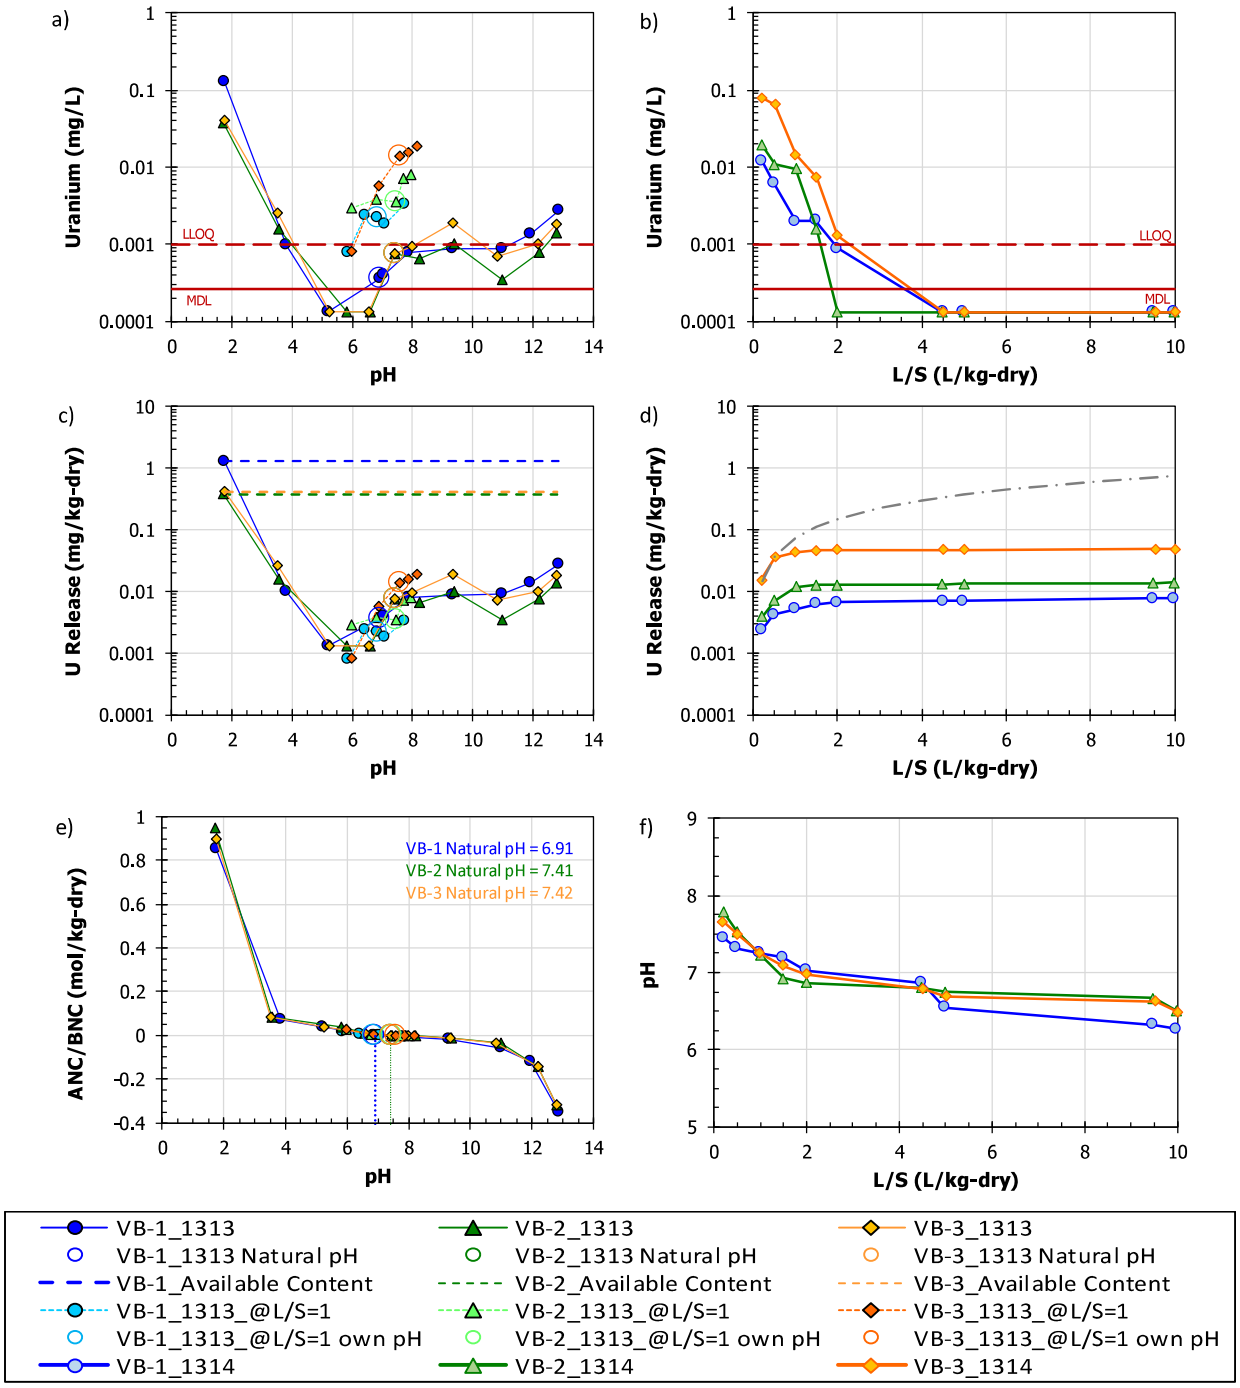

Figure D-35
Uranium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

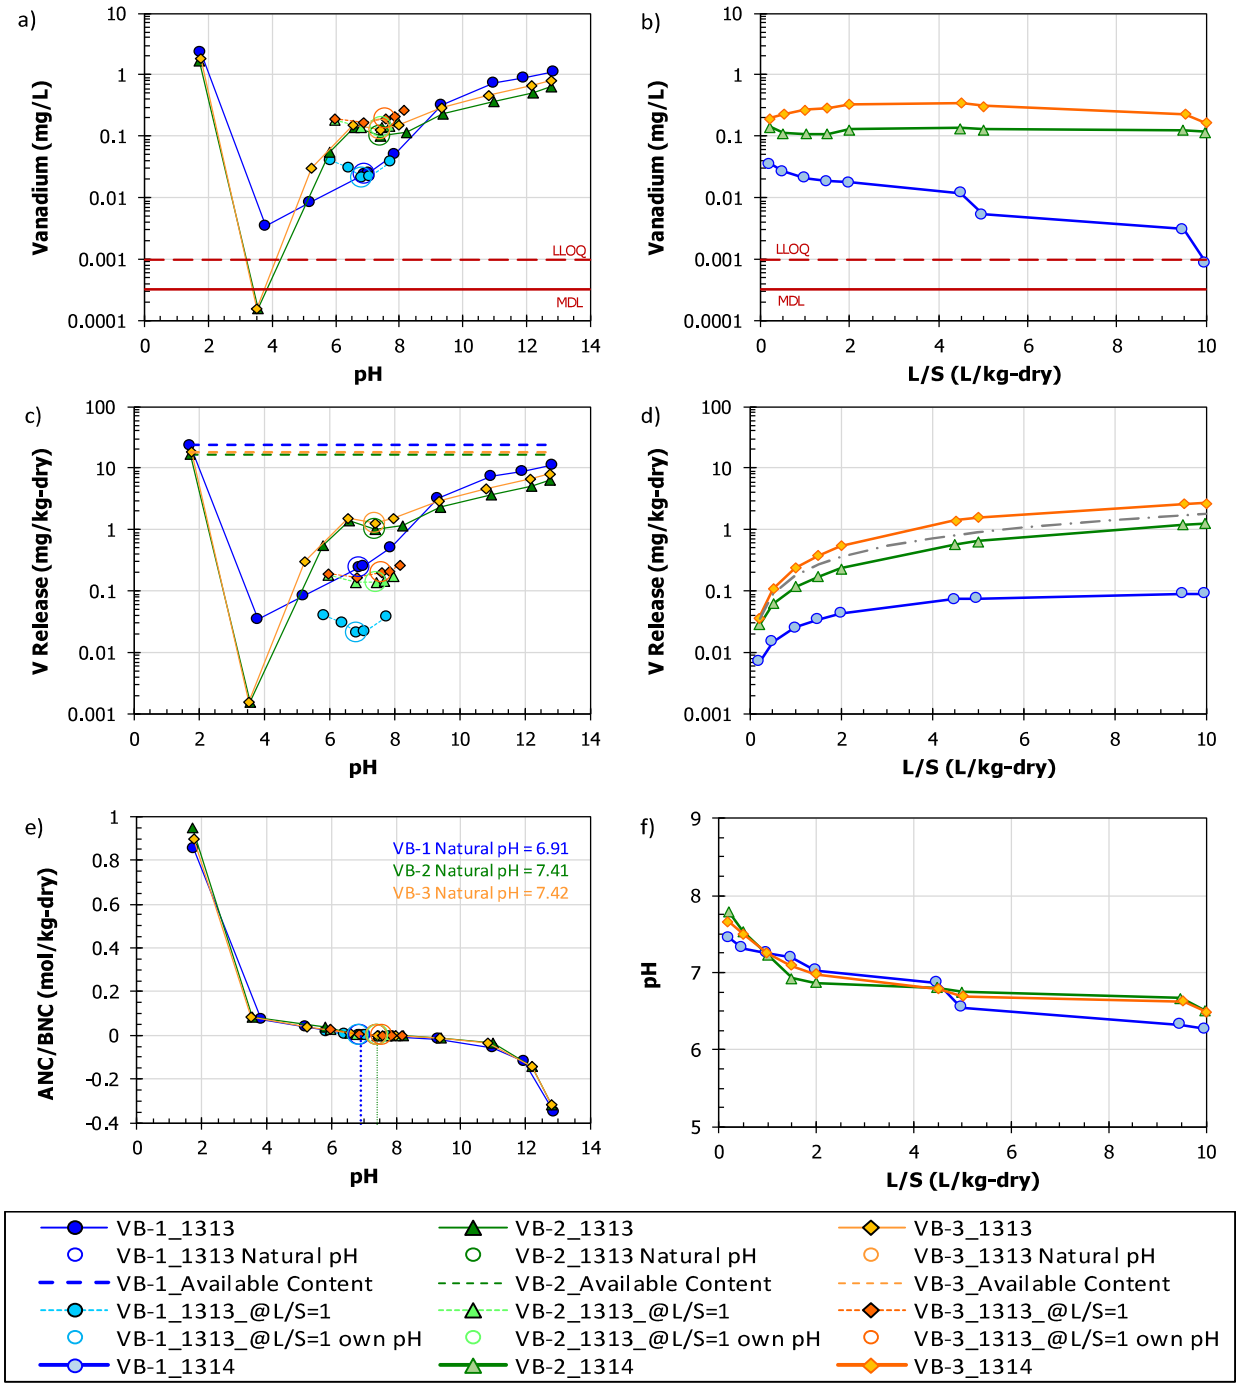

Figure D-36
Vanadium LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

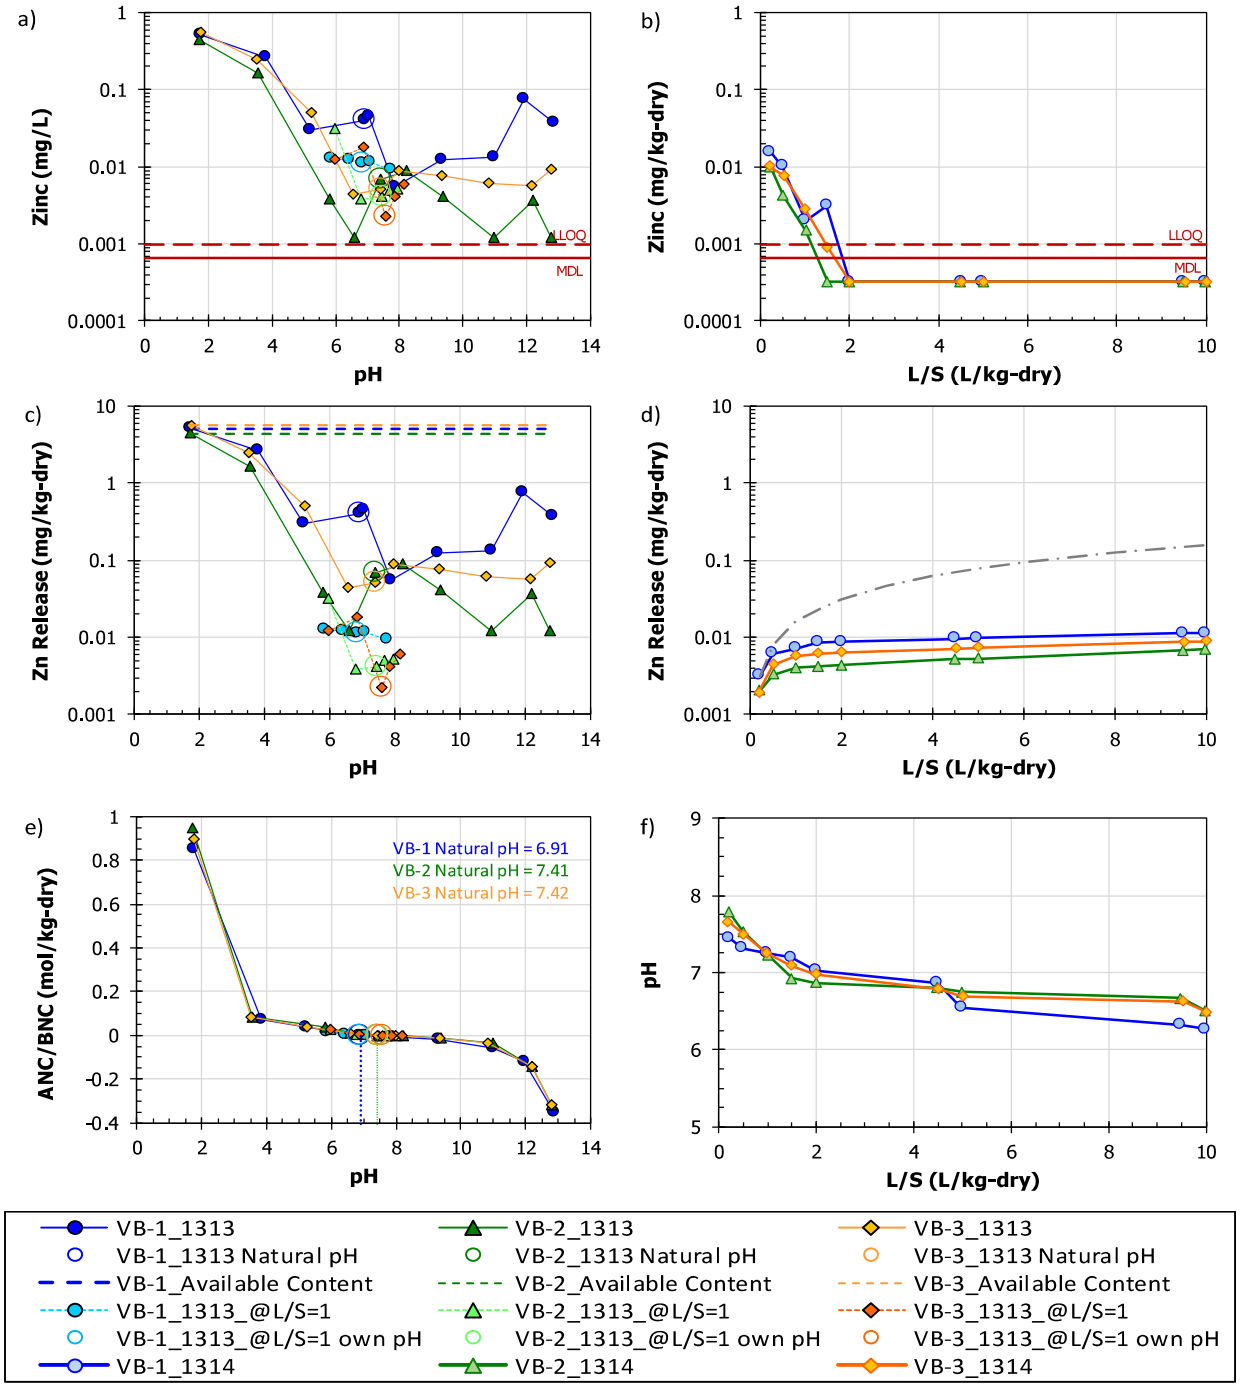

Figure D-37
Zinc LEAF test results from composite samples VB-1, VB-2, and VB-3: a) concentration as a function of pH, b) concentration as a function of L/S, c) mass release as a function of pH with available content, d) mass release as a function of L/S, e) acid/base neutralization capacity (ANC/BNC) as a function of pH, and f) column pH as a function of L/S

D.2 Comparison of Individual Split Spoon and Composite Sample Data

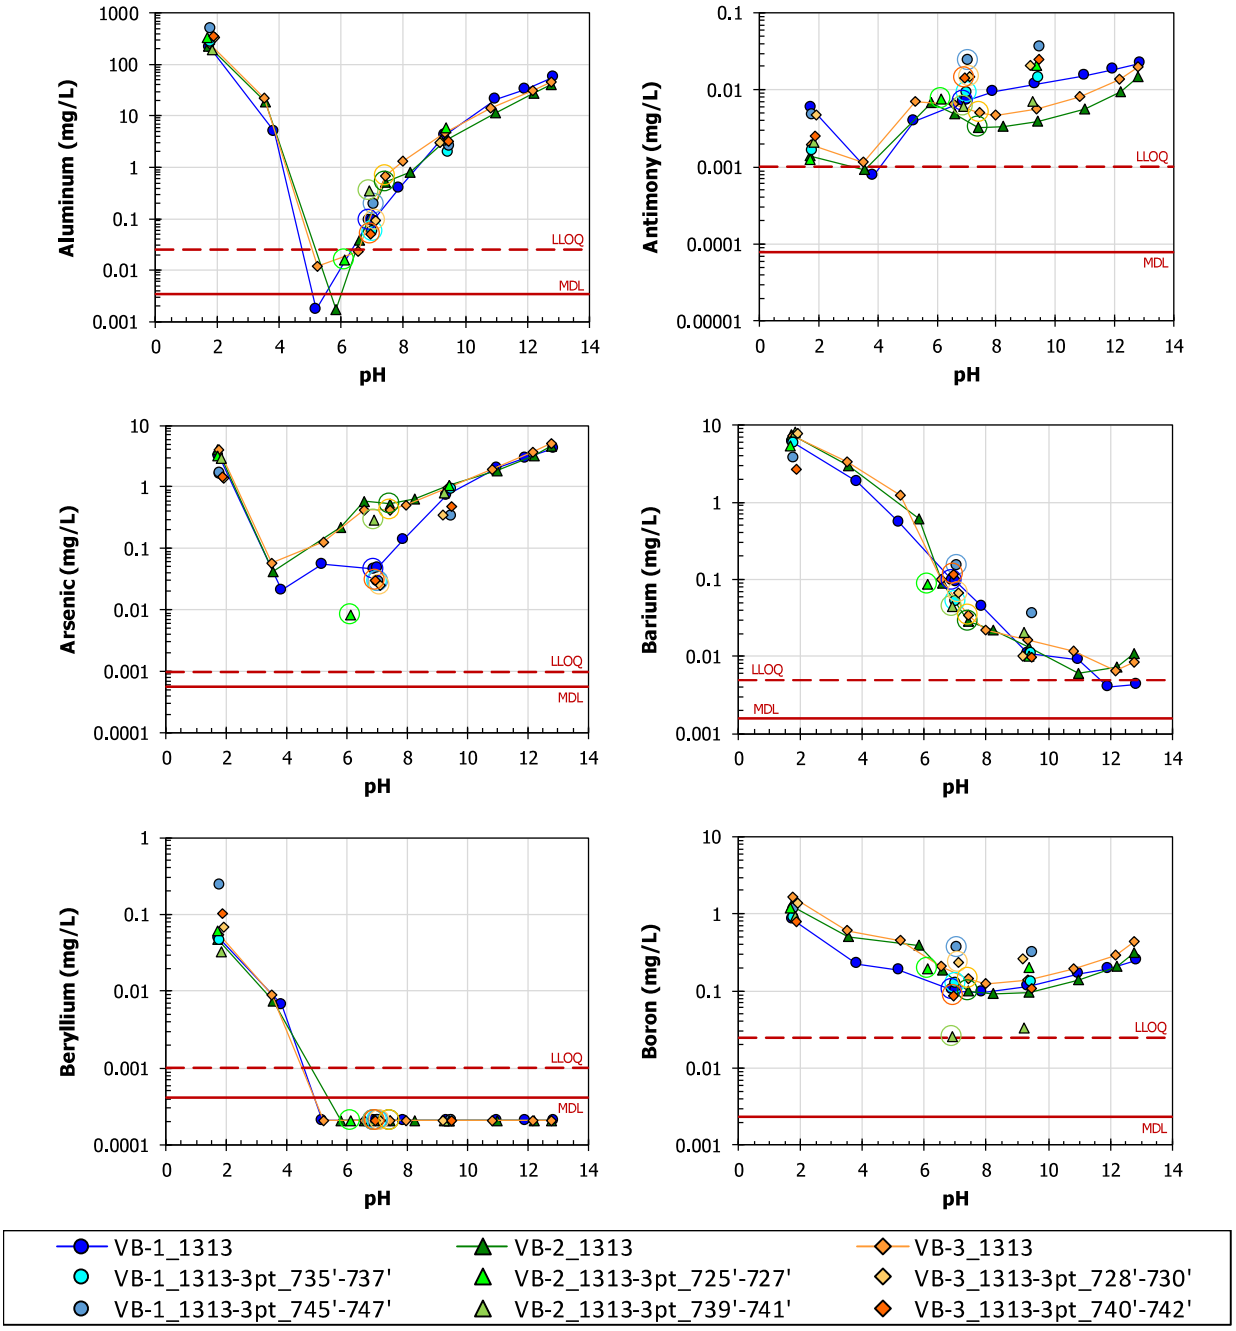

Figure D-38
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: aluminum, antimony, arsenic, barium, beryllium, and boron

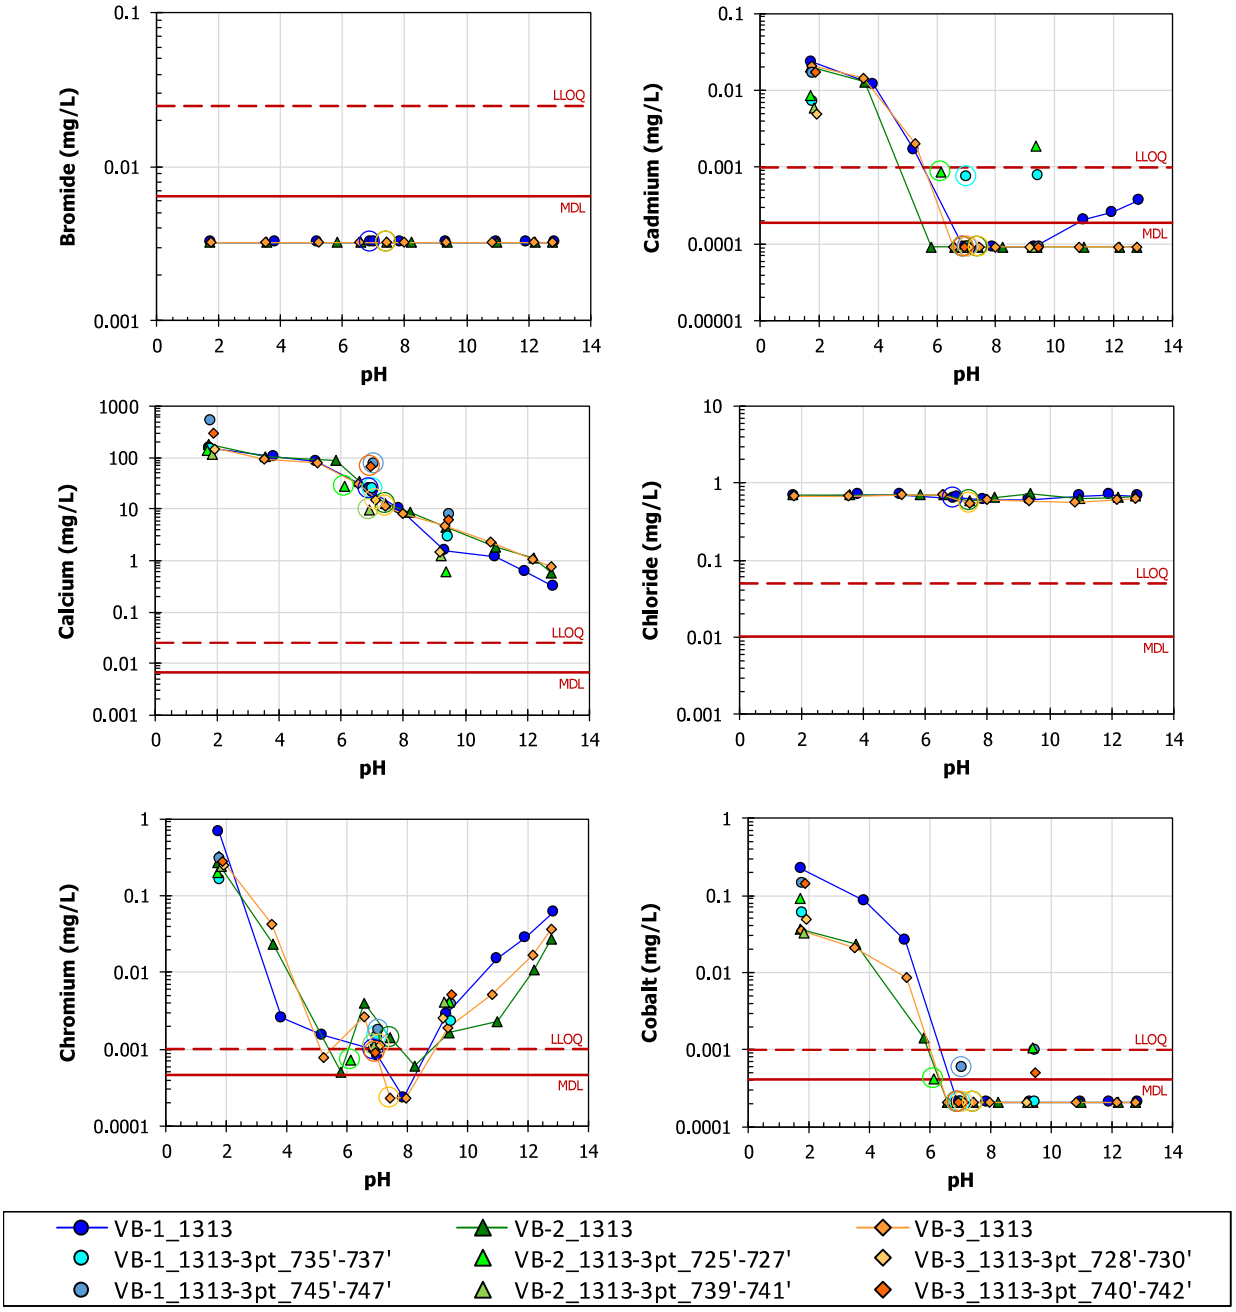

Figure D-39
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: bromide, cadmium, calcium, chloride, chromium, and cobalt

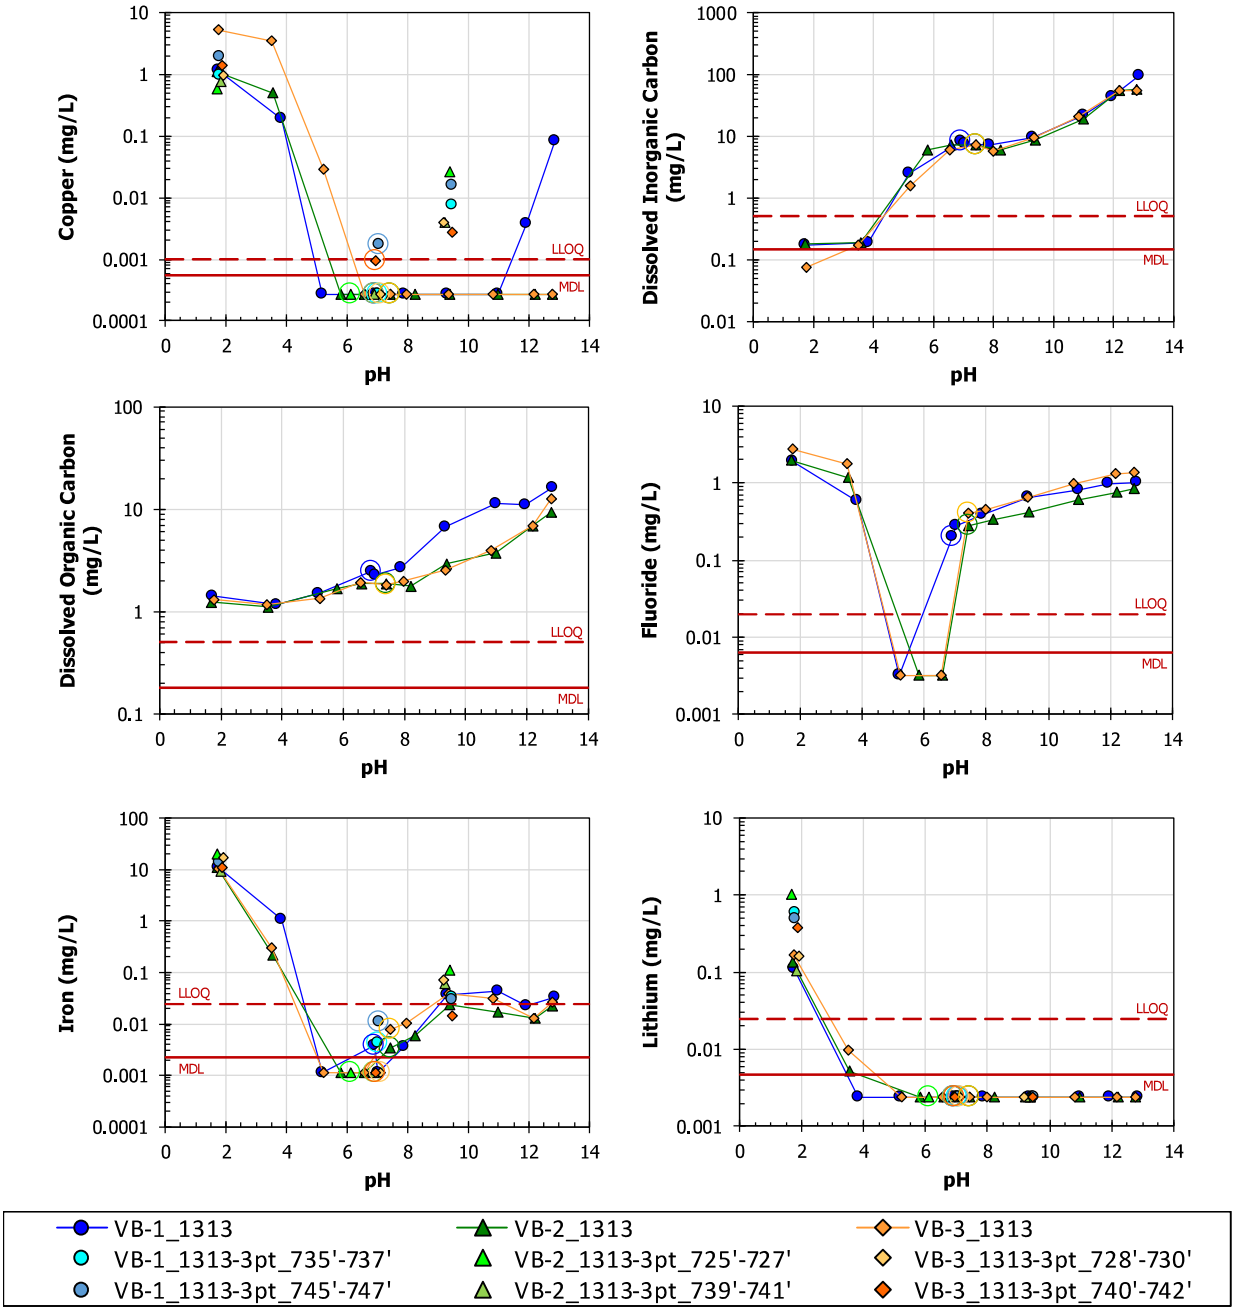

Figure D-40
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: copper, dissolved inorganic carbon, dissolved organic carbon, fluoride, iron, and lithium

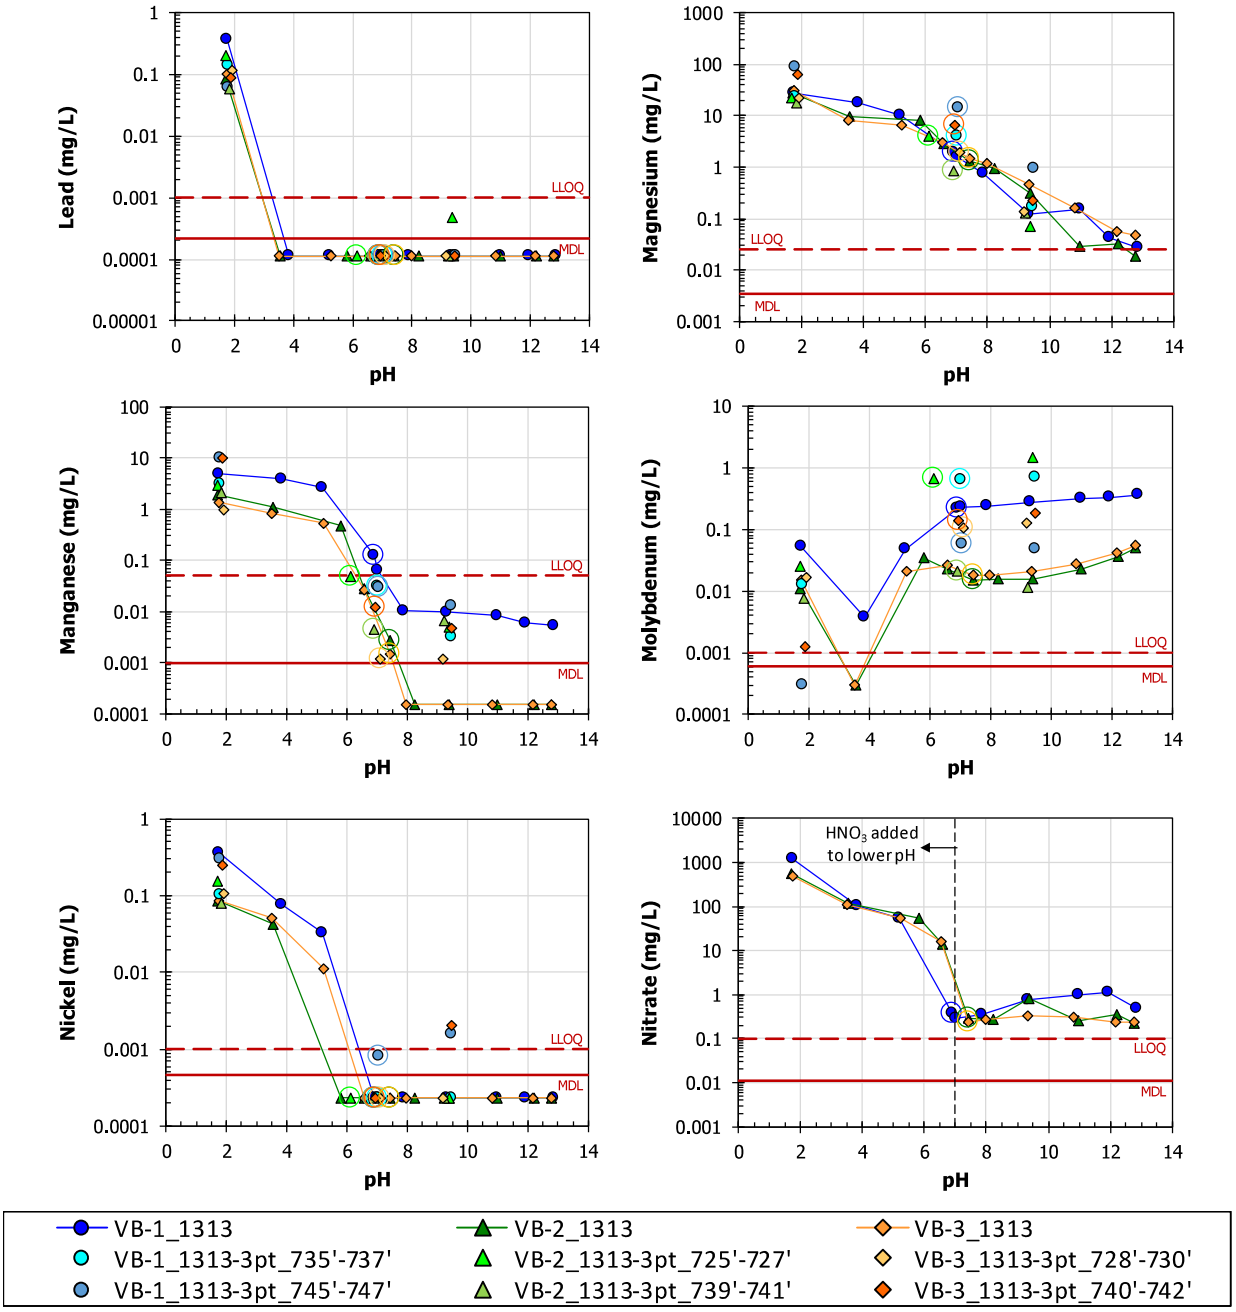

Figure D-41
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: lead, magnesium, manganese, molybdenum, nickel, and nitrate

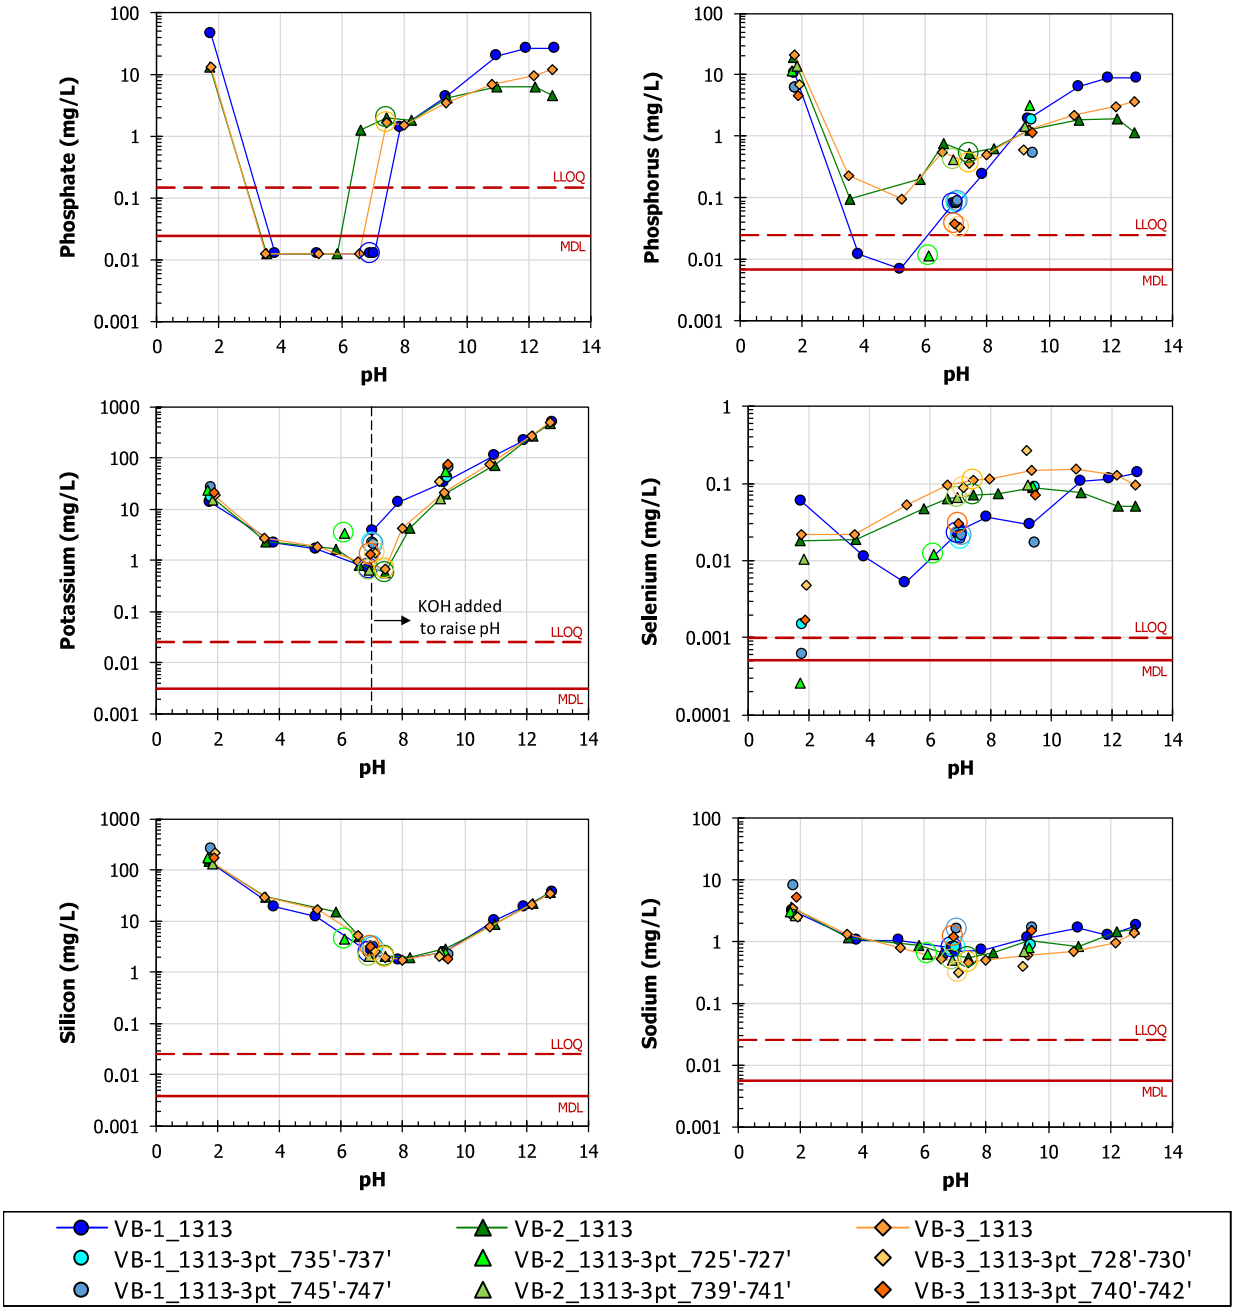

Figure D-42
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: phosphate, phosphorus, potassium, selenium, silicon, and sodium

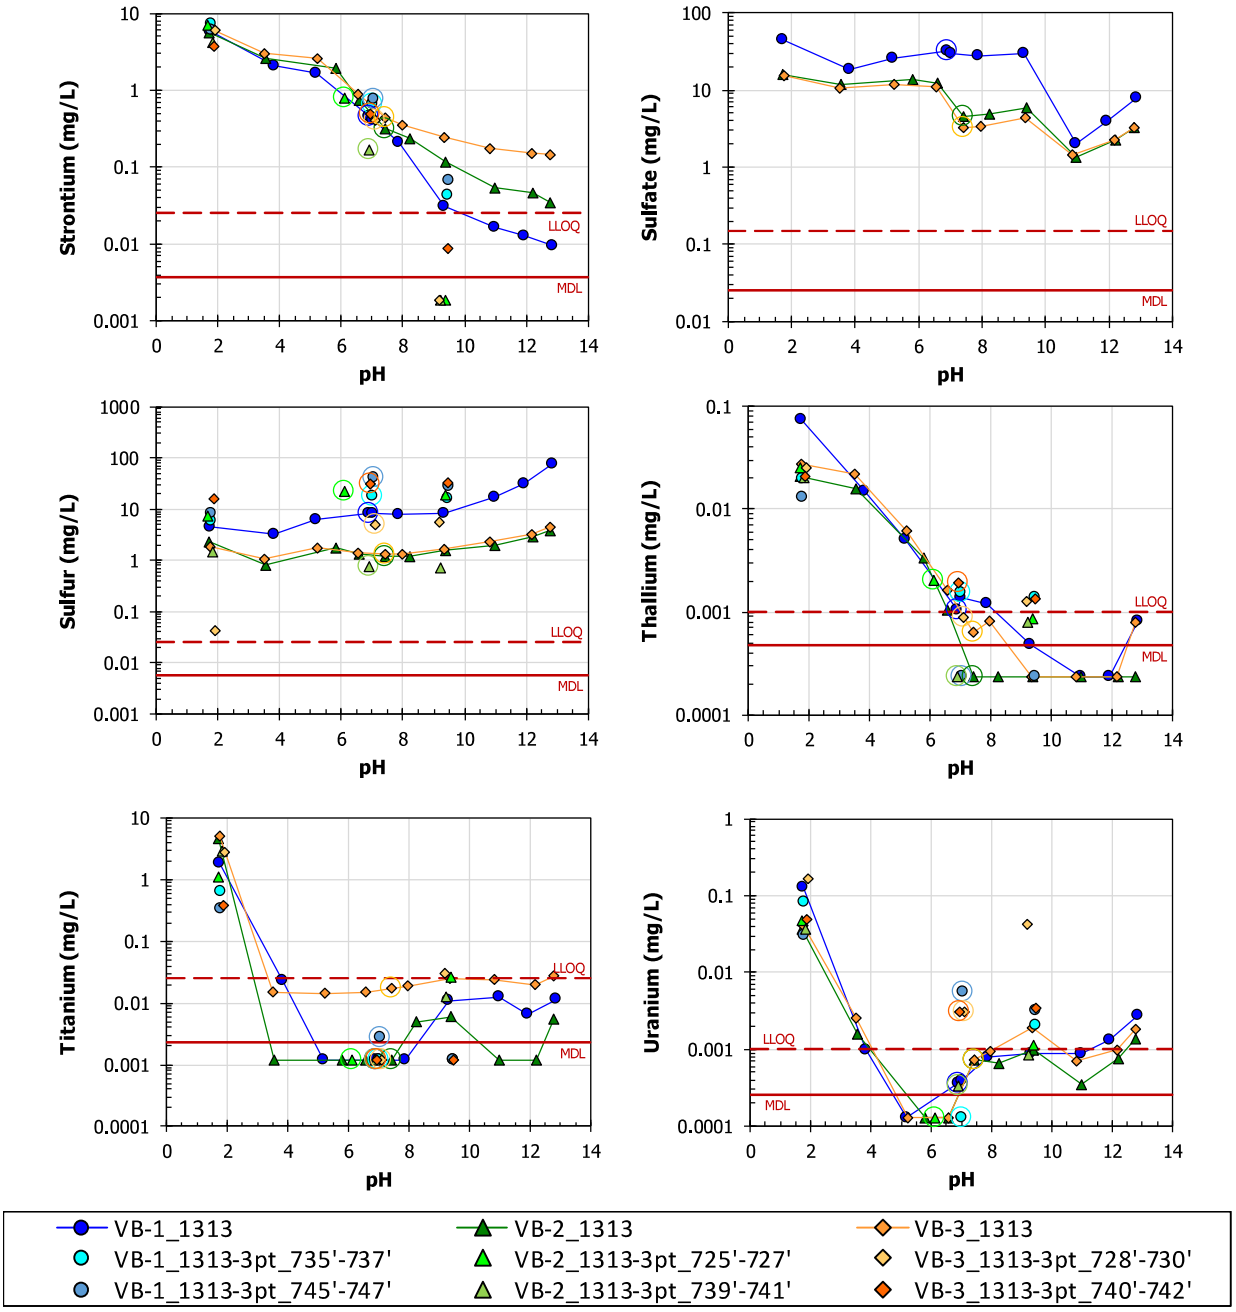

Figure D-43
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: strontium, sulfate, sulfur, thallium, titanium, and uranium

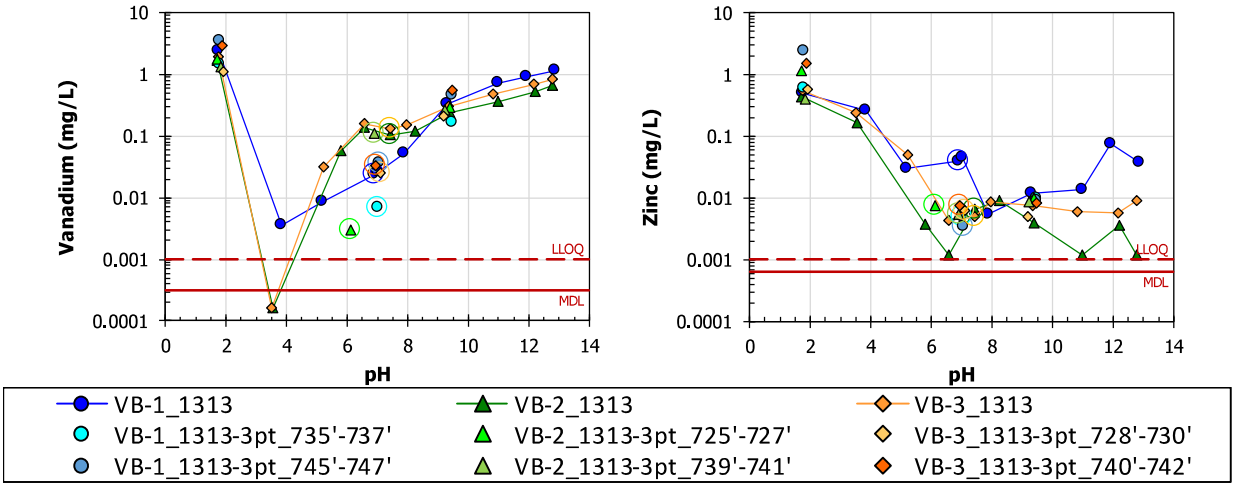

Figure D-44
pH-dependent concentration of composite samples (Method 1313) and discrete split spoon samples (Method 1313-3pt) from boreholes VB-1, VB-2 and VB-3: vanadium and zinc

E
COMPARISON OF TEST METHOD RESULTS

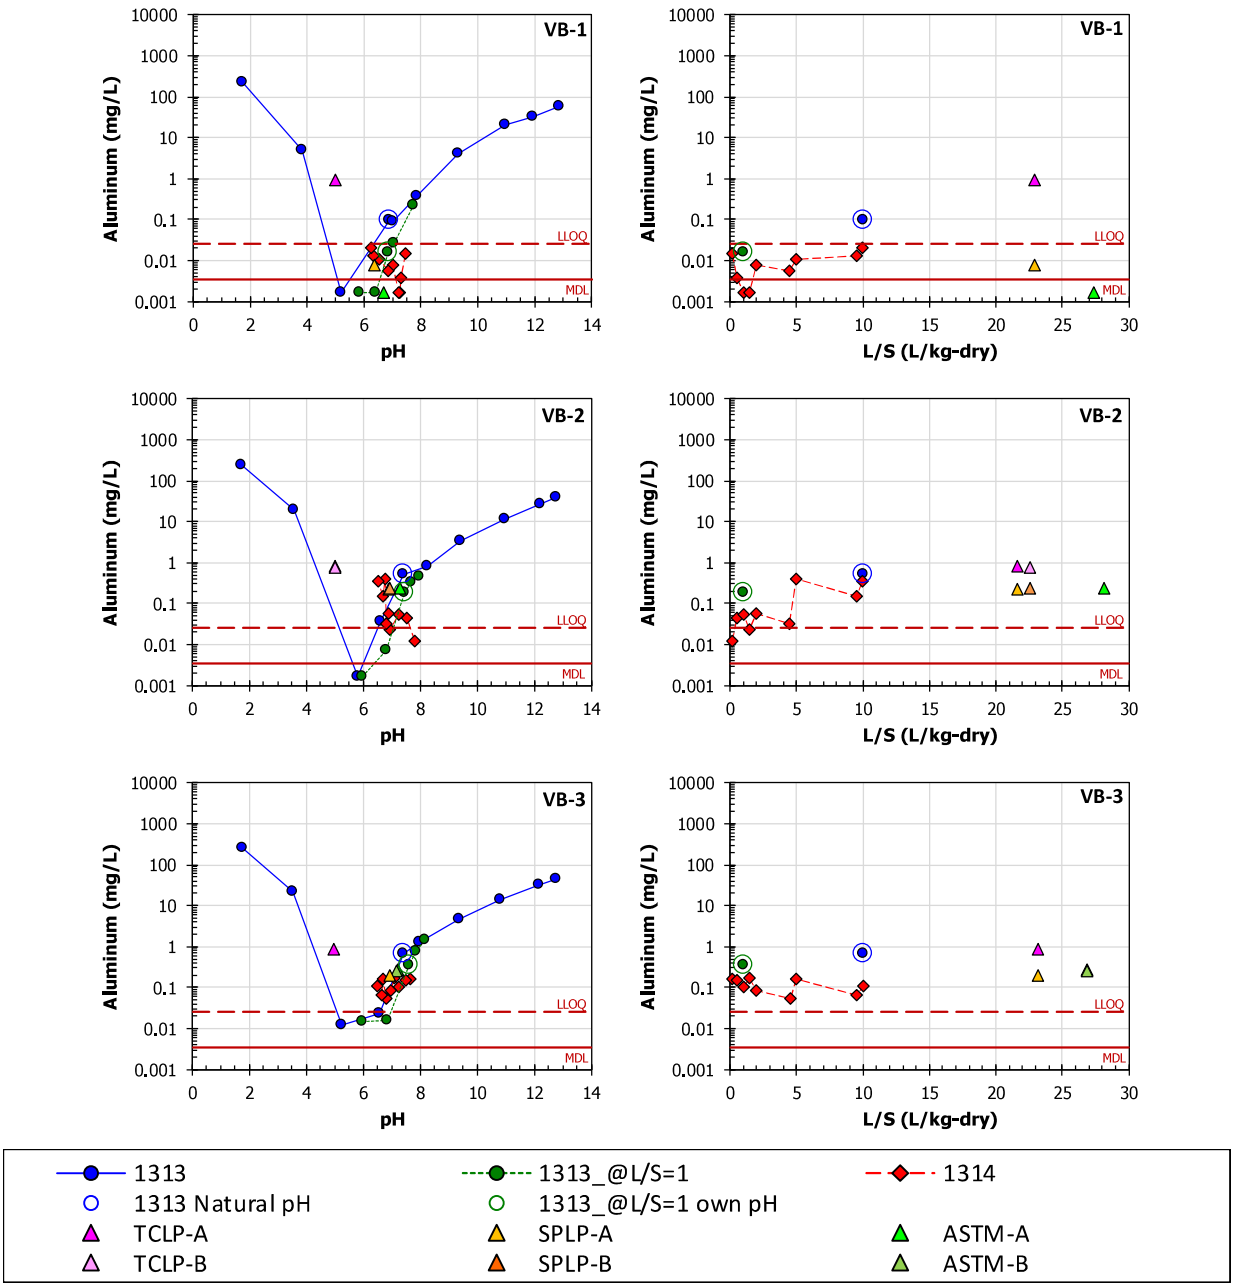

Figure E-1
Aluminum concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

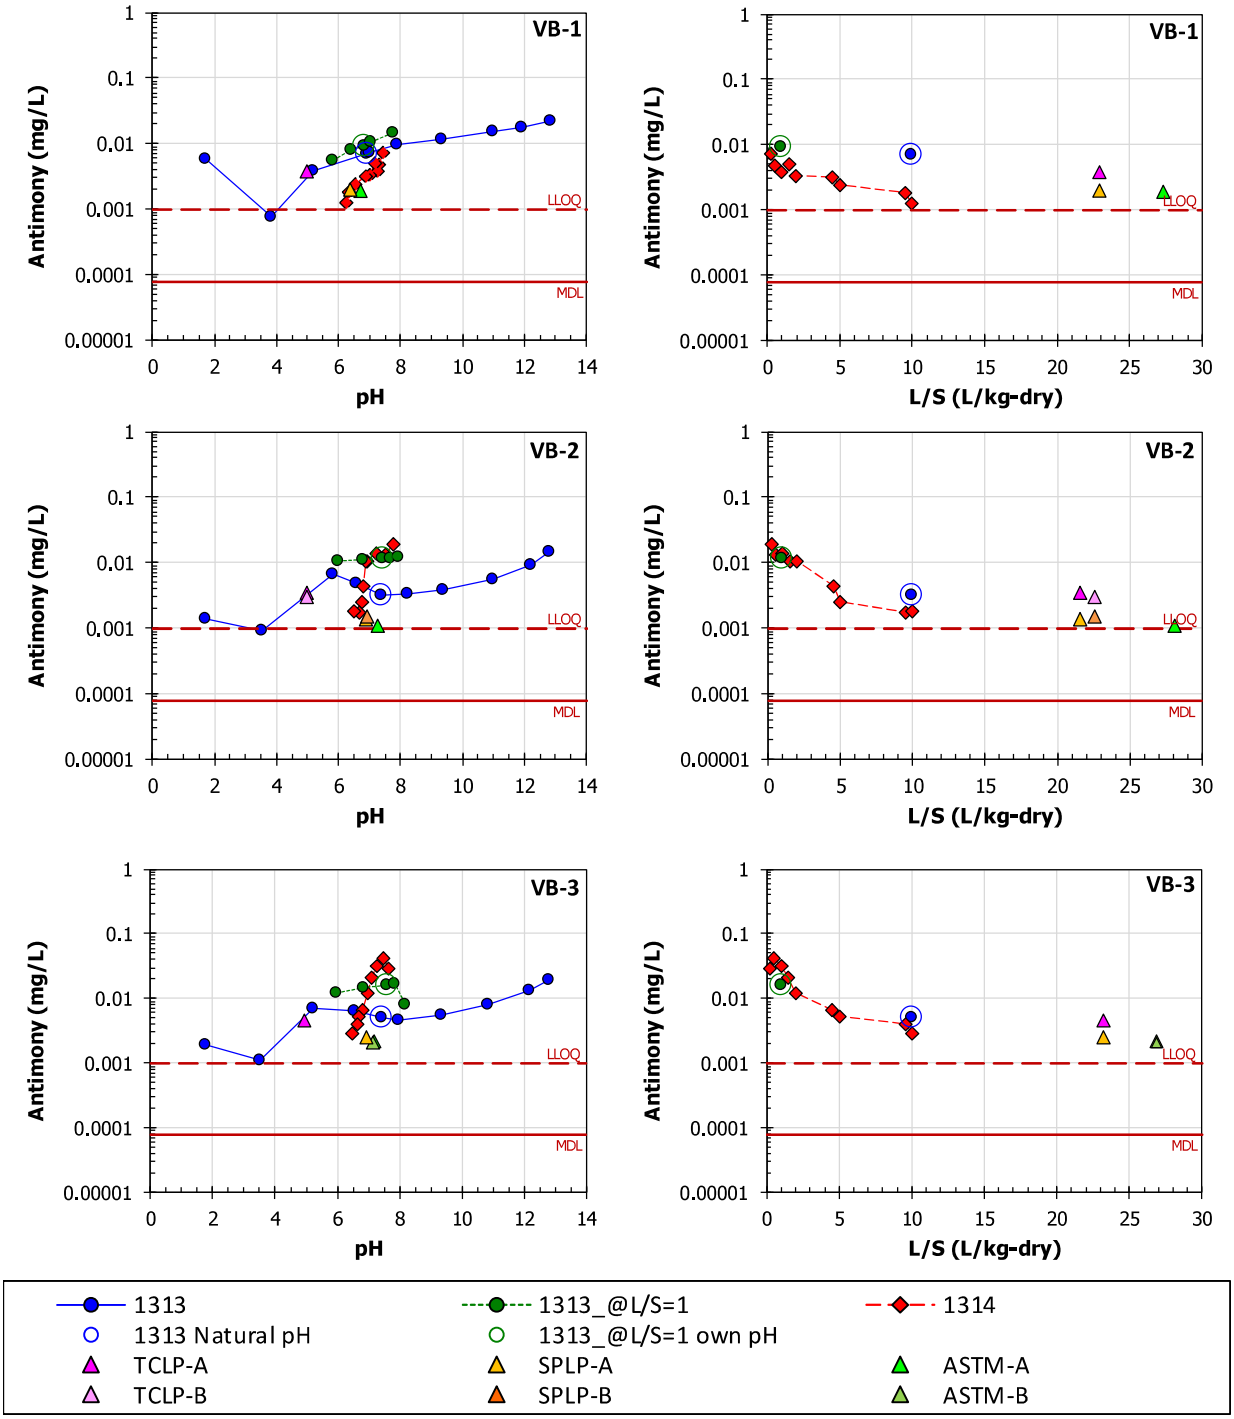

Figure E-2
Antimony concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

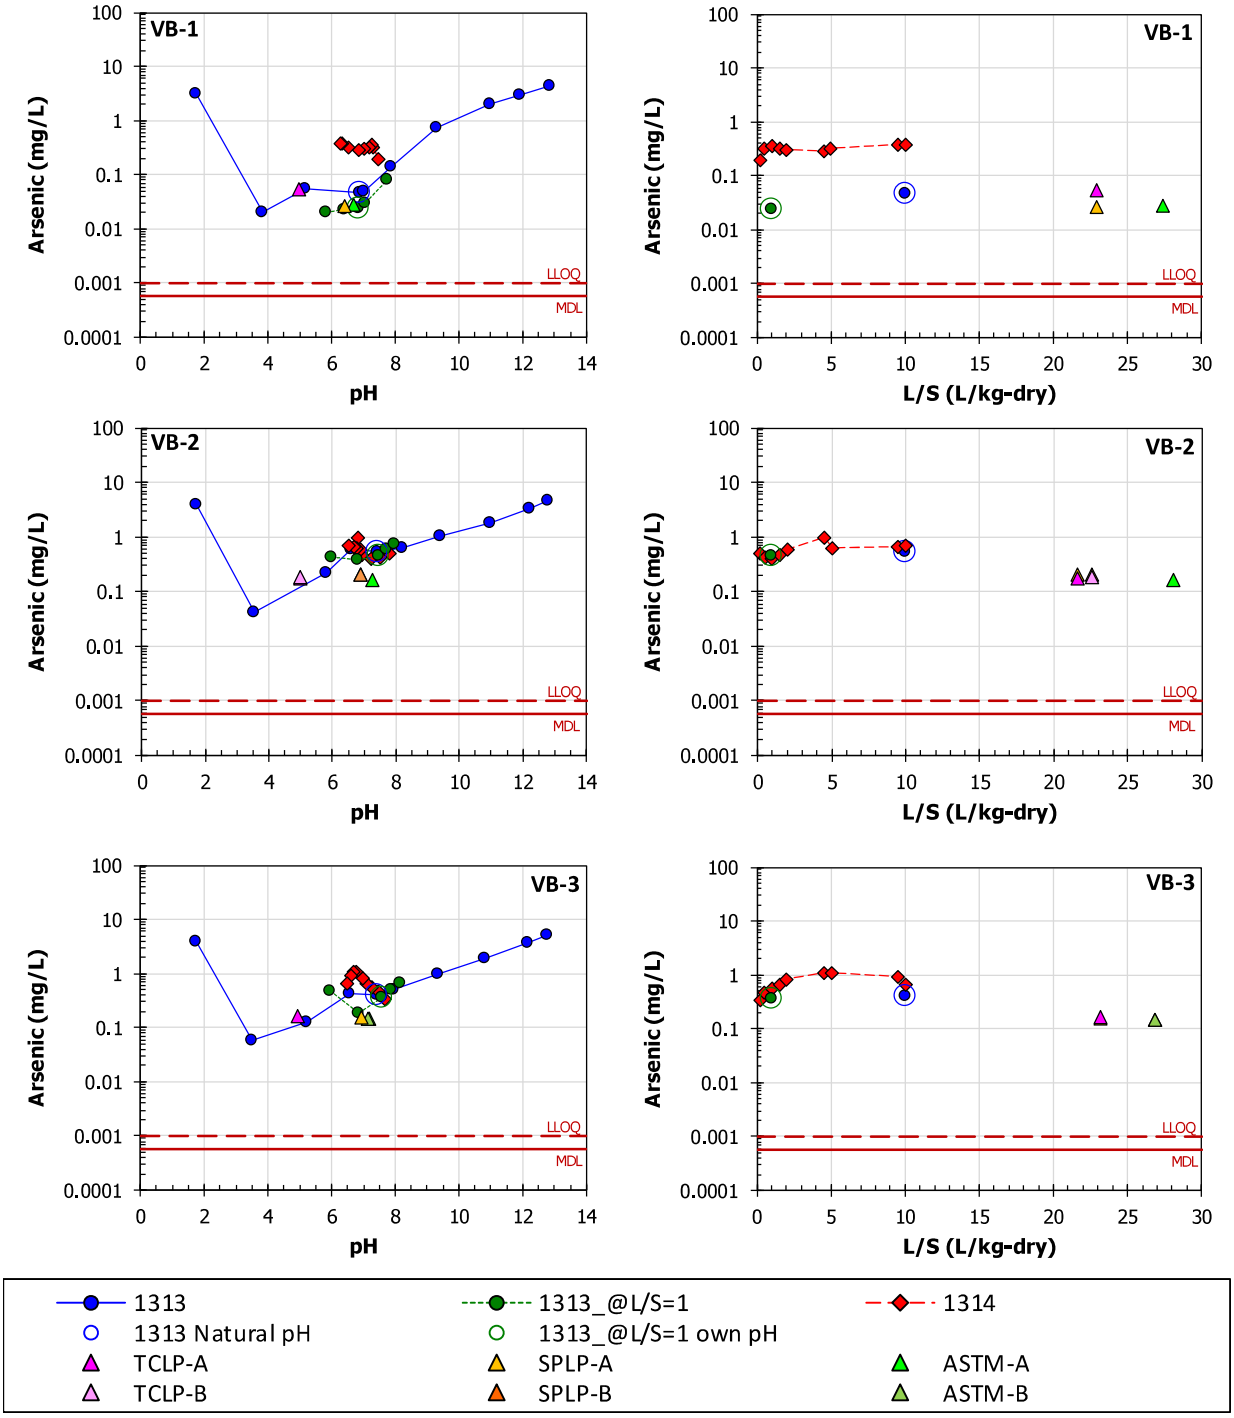

Figure E-3
Arsenic concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

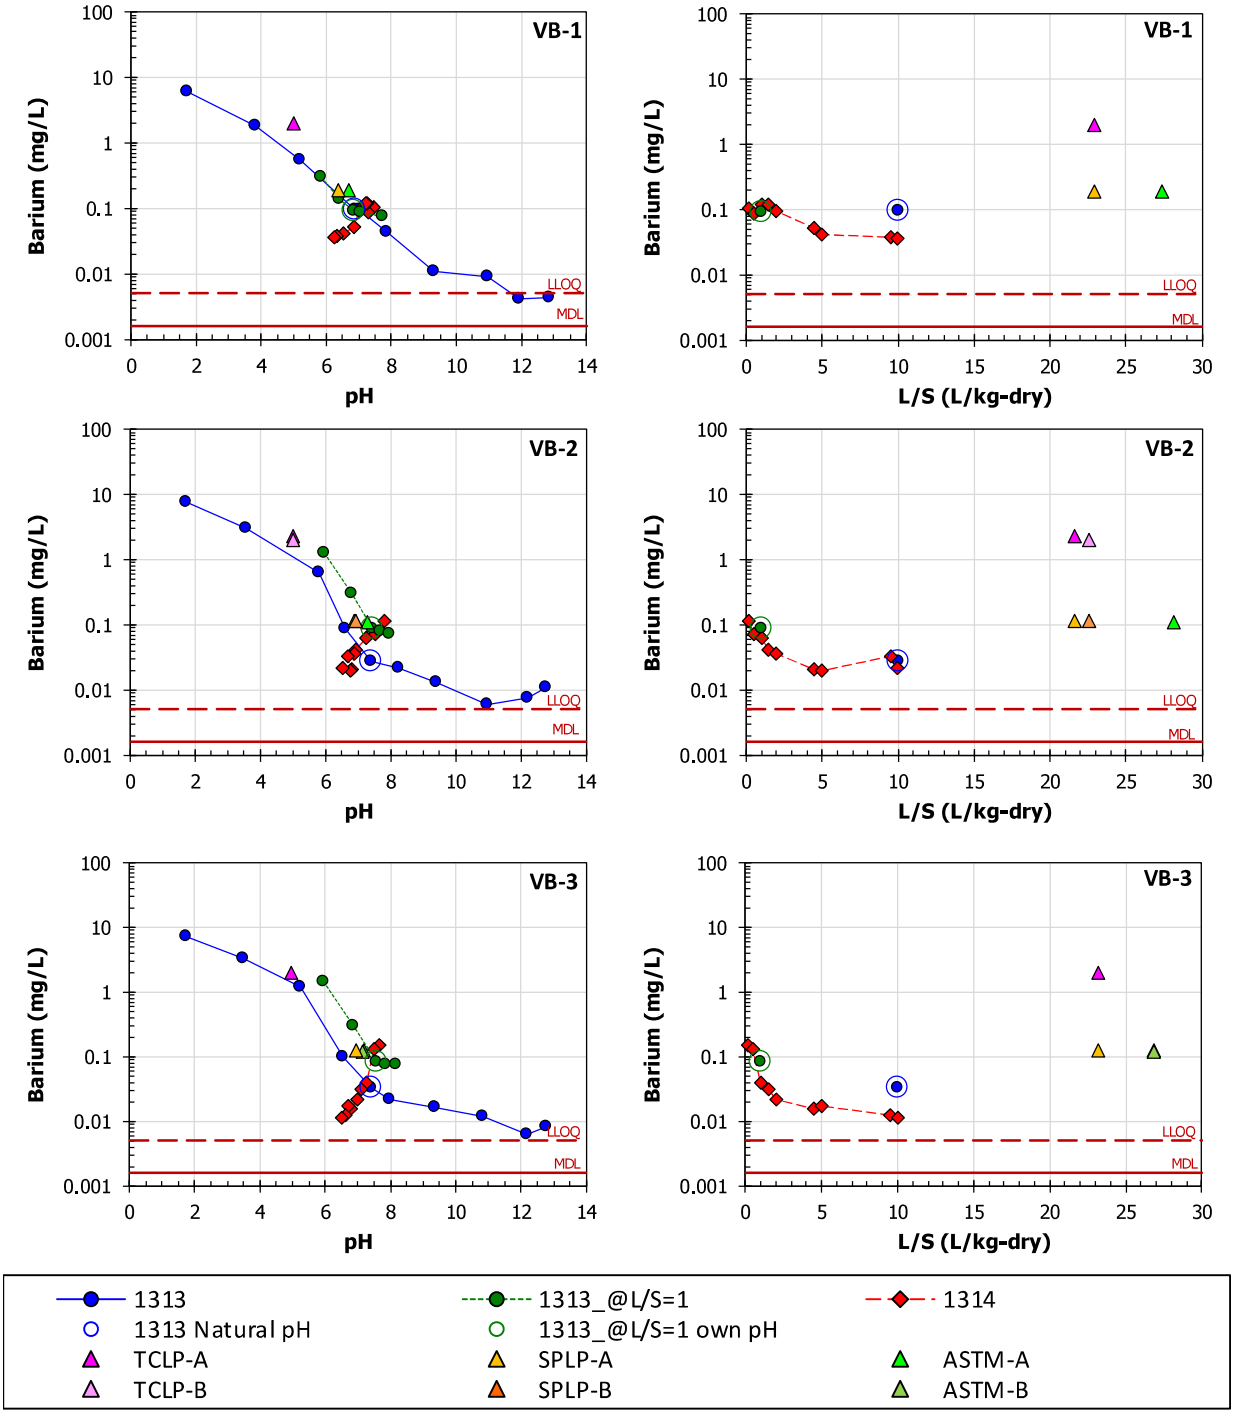

Figure E-4
Barium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

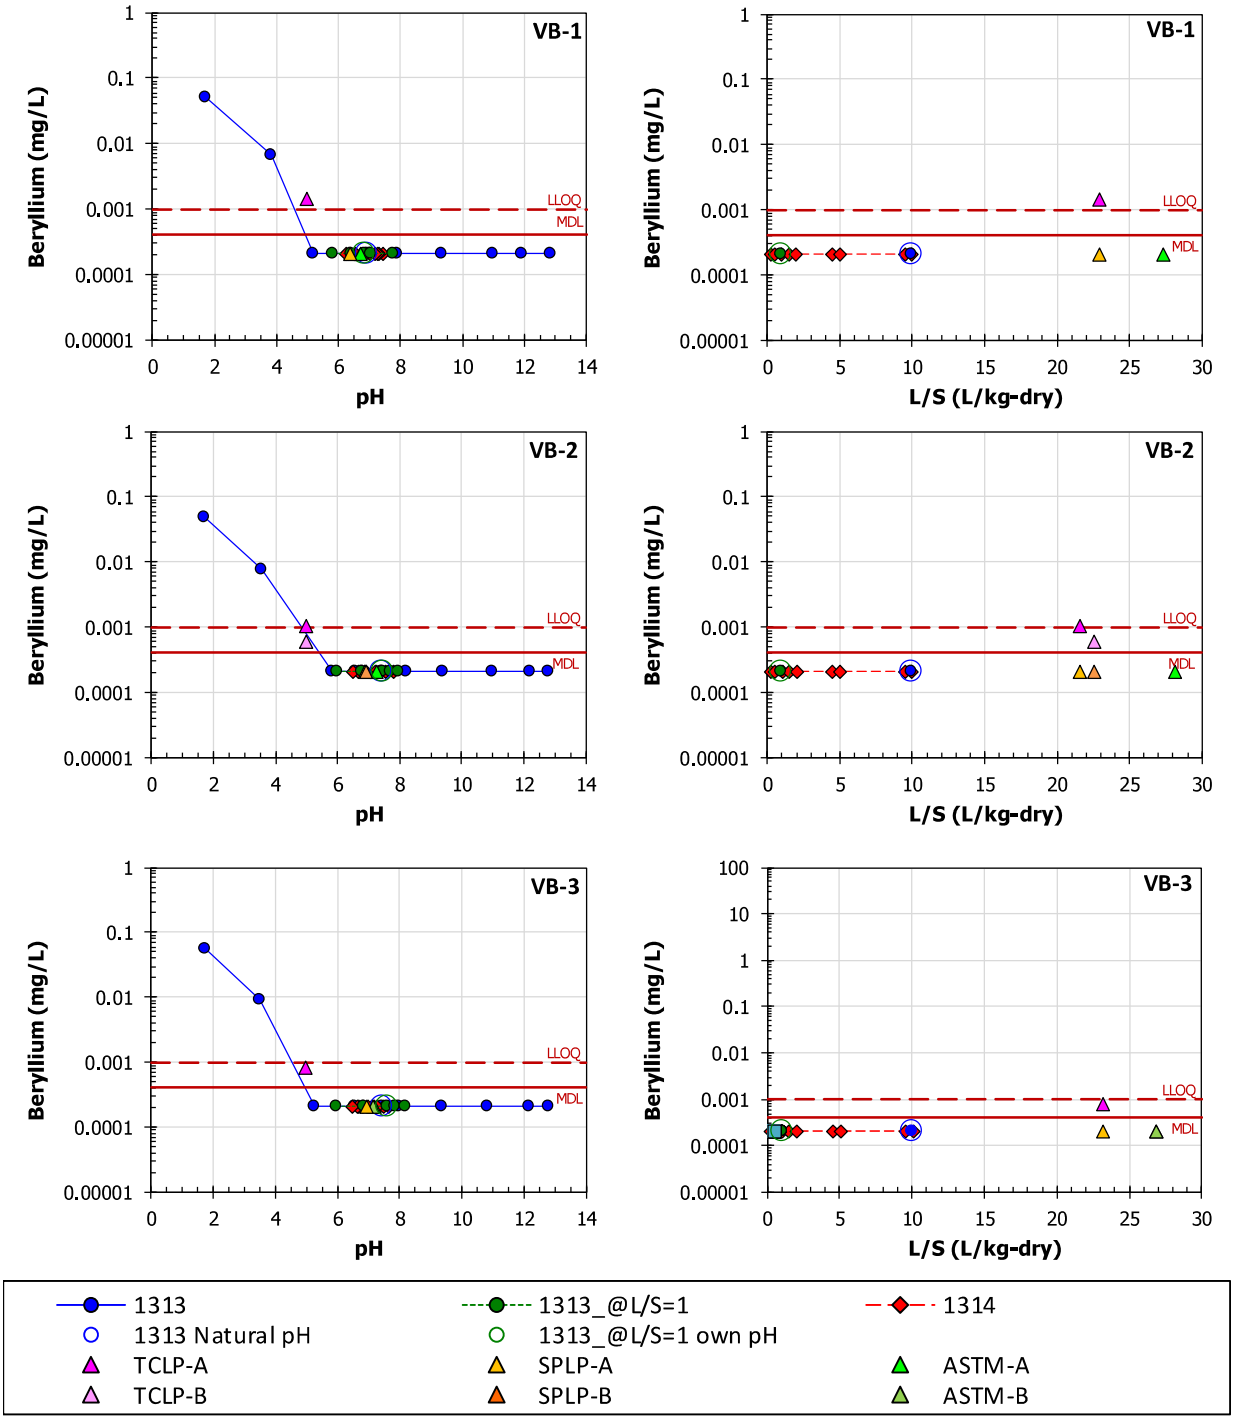

Figure E-5
Beryllium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

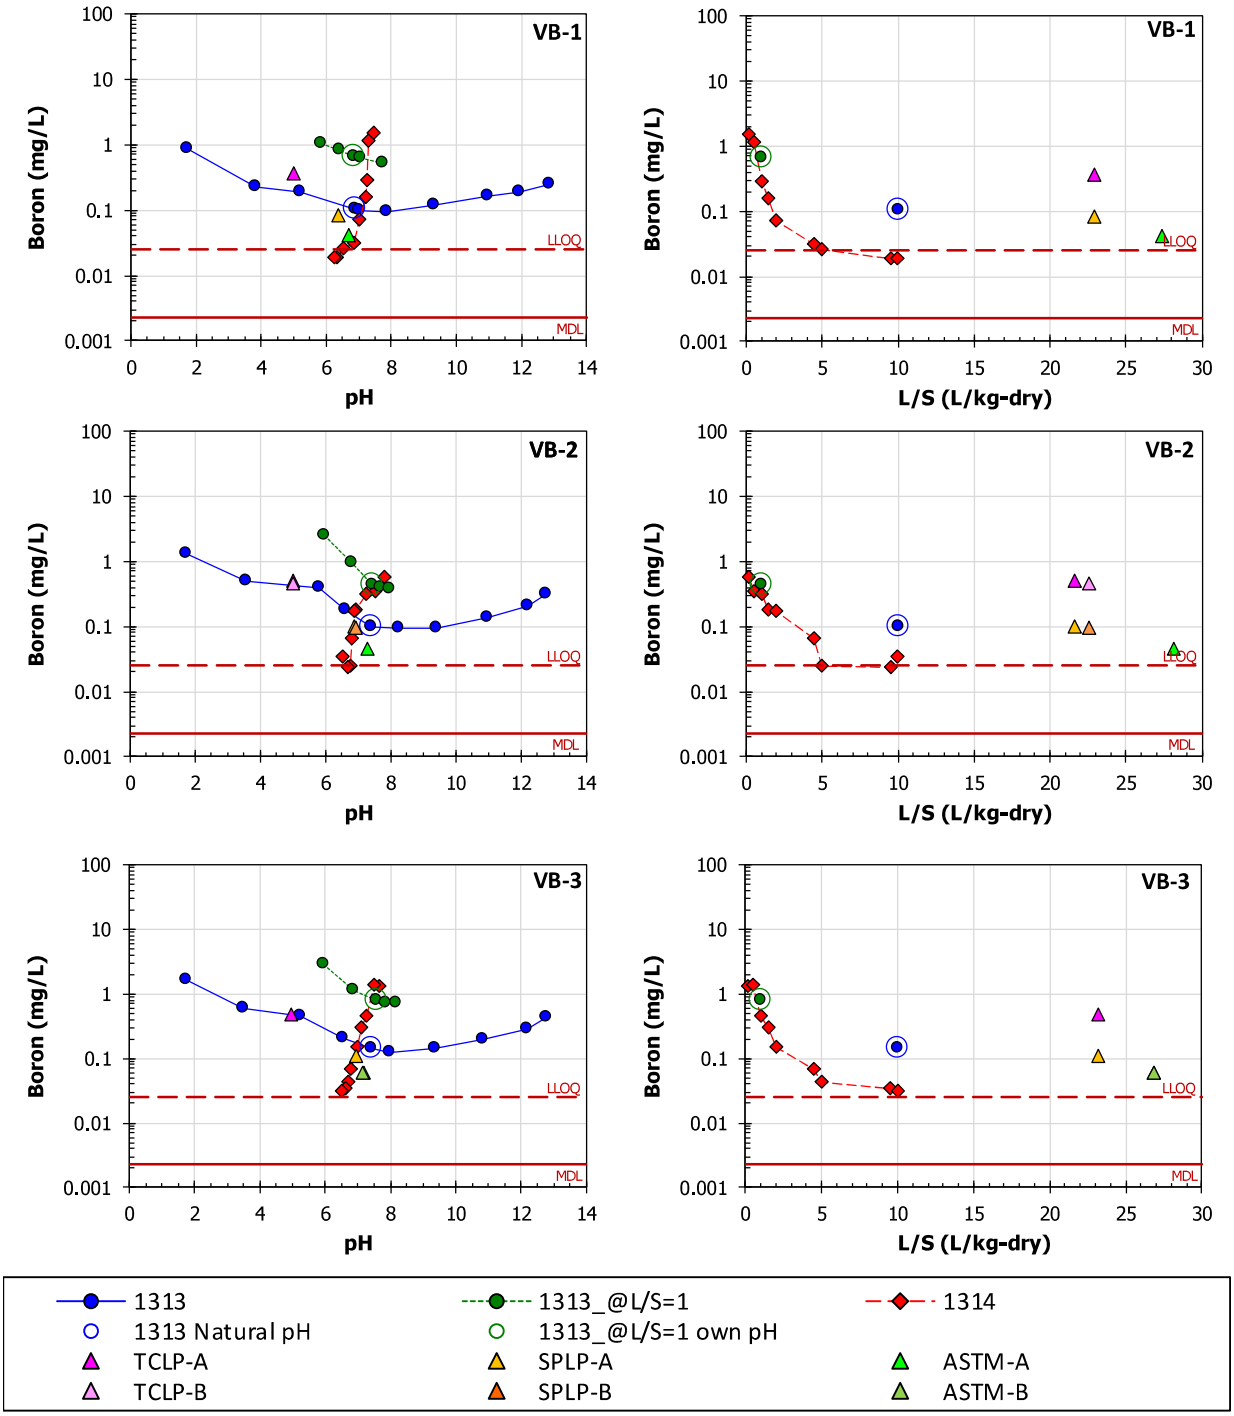

Figure E-6
Boron concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

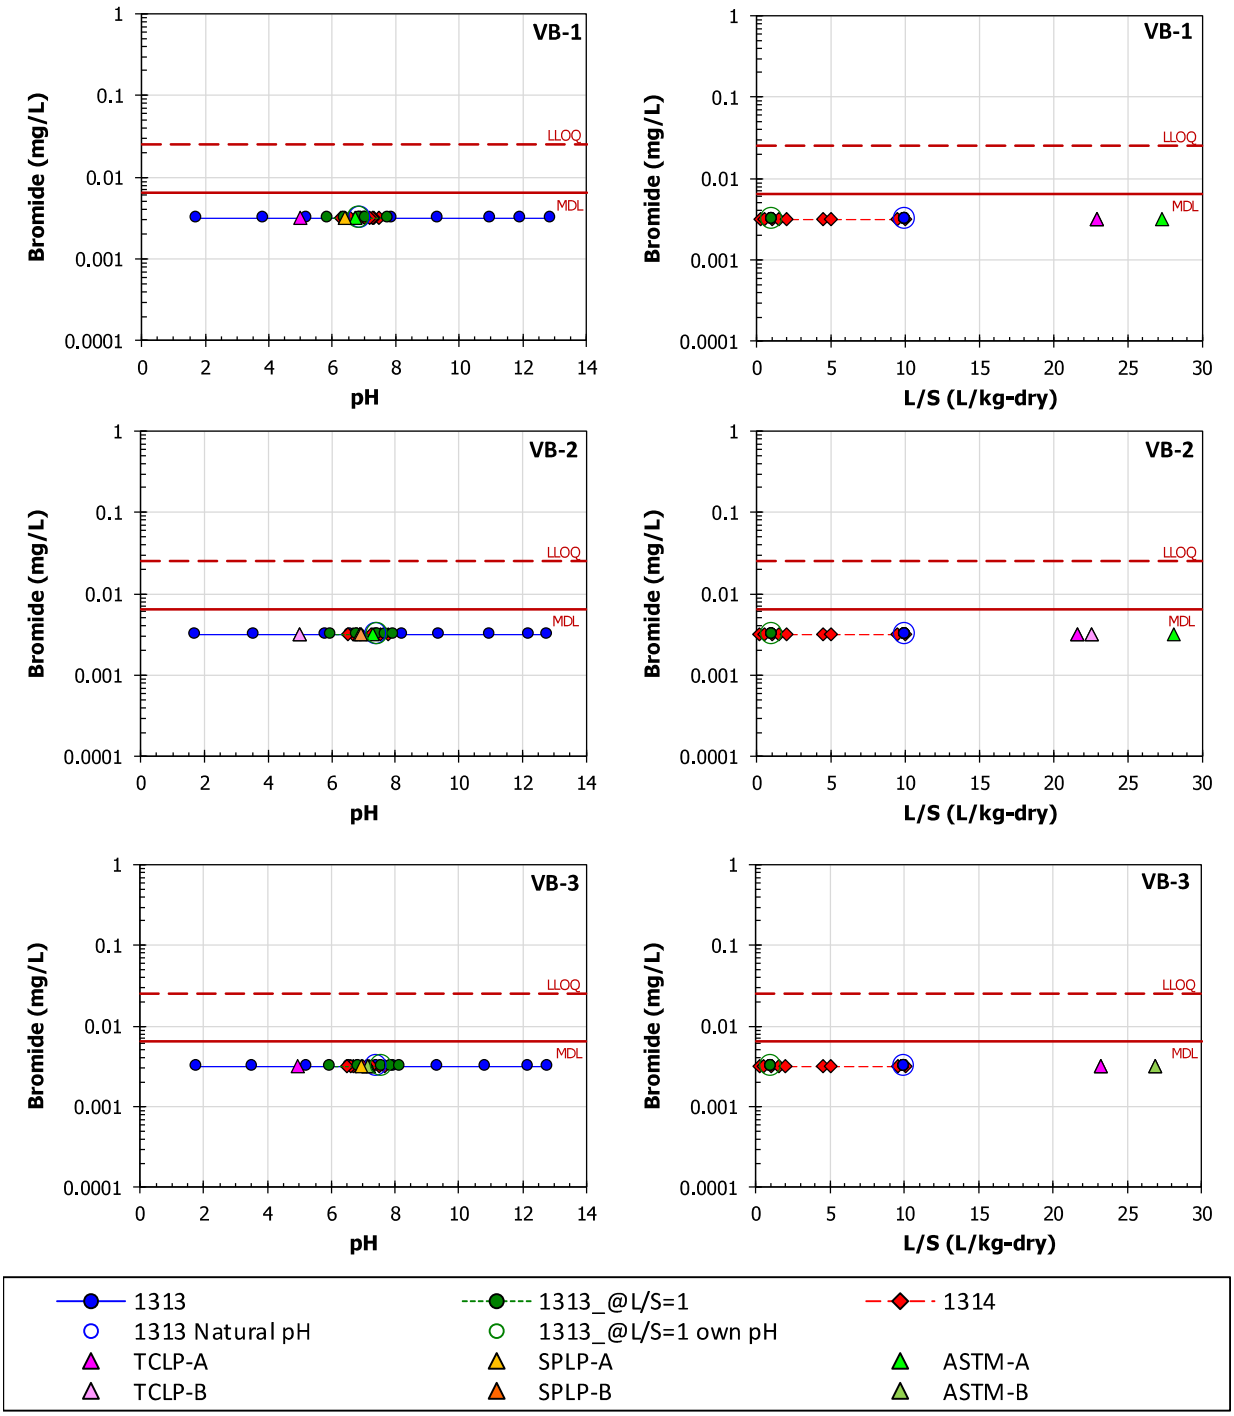

Figure E-7
Bromide concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

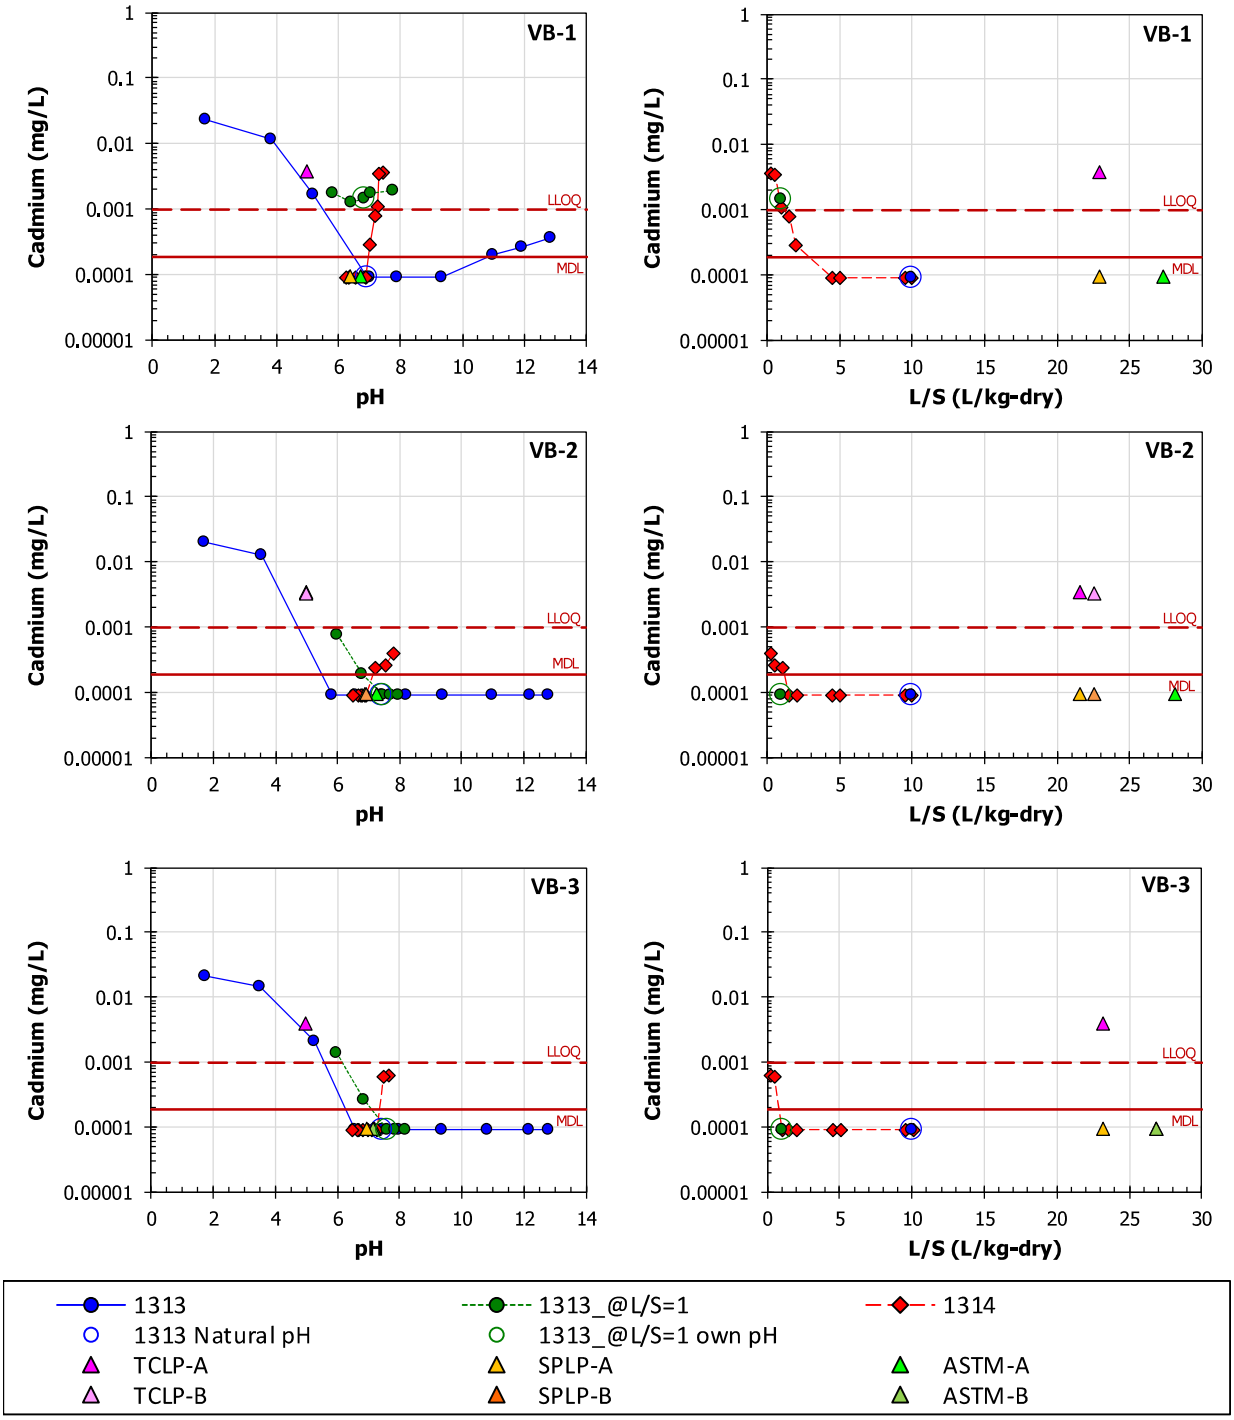

Figure E-8
Cadmium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

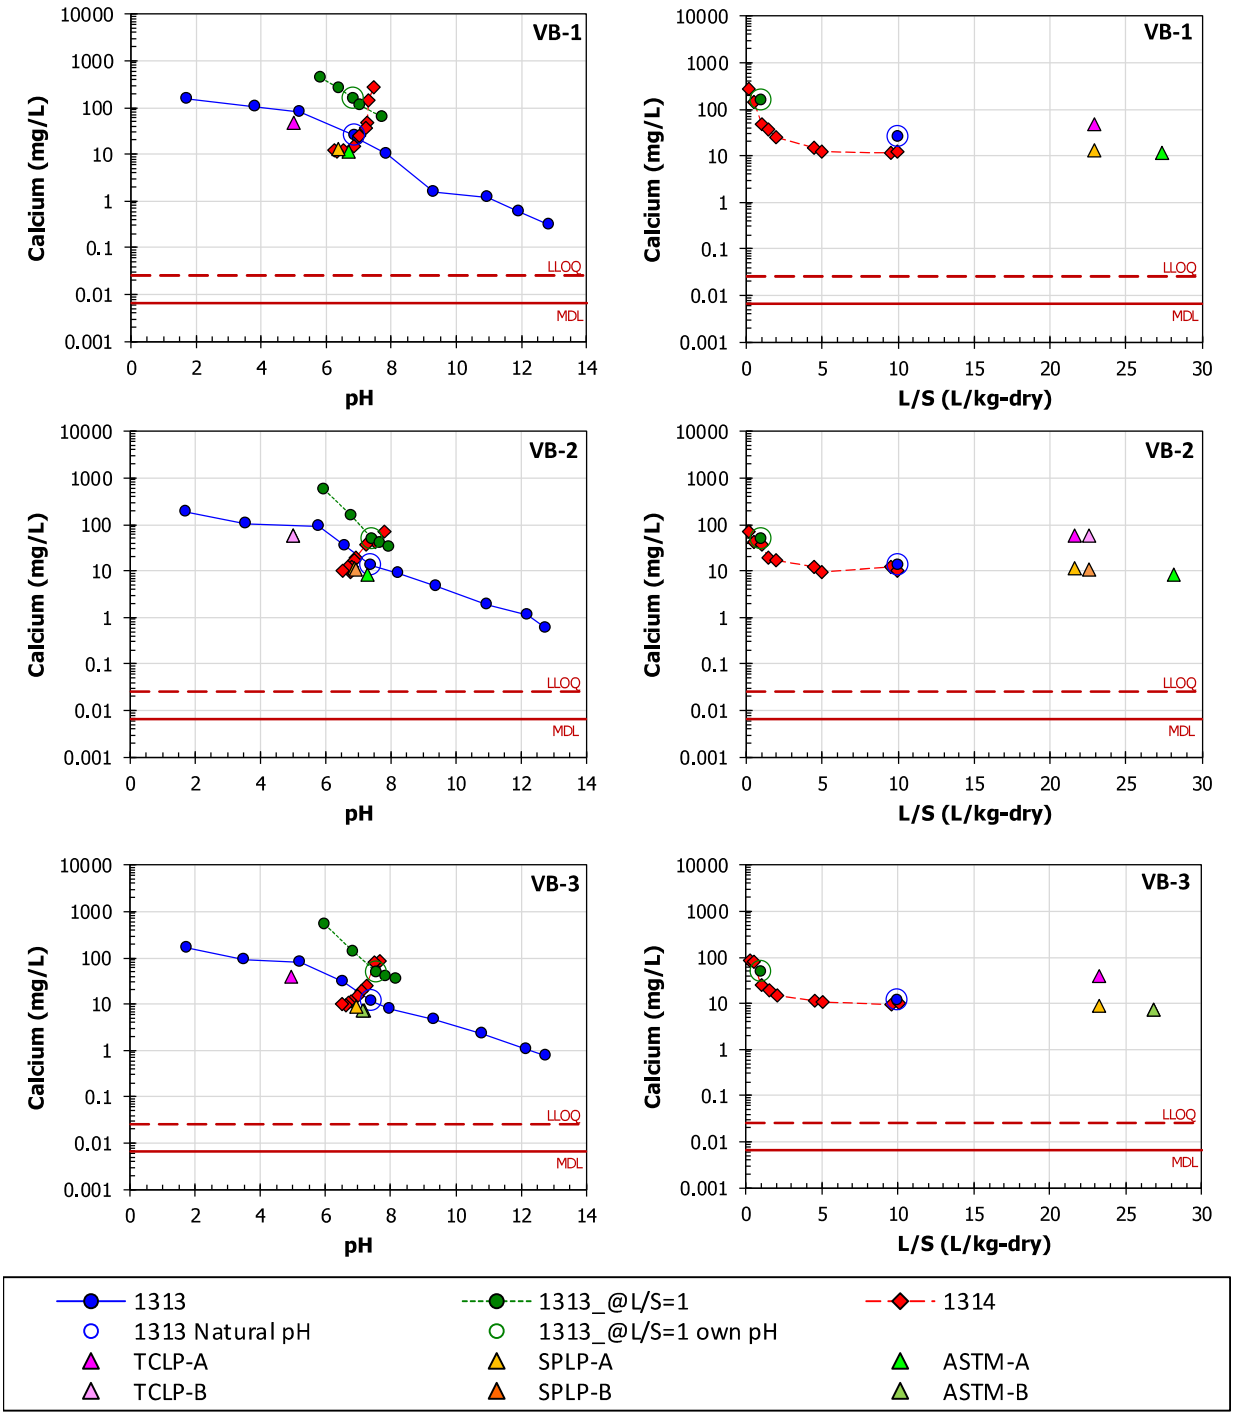

Figure E-9
Calcium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

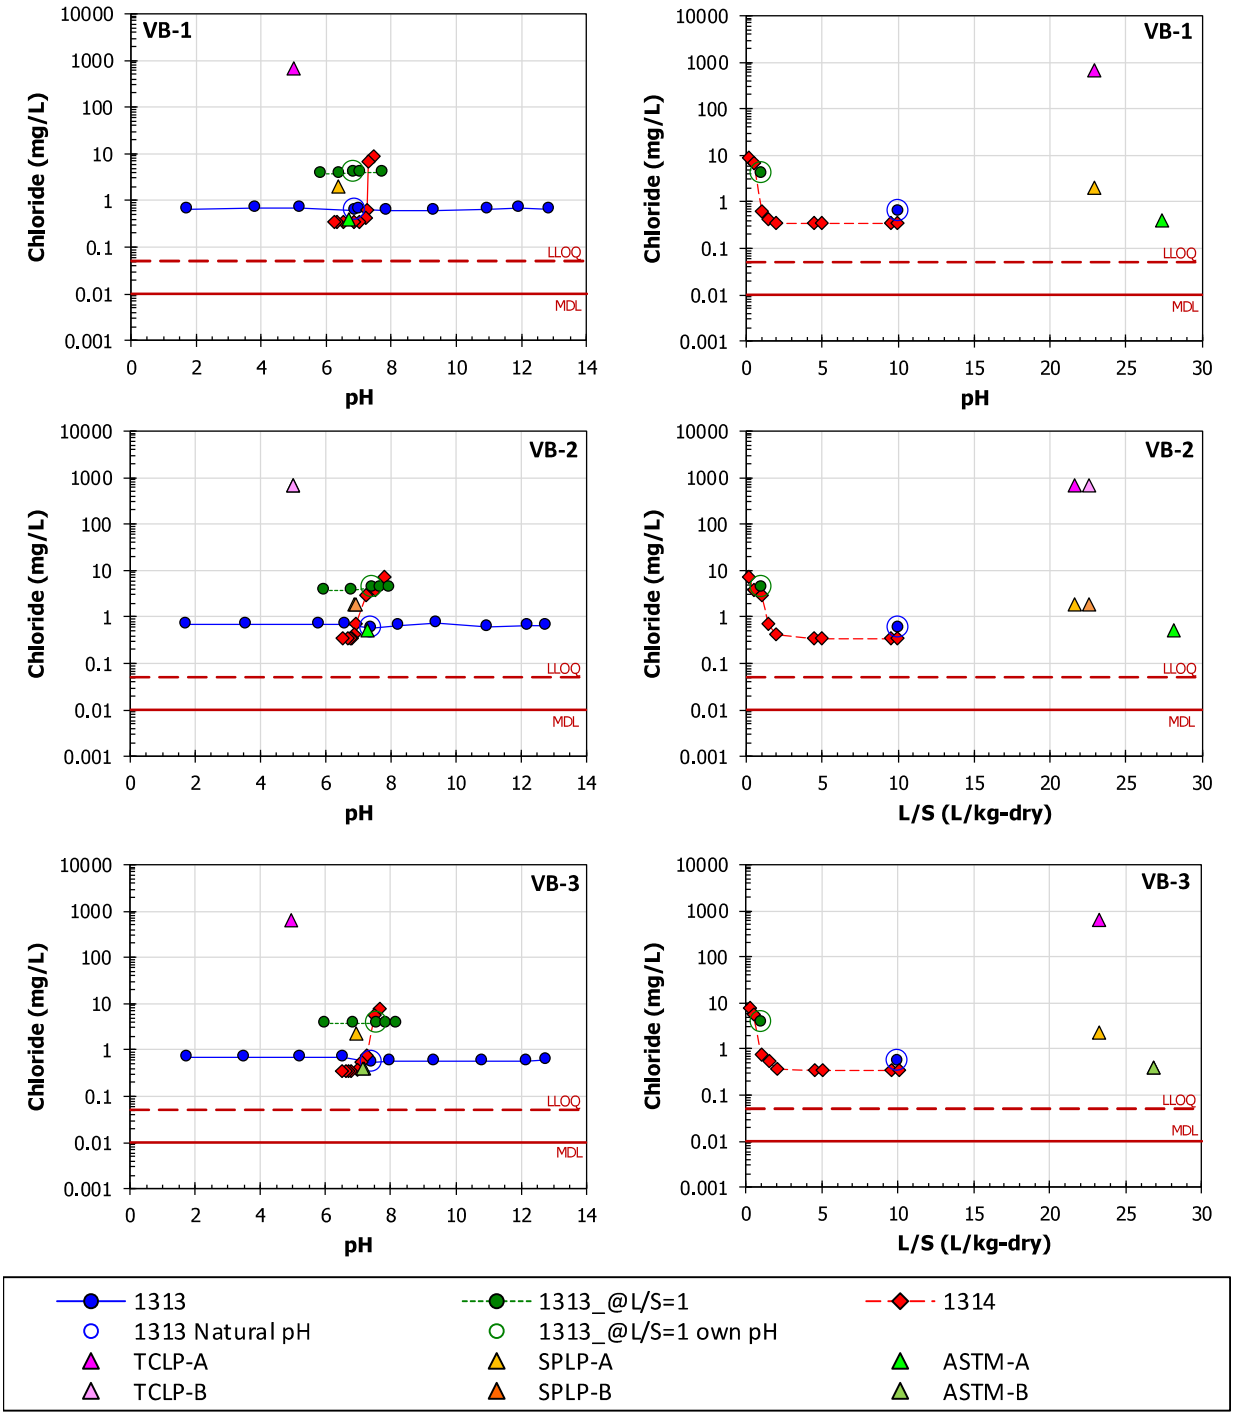

Figure E-10
Chloride concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

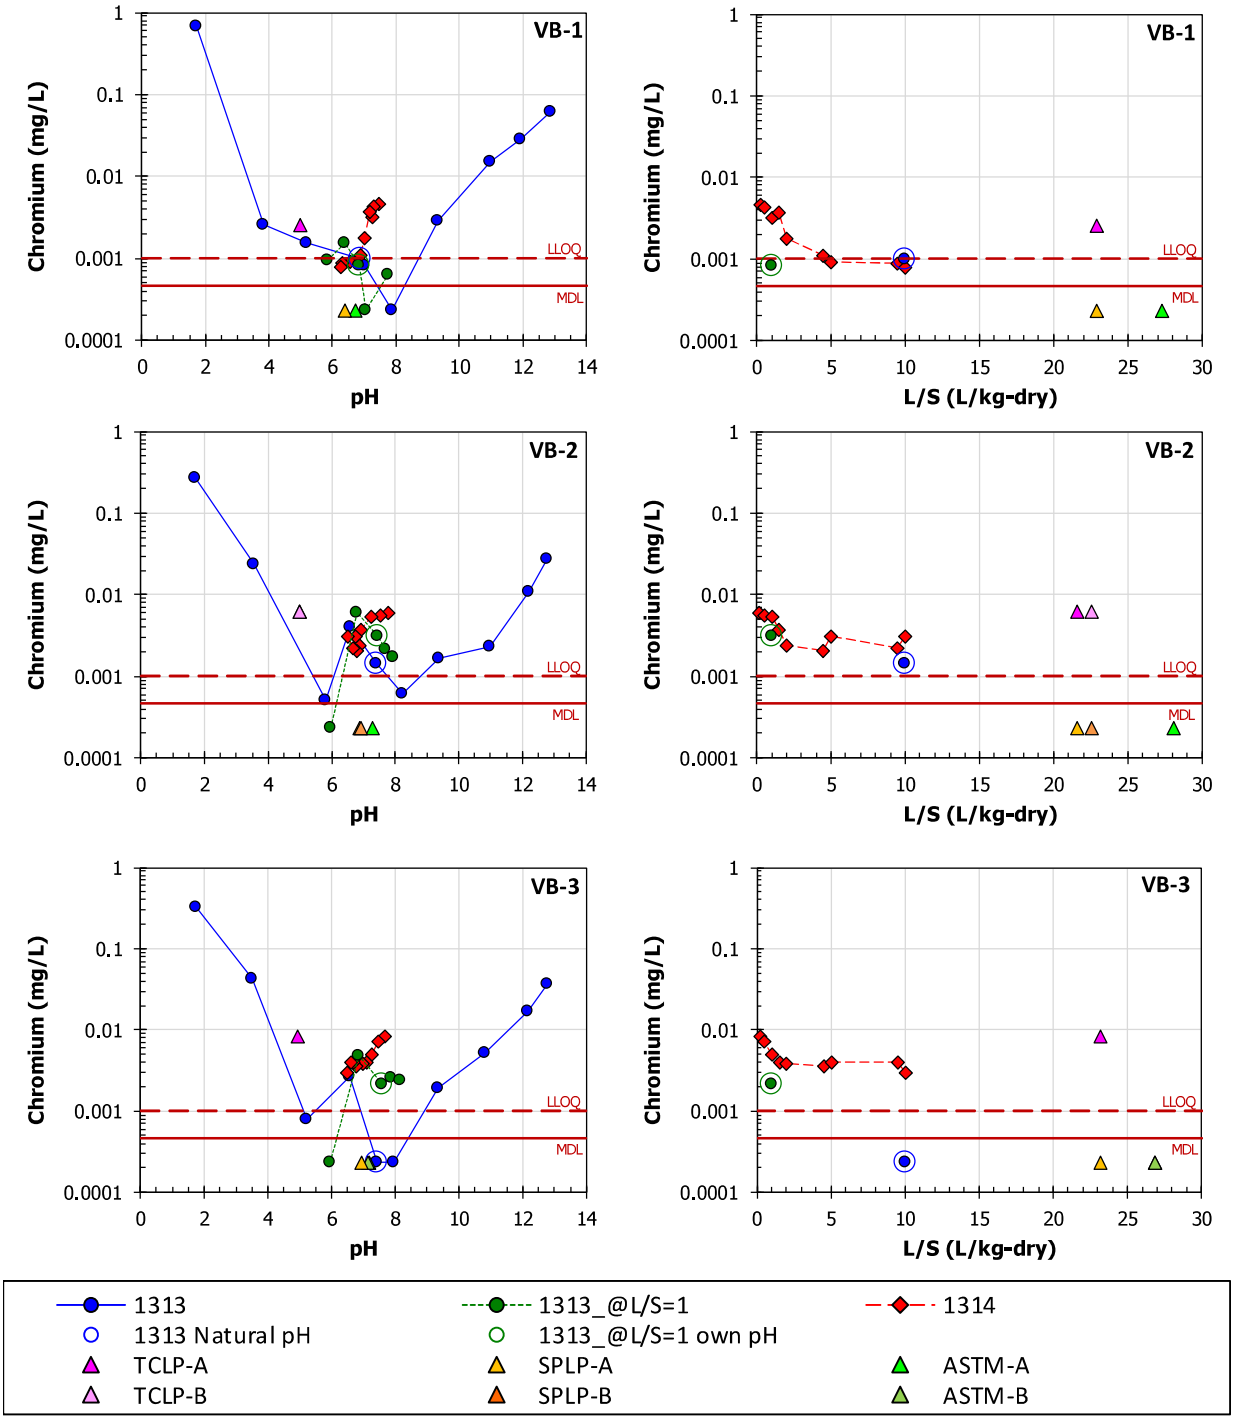

Figure E-11
Chromium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

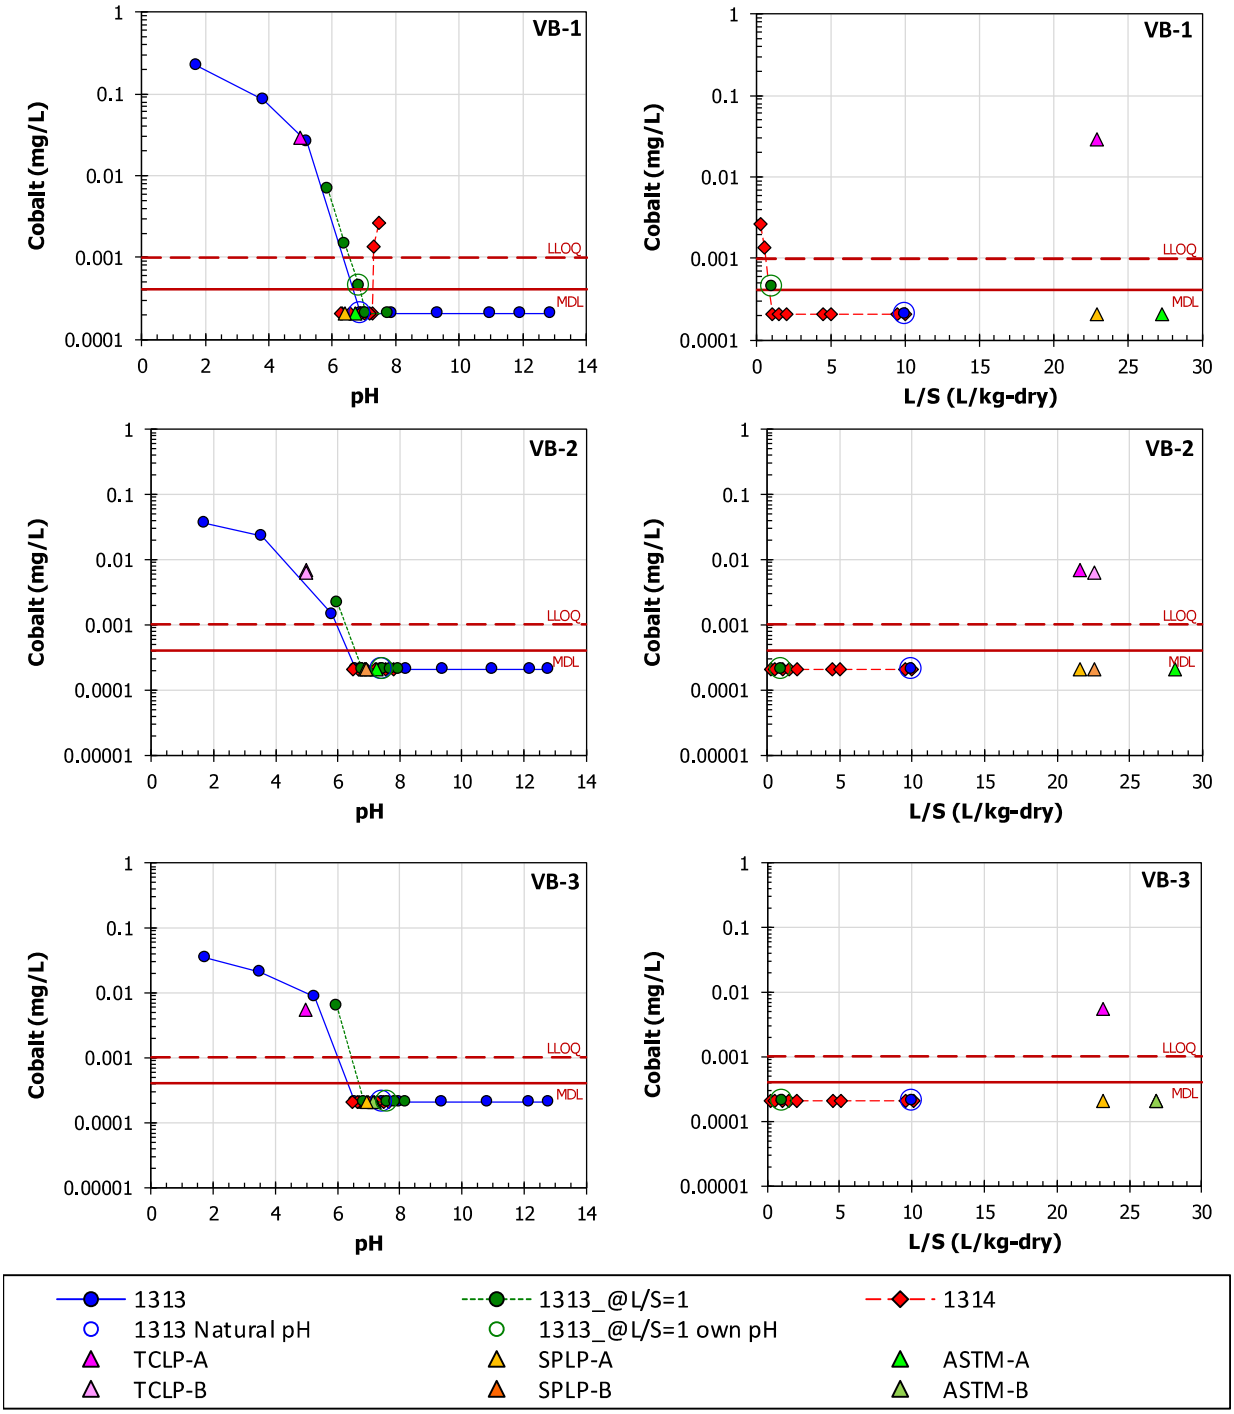

Figure E-12
Cobalt concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

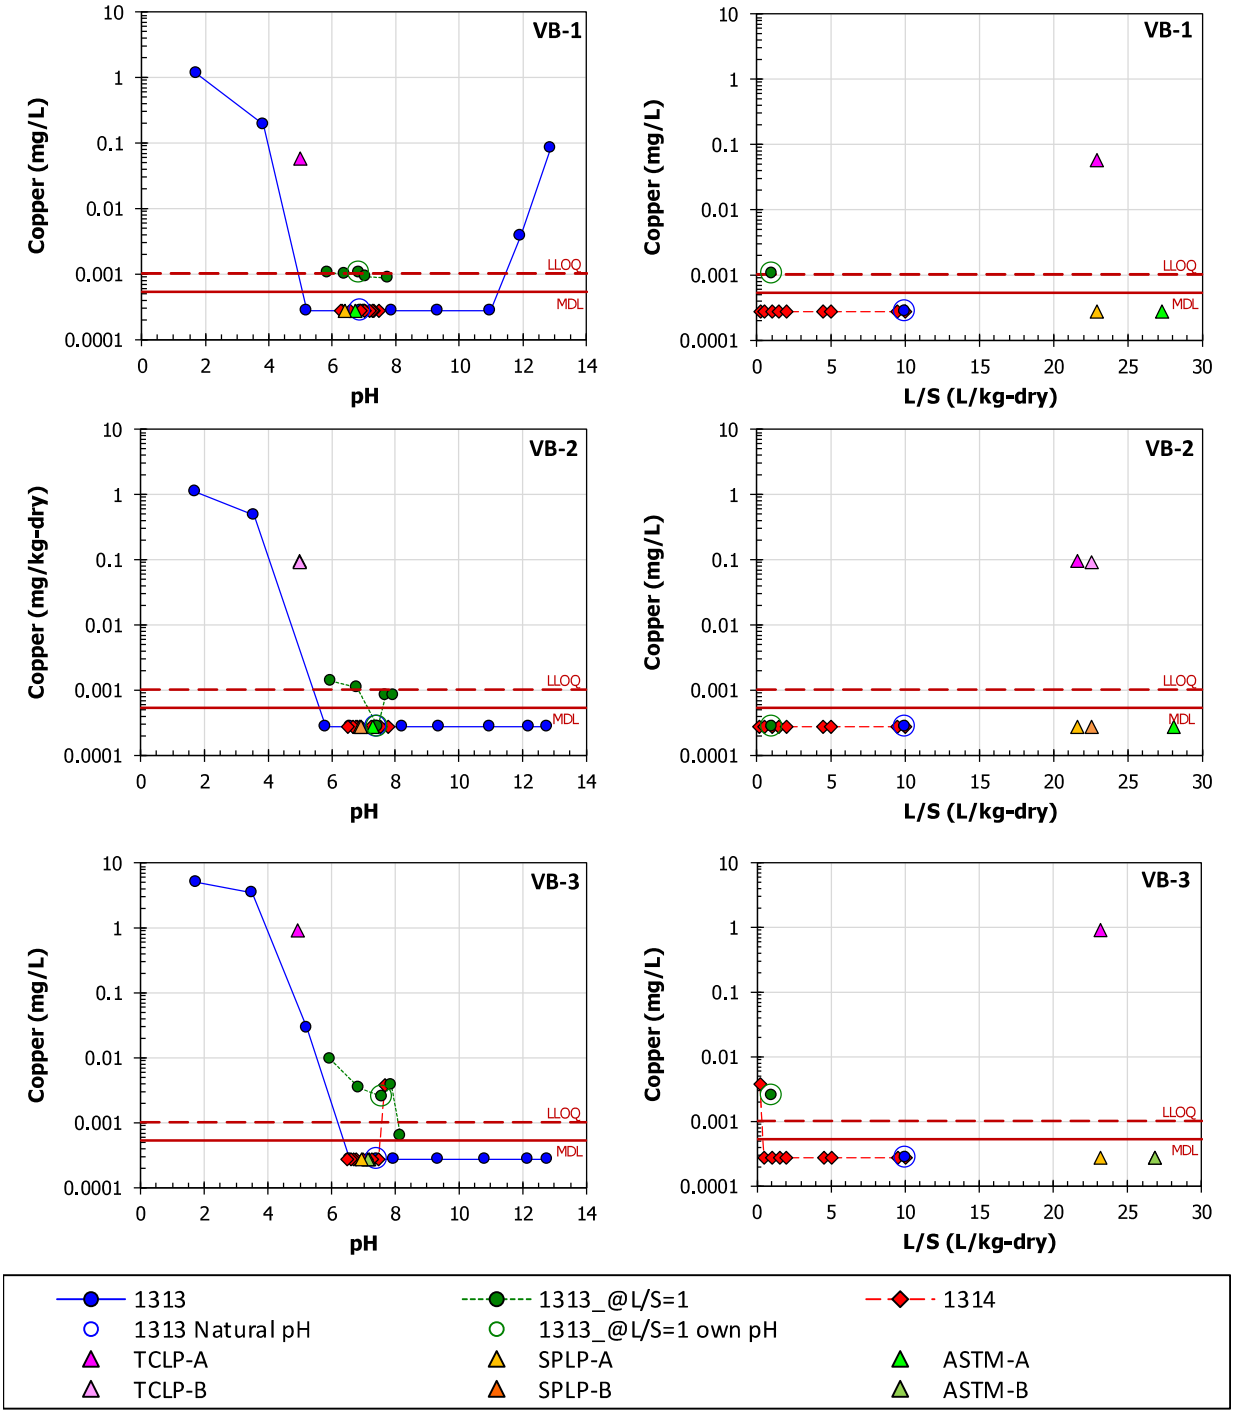

Figure E-13
Copper concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

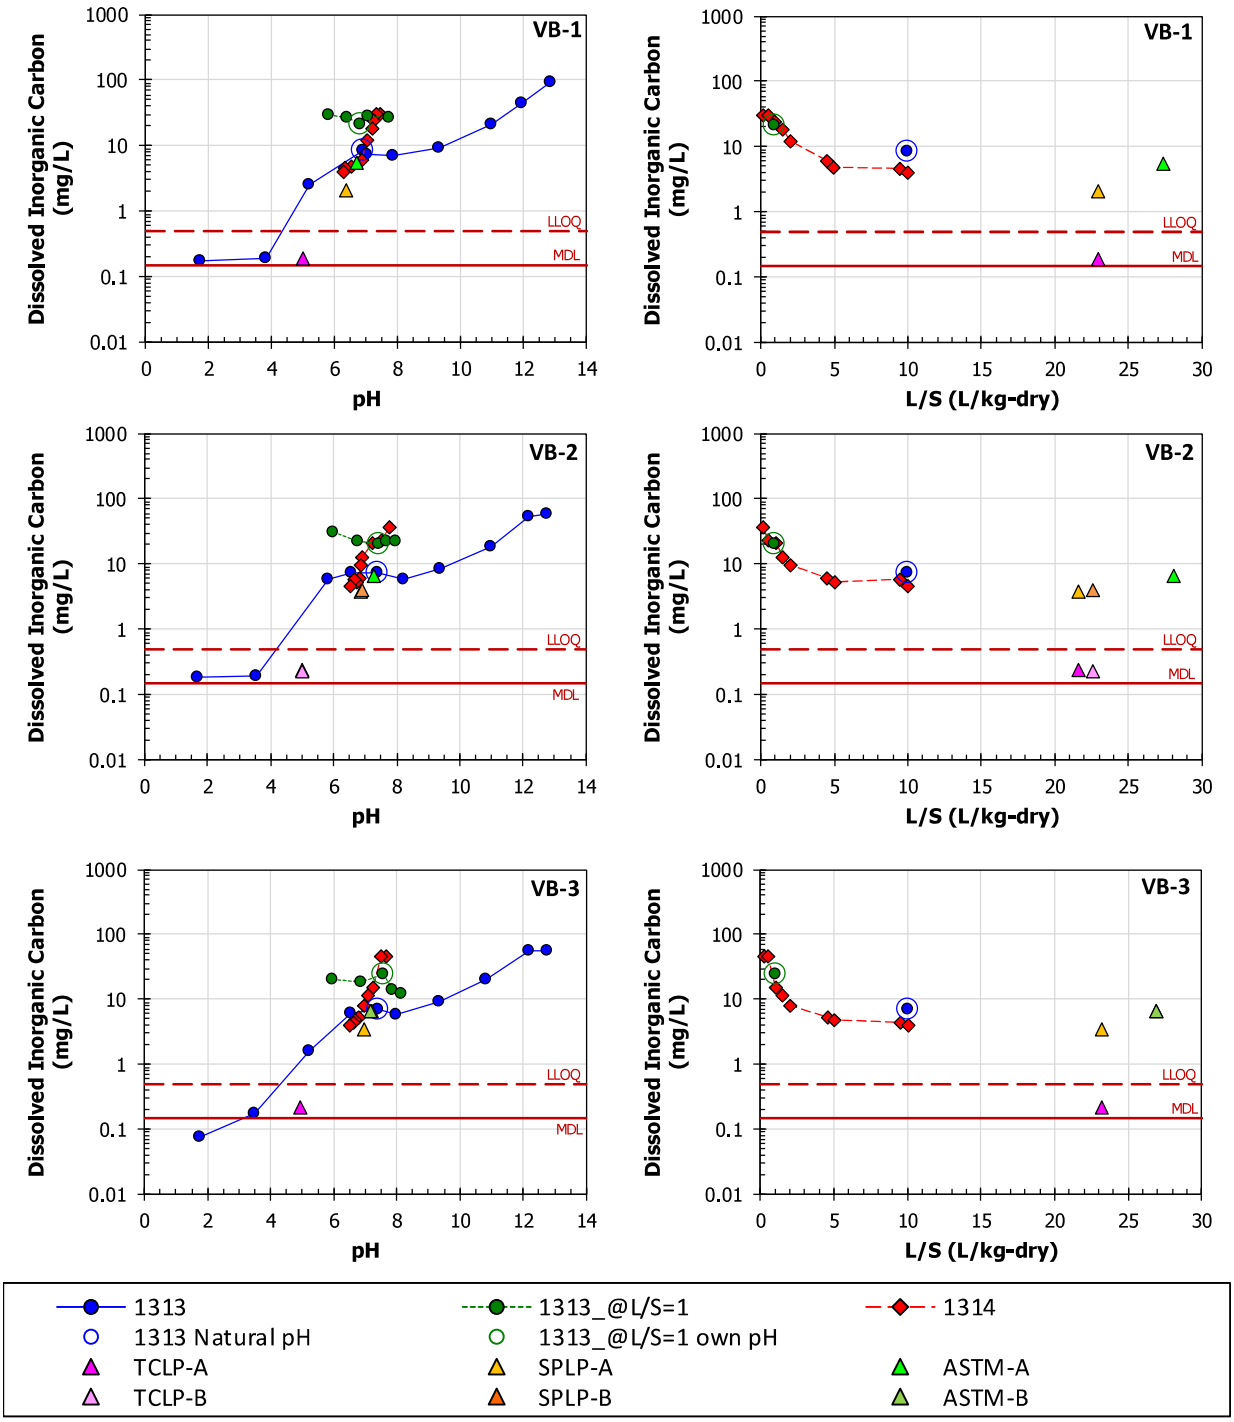

Figure E-14
Dissolved inorganic carbon concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

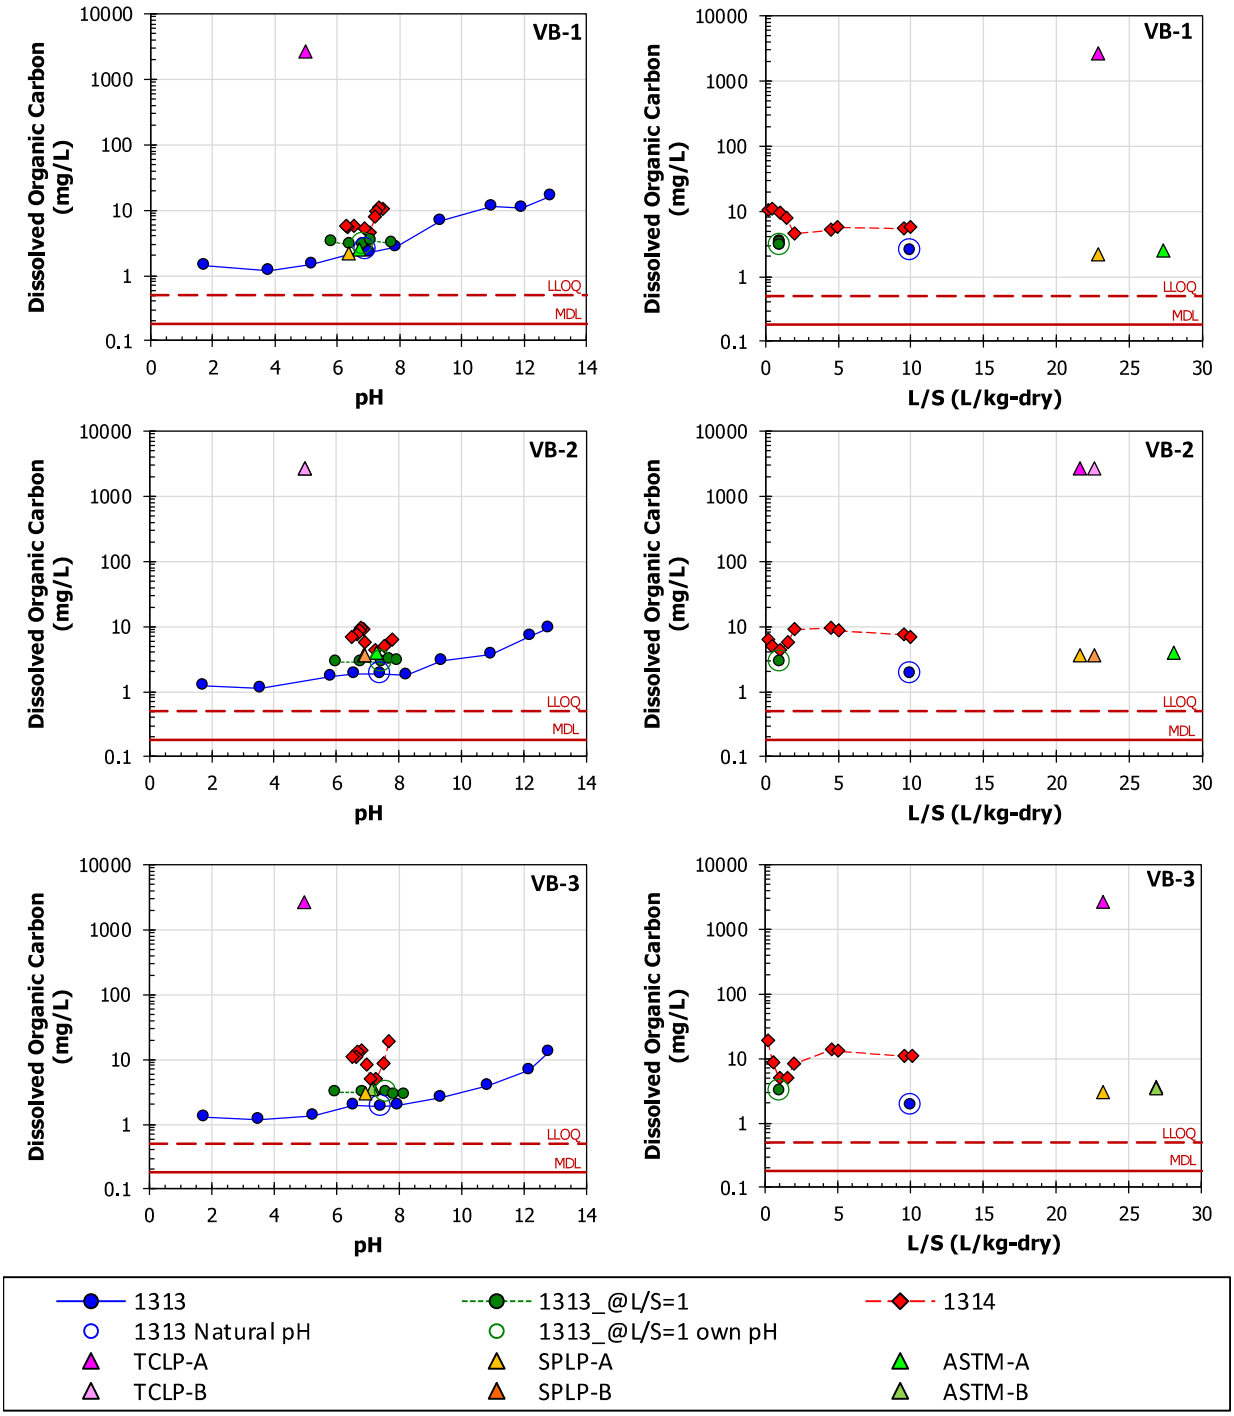

Figure E-15
Dissolved organic carbon concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

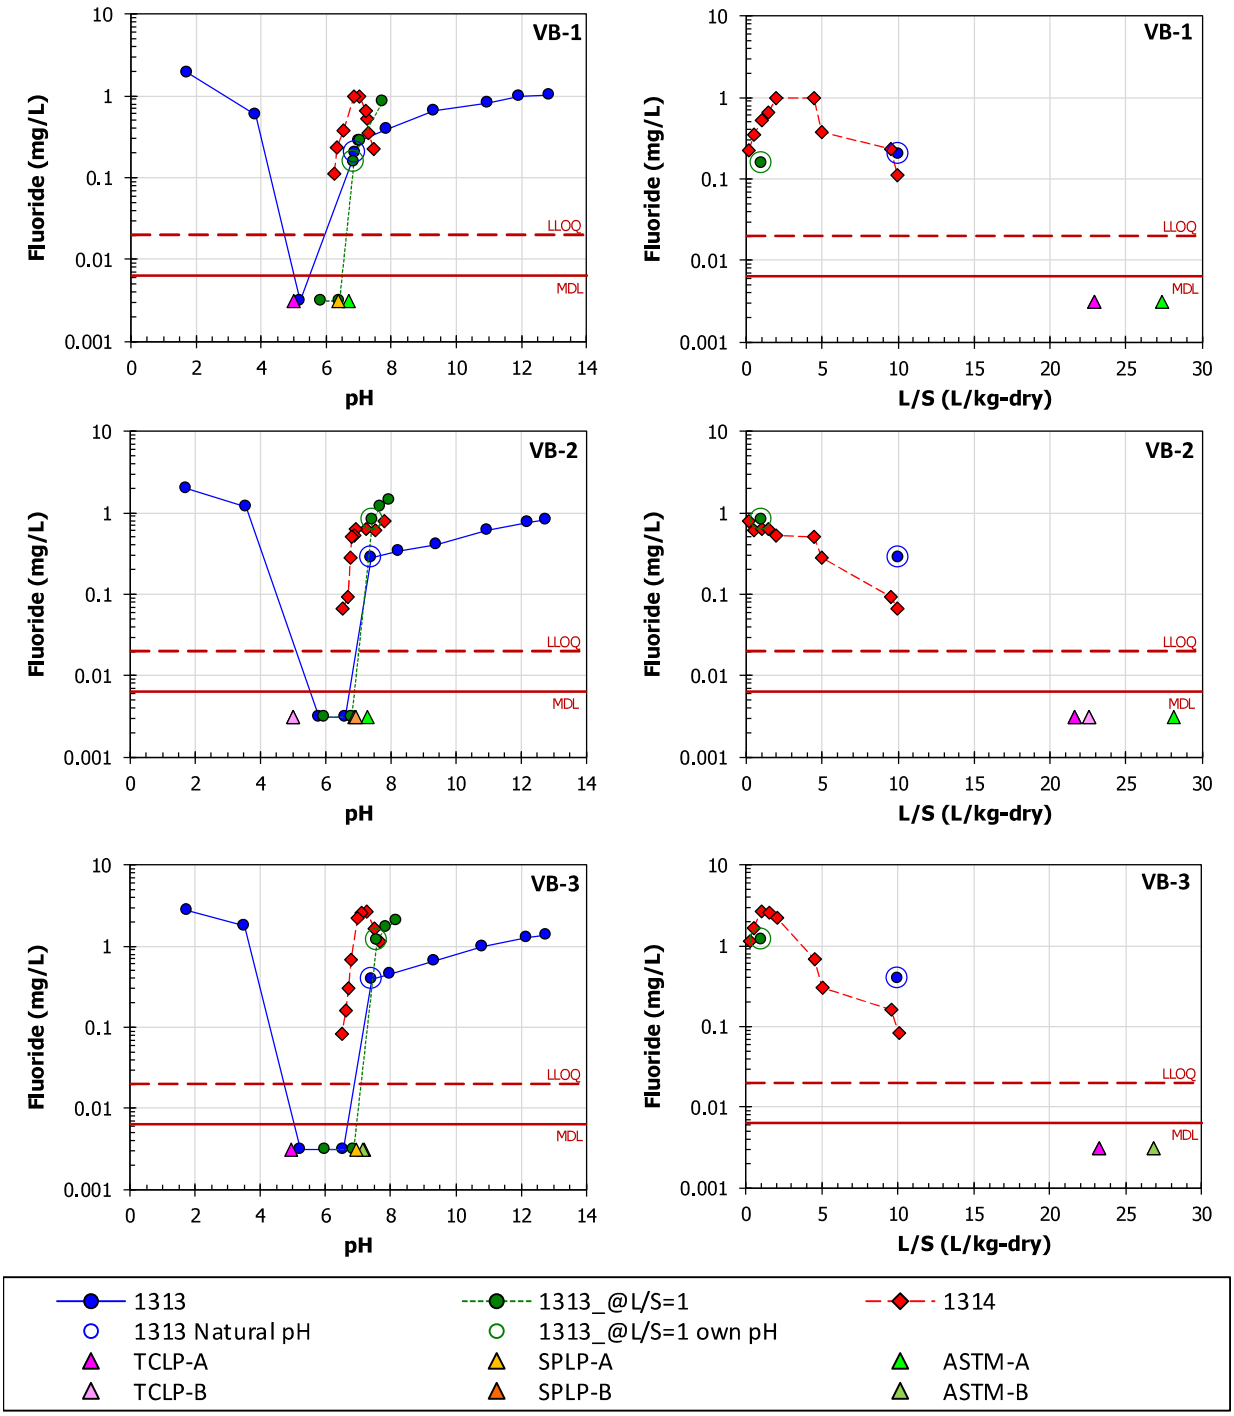

Figure E-16
Flouride concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

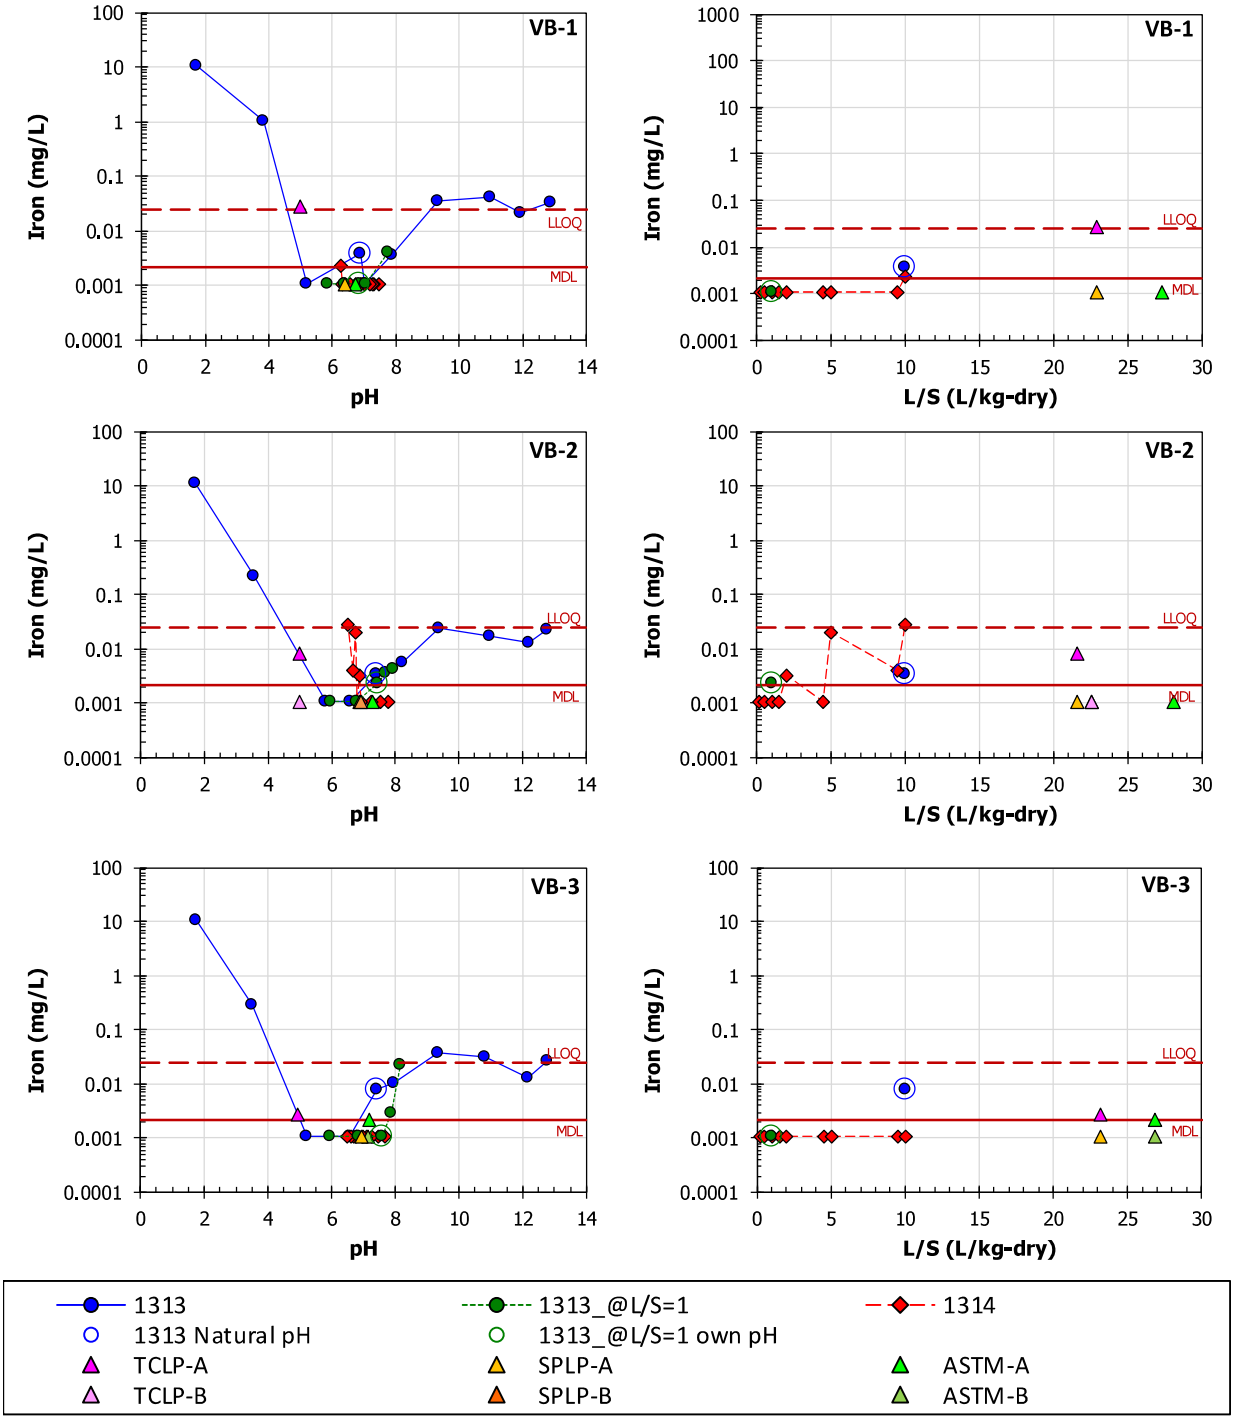

Figure E-17
Iron concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

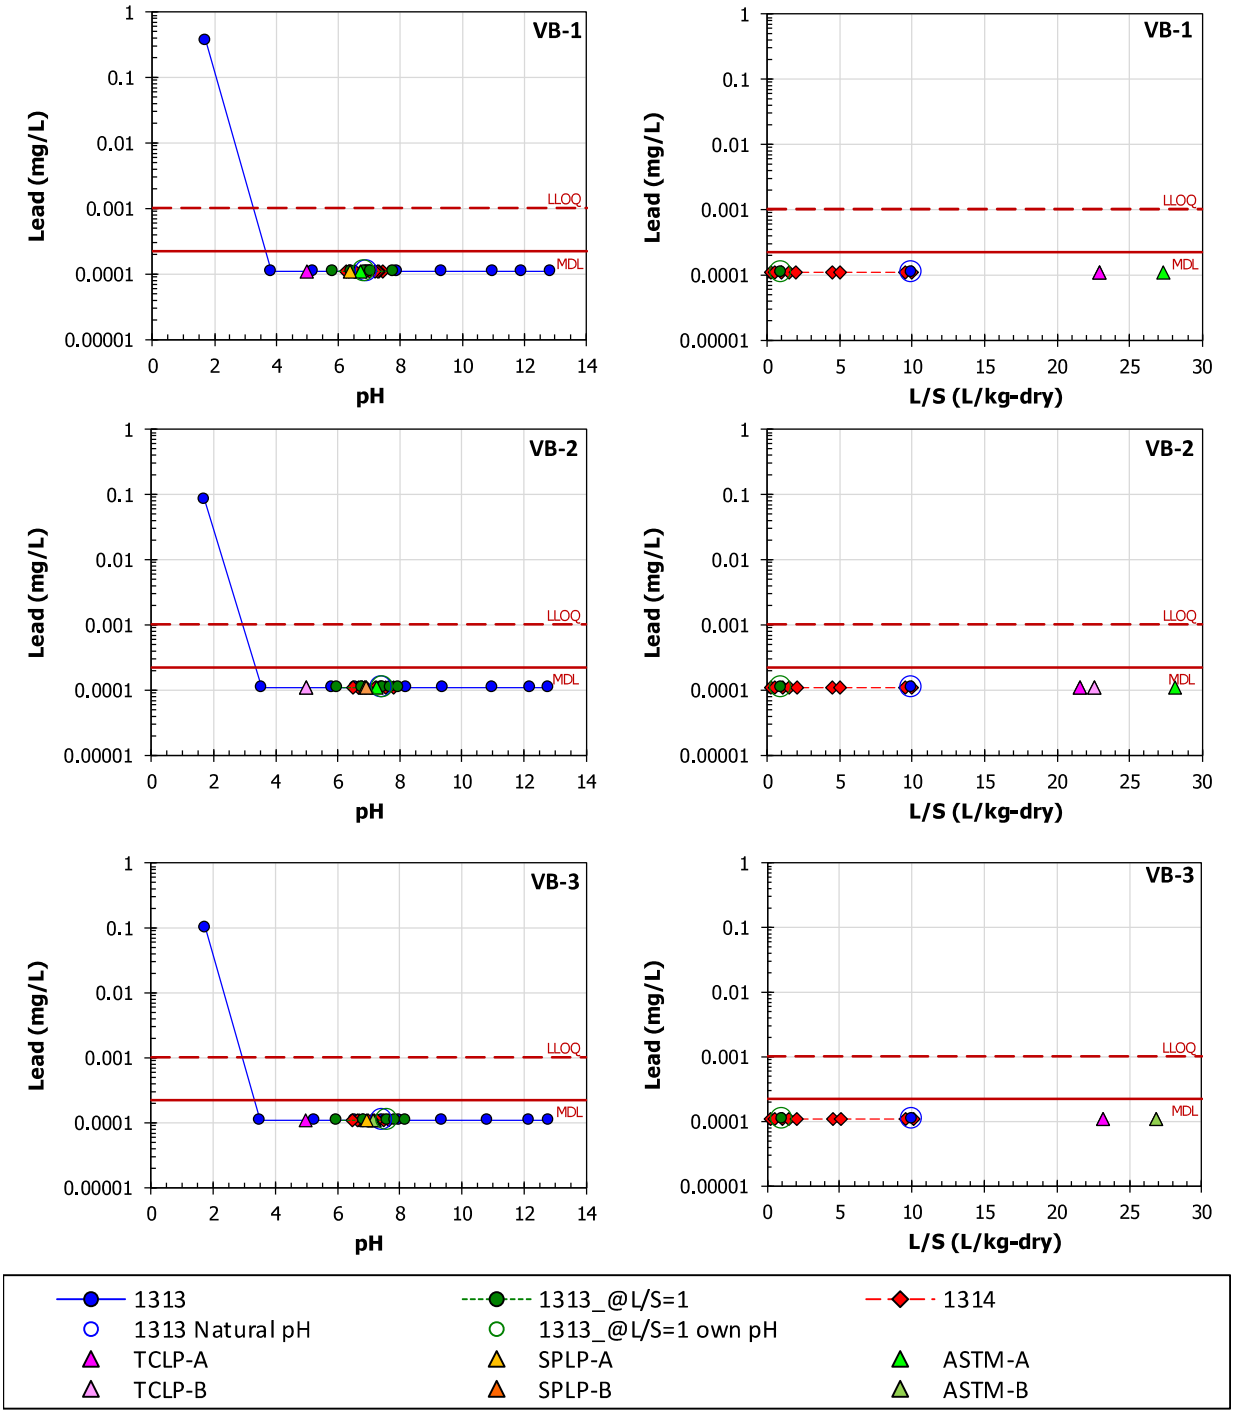

Figure E-18
Lead concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

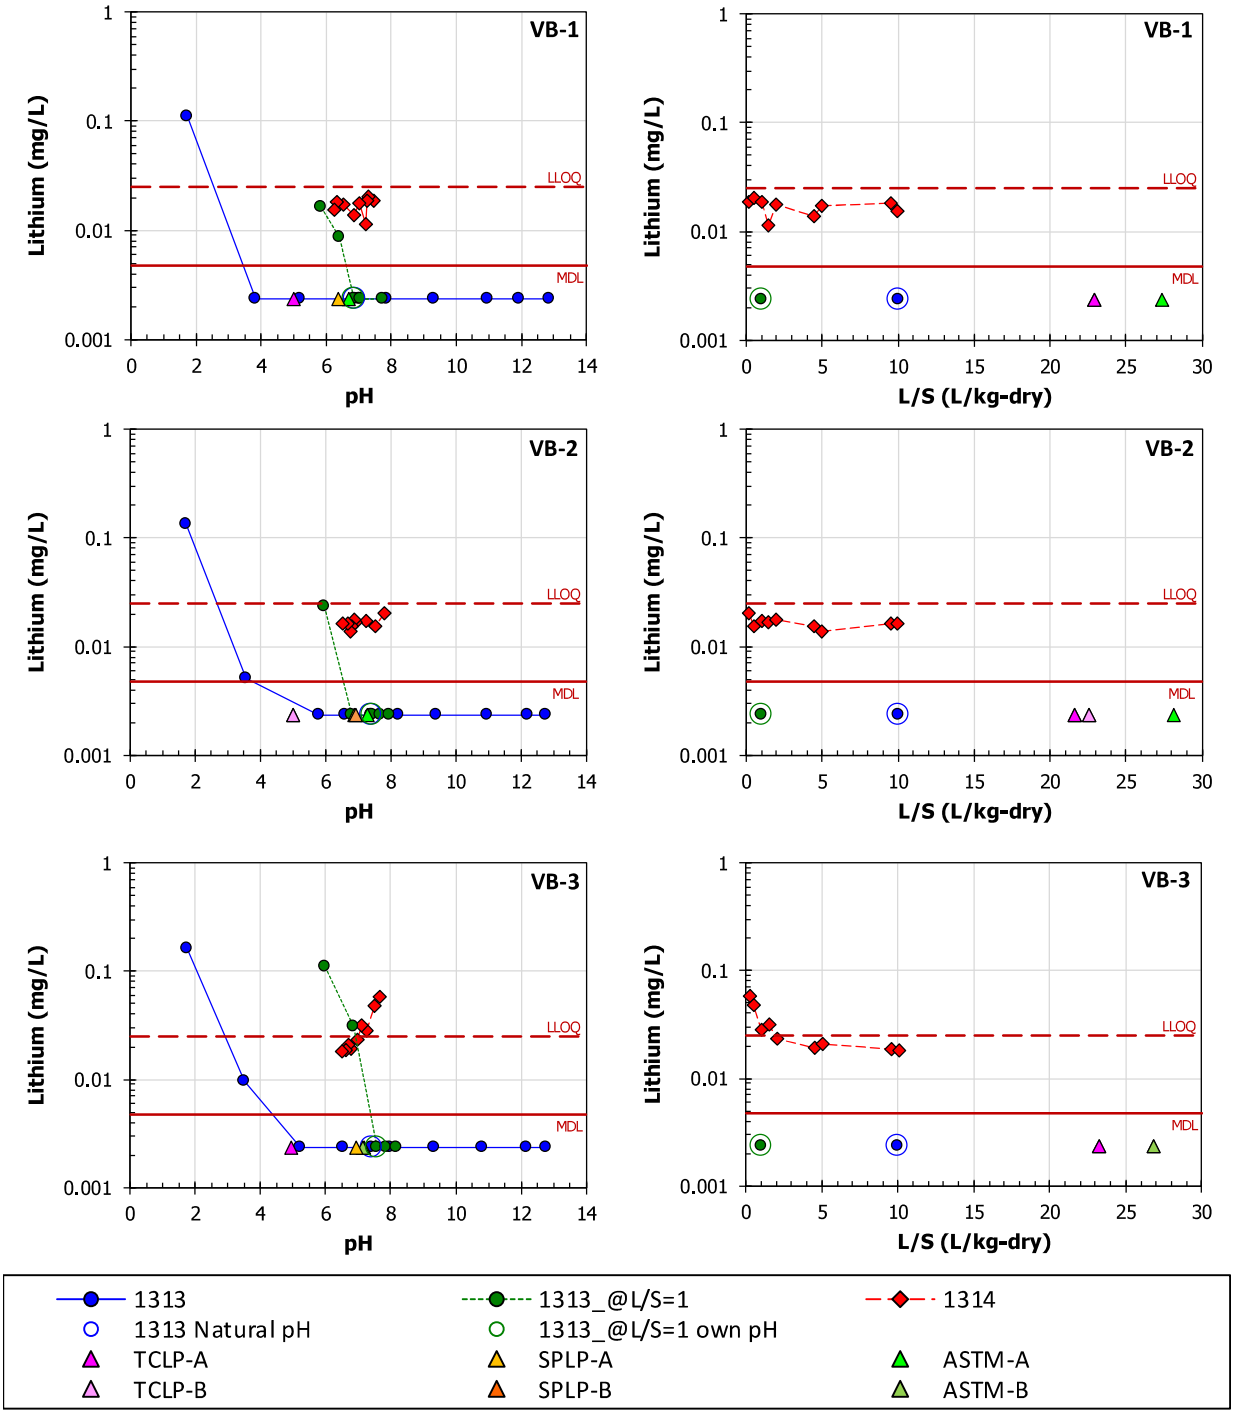

Figure E-19
Lithium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

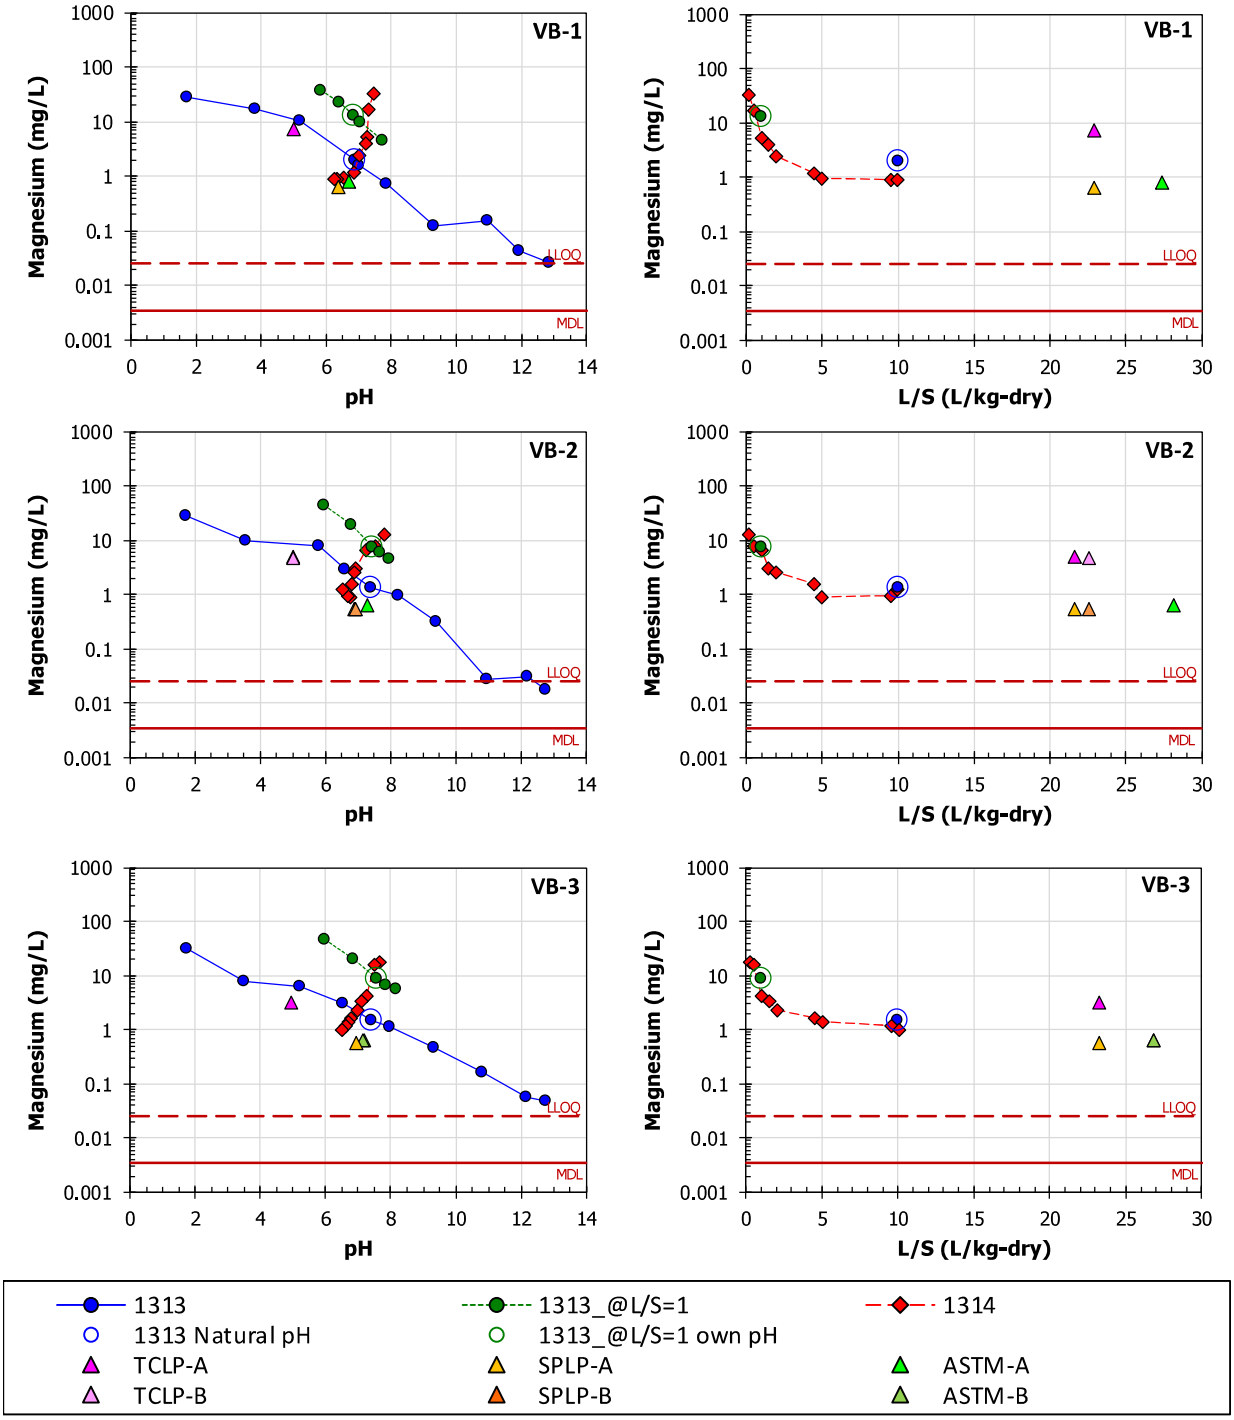

Figure E-20
Magnesium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

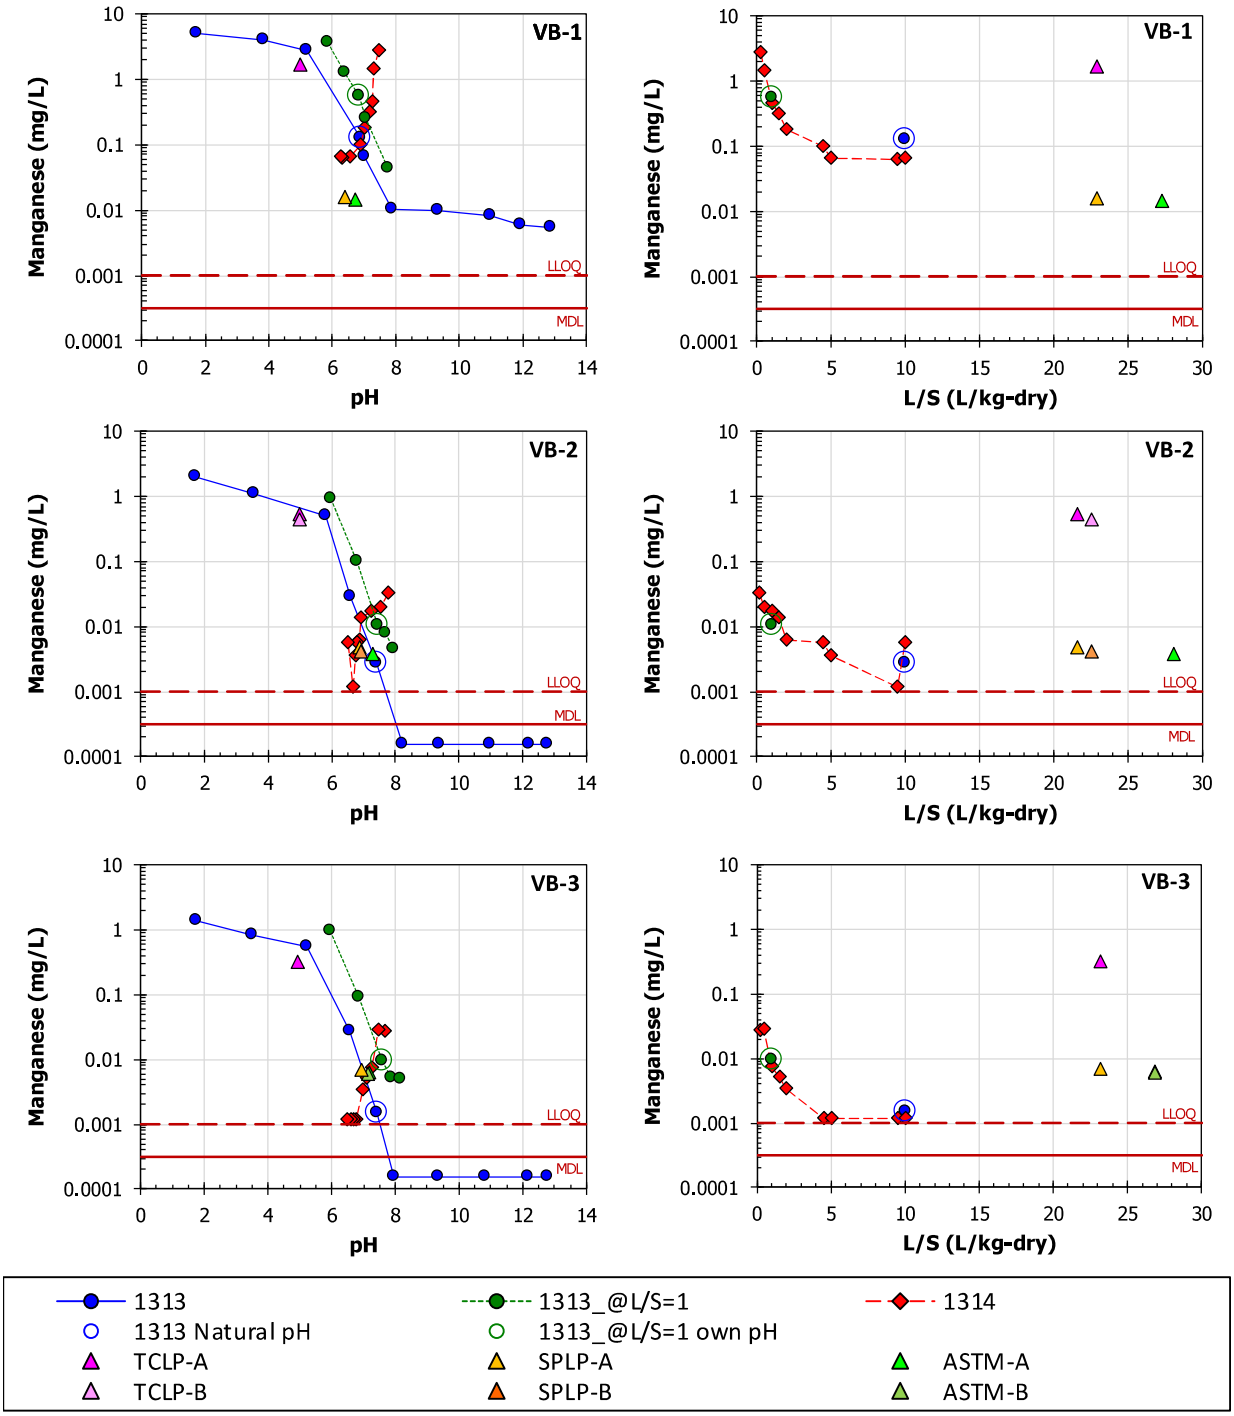

Figure E-21
Manganese concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

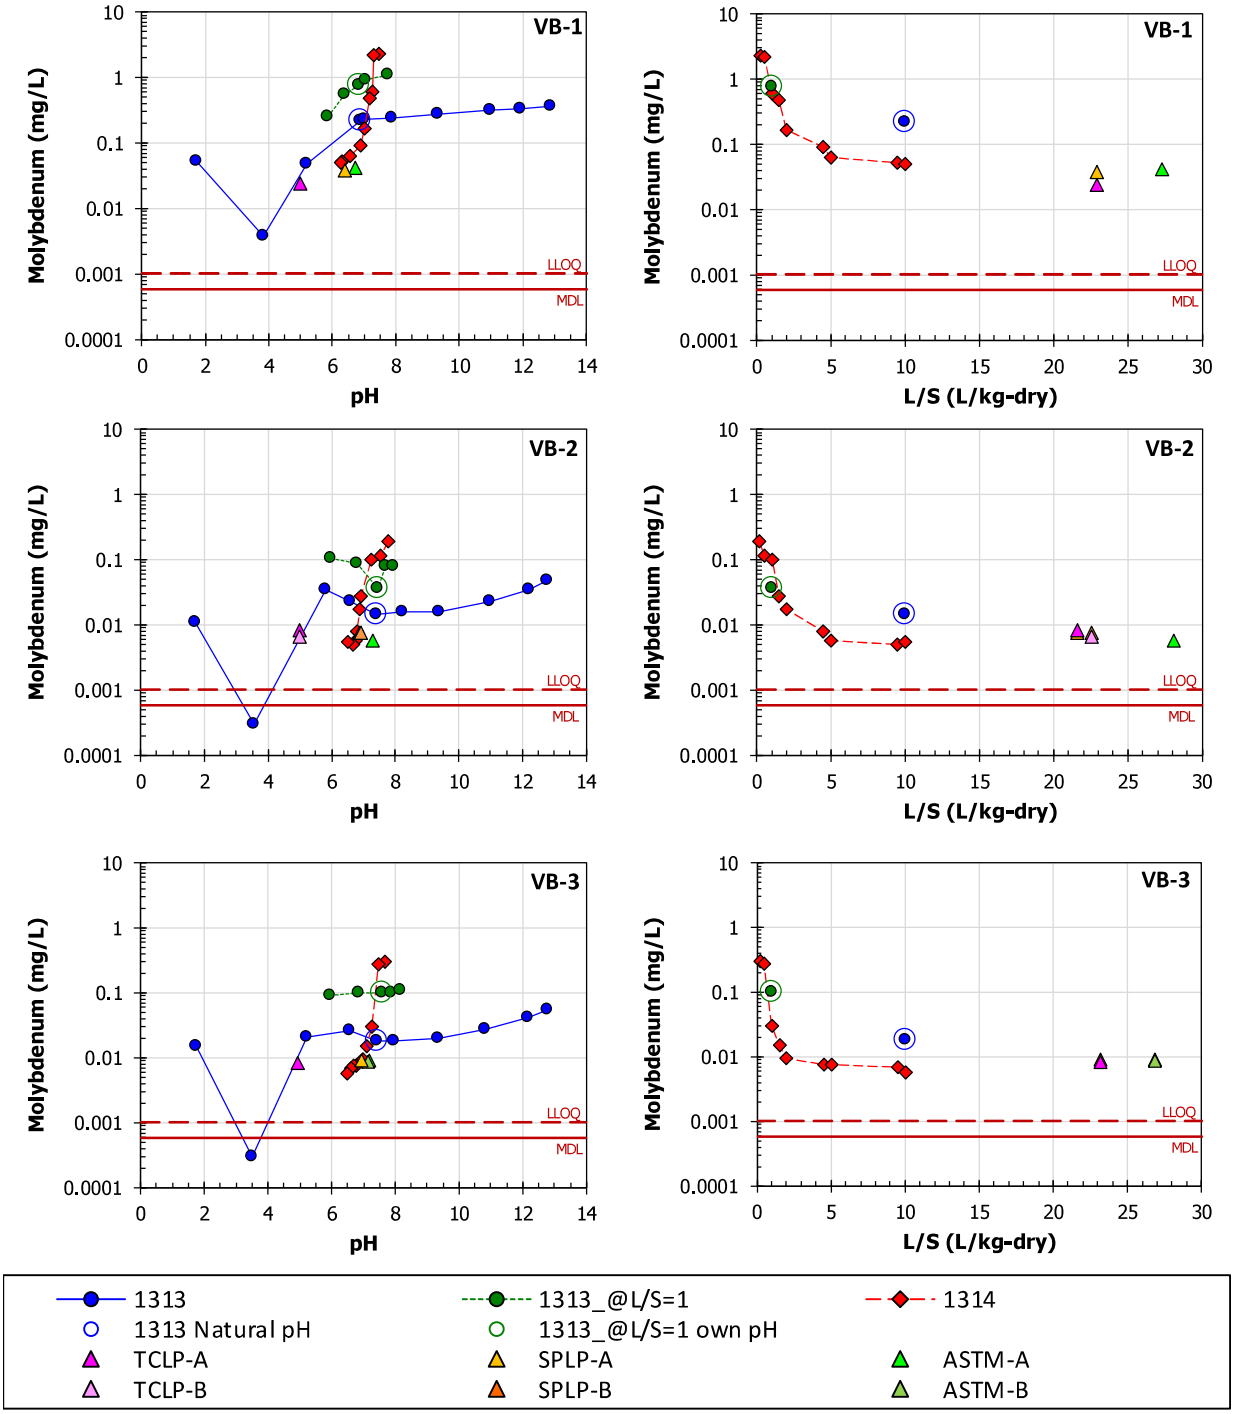

Figure E-22
Molybdenum concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

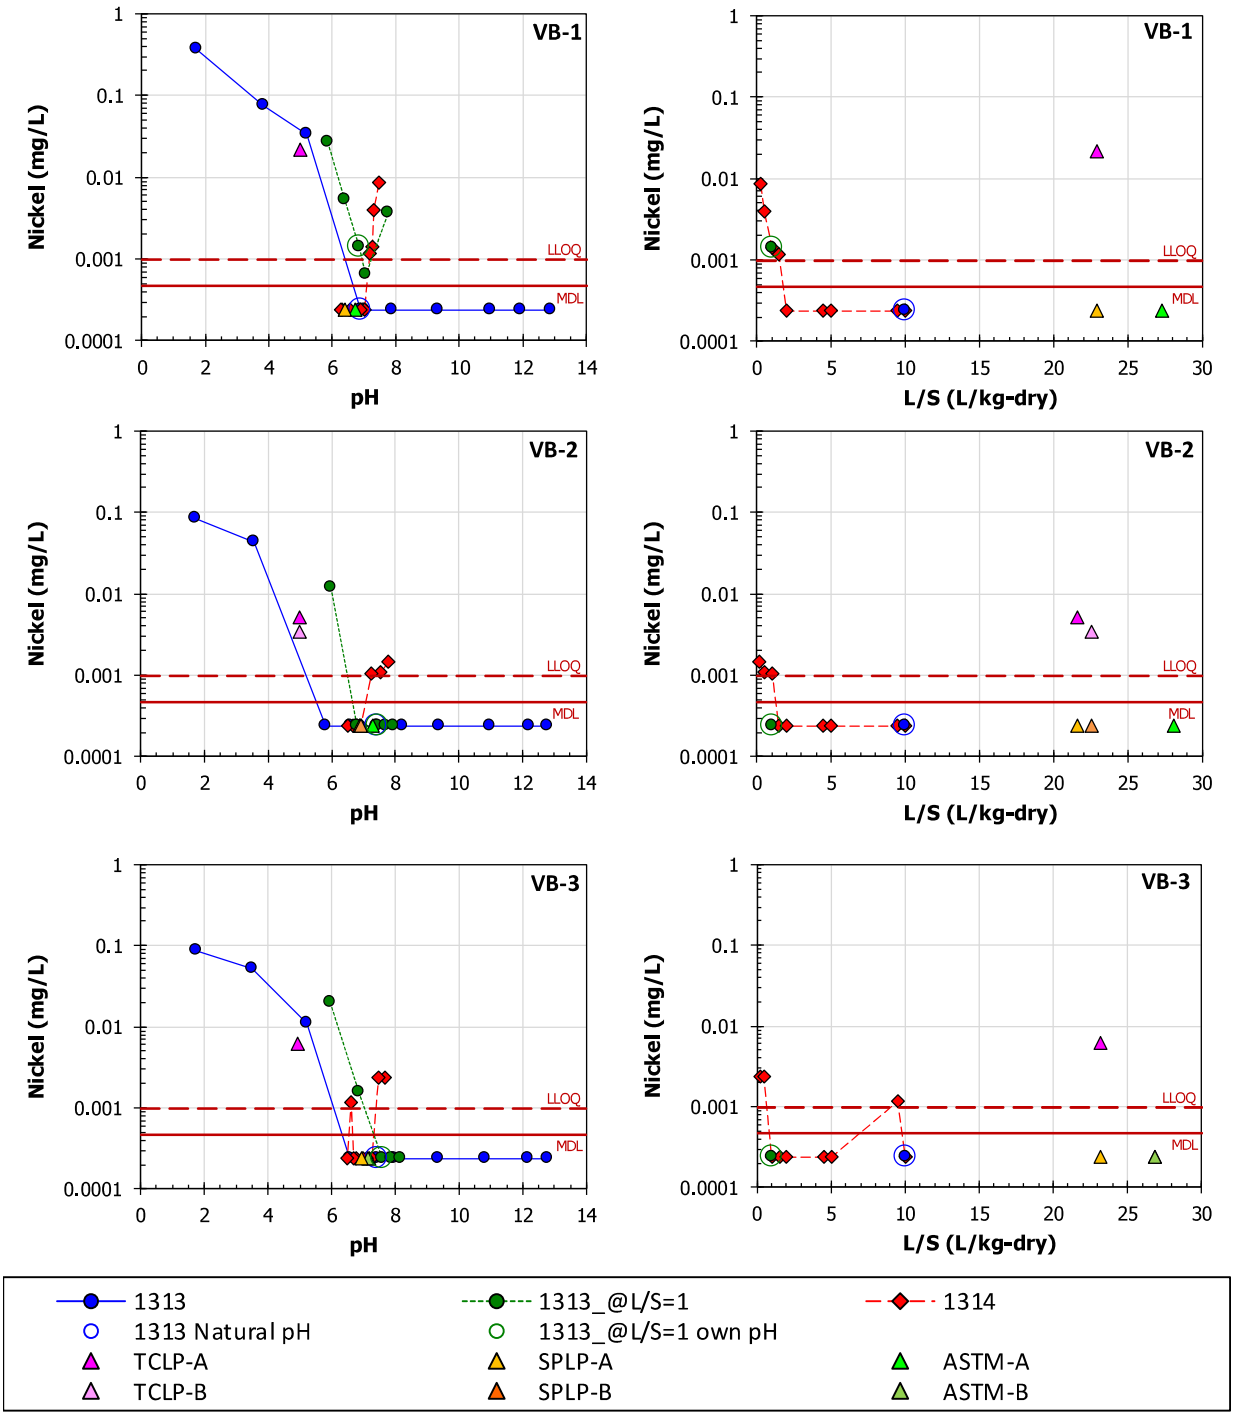

Figure E-23
Nickel concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

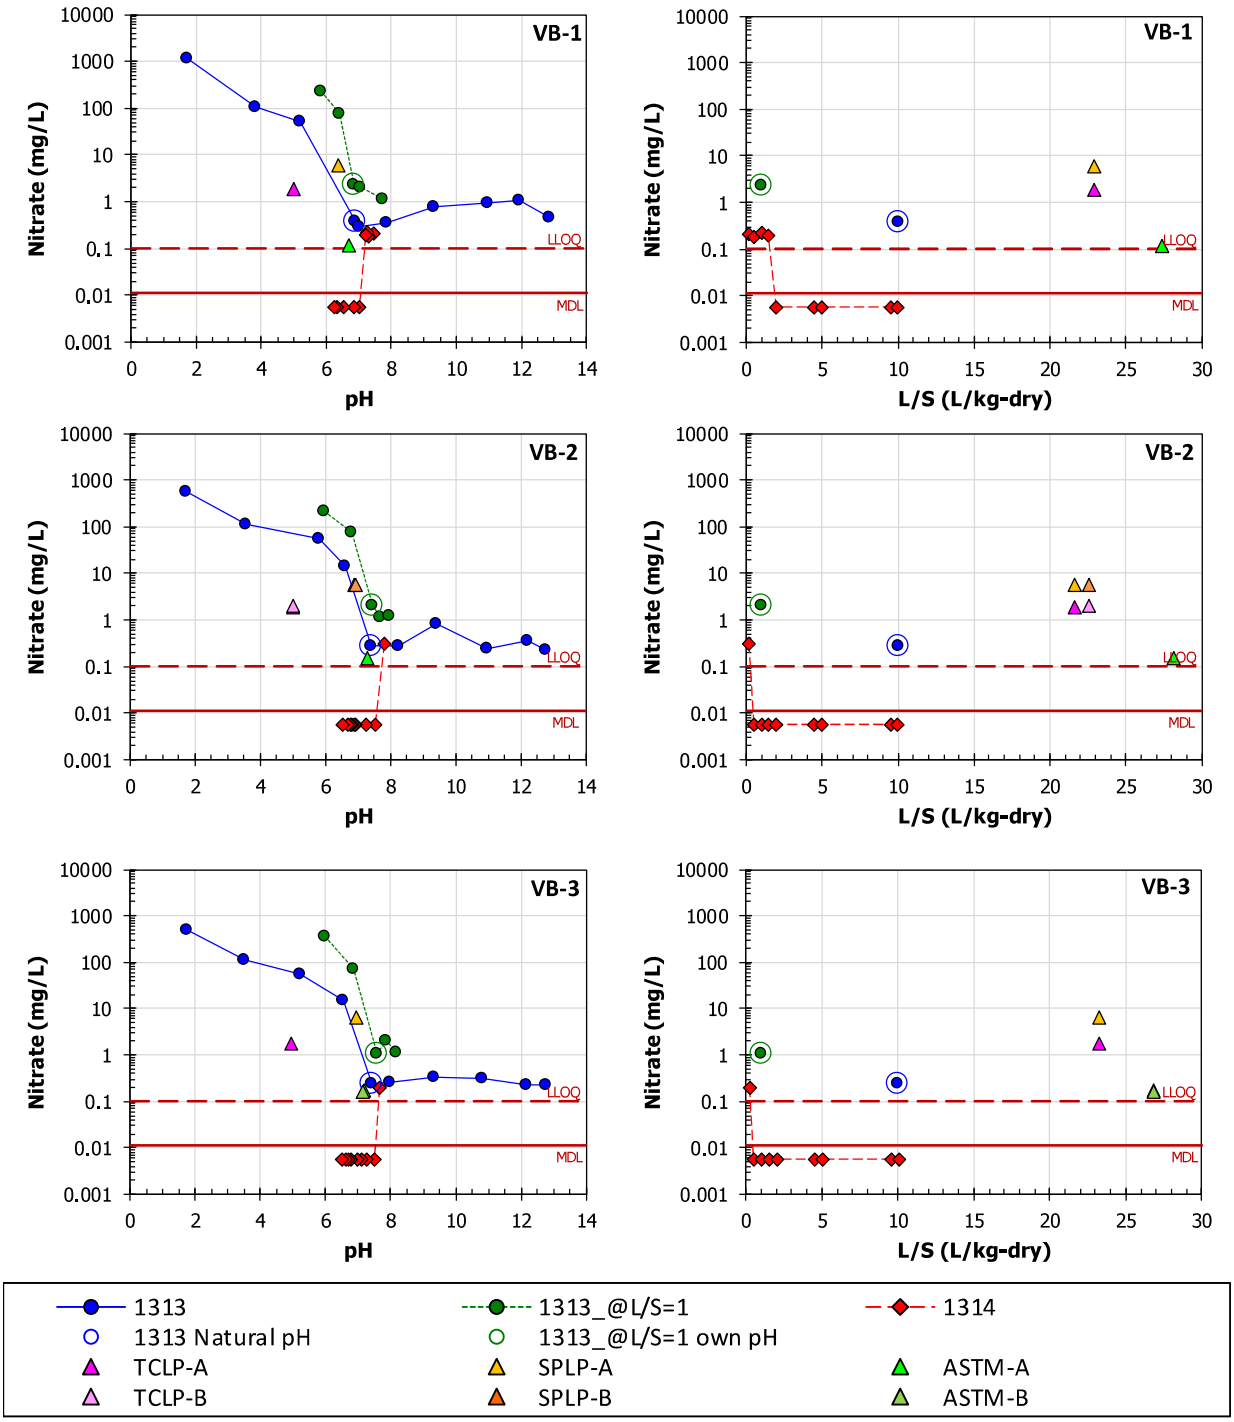

Figure E-24
Nitrate concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

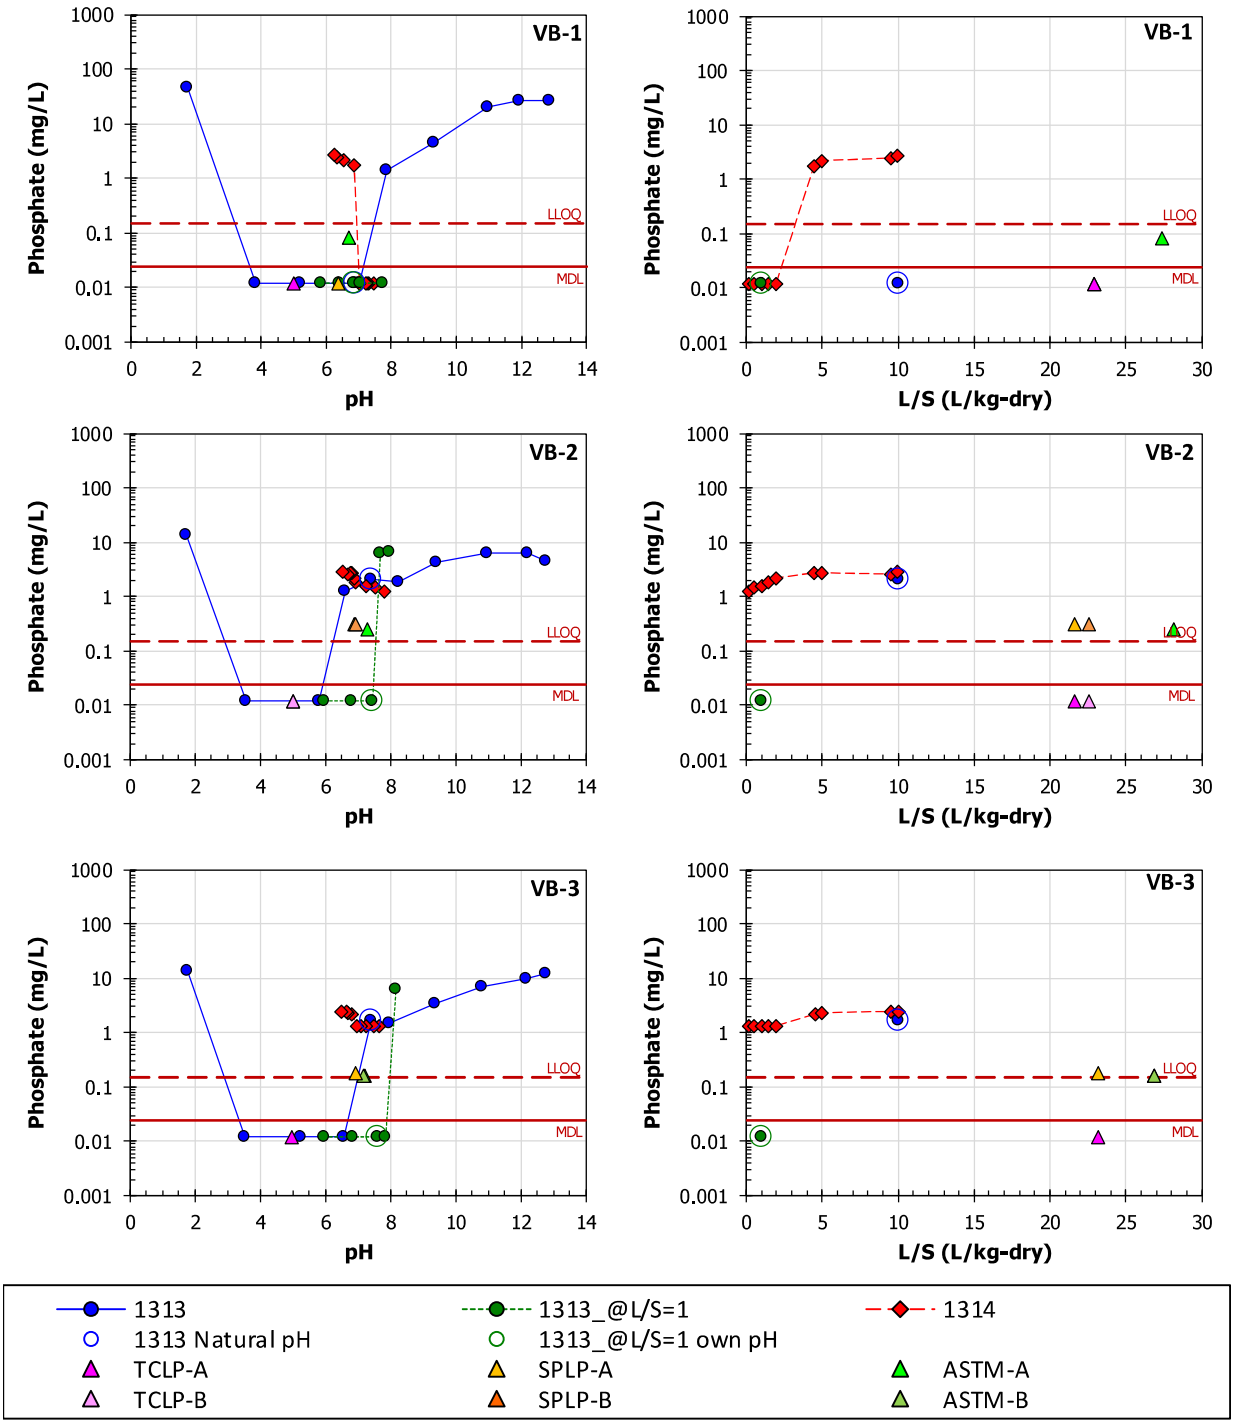

Figure E-25
Phosphate concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

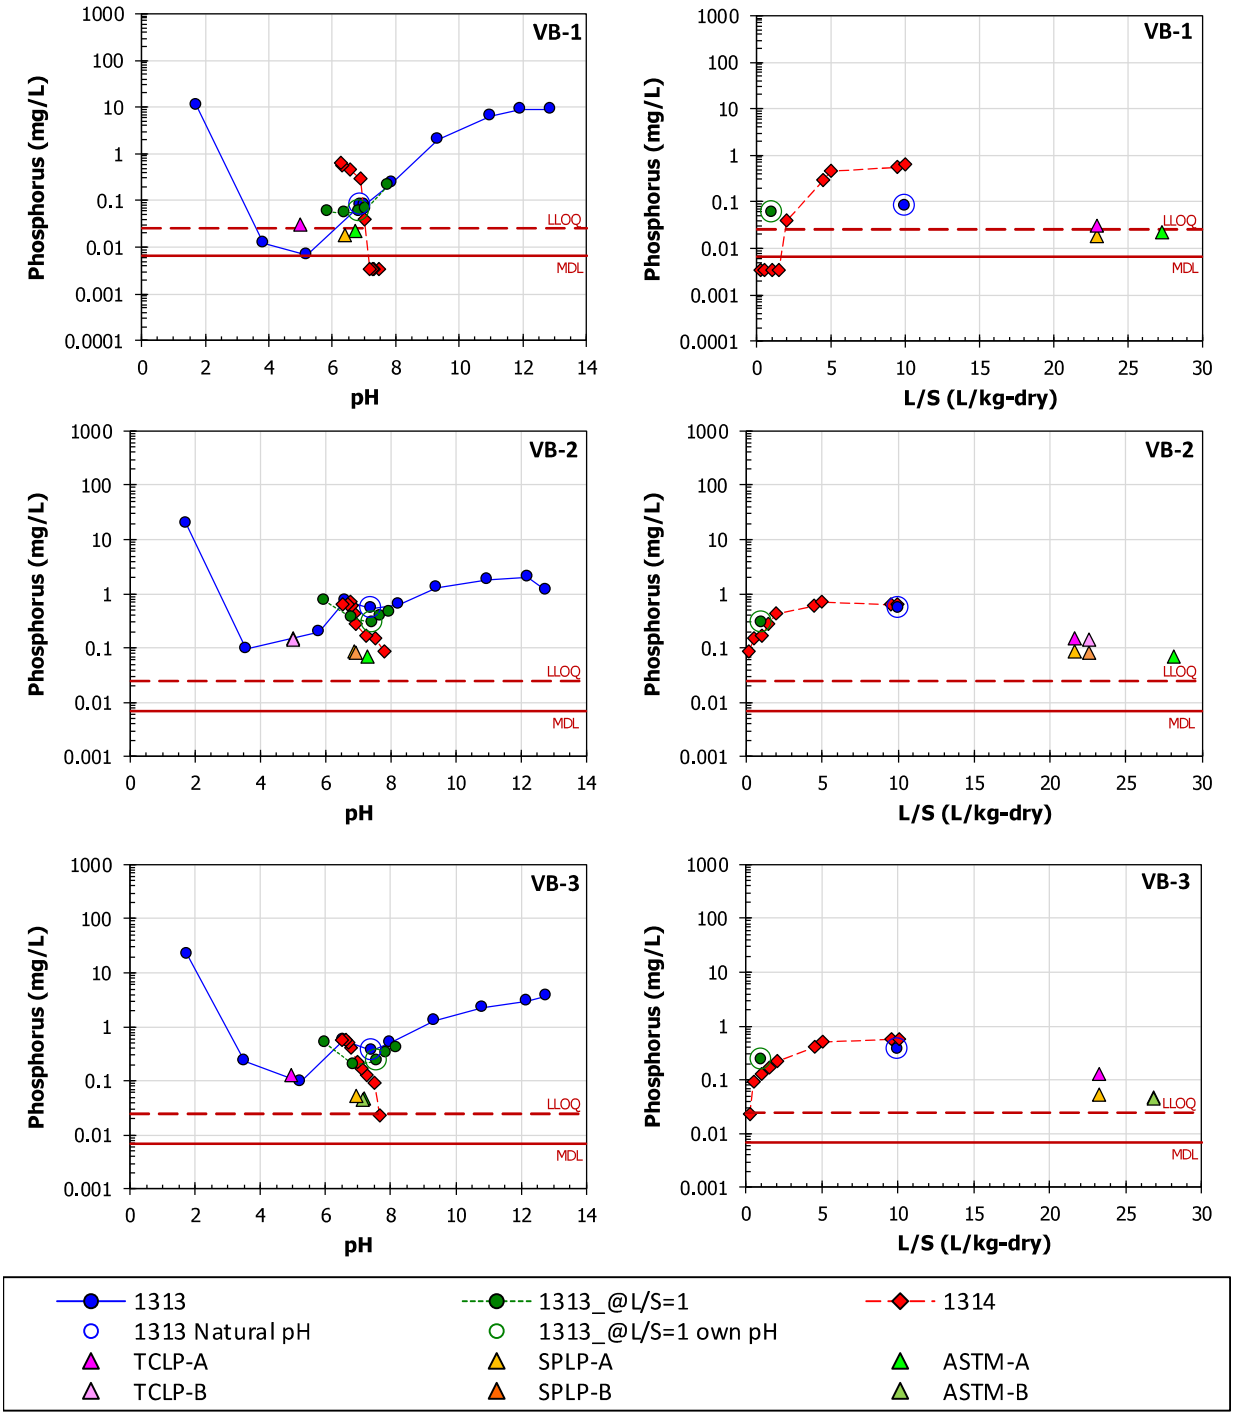

Figure E-26
Phosphorus concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

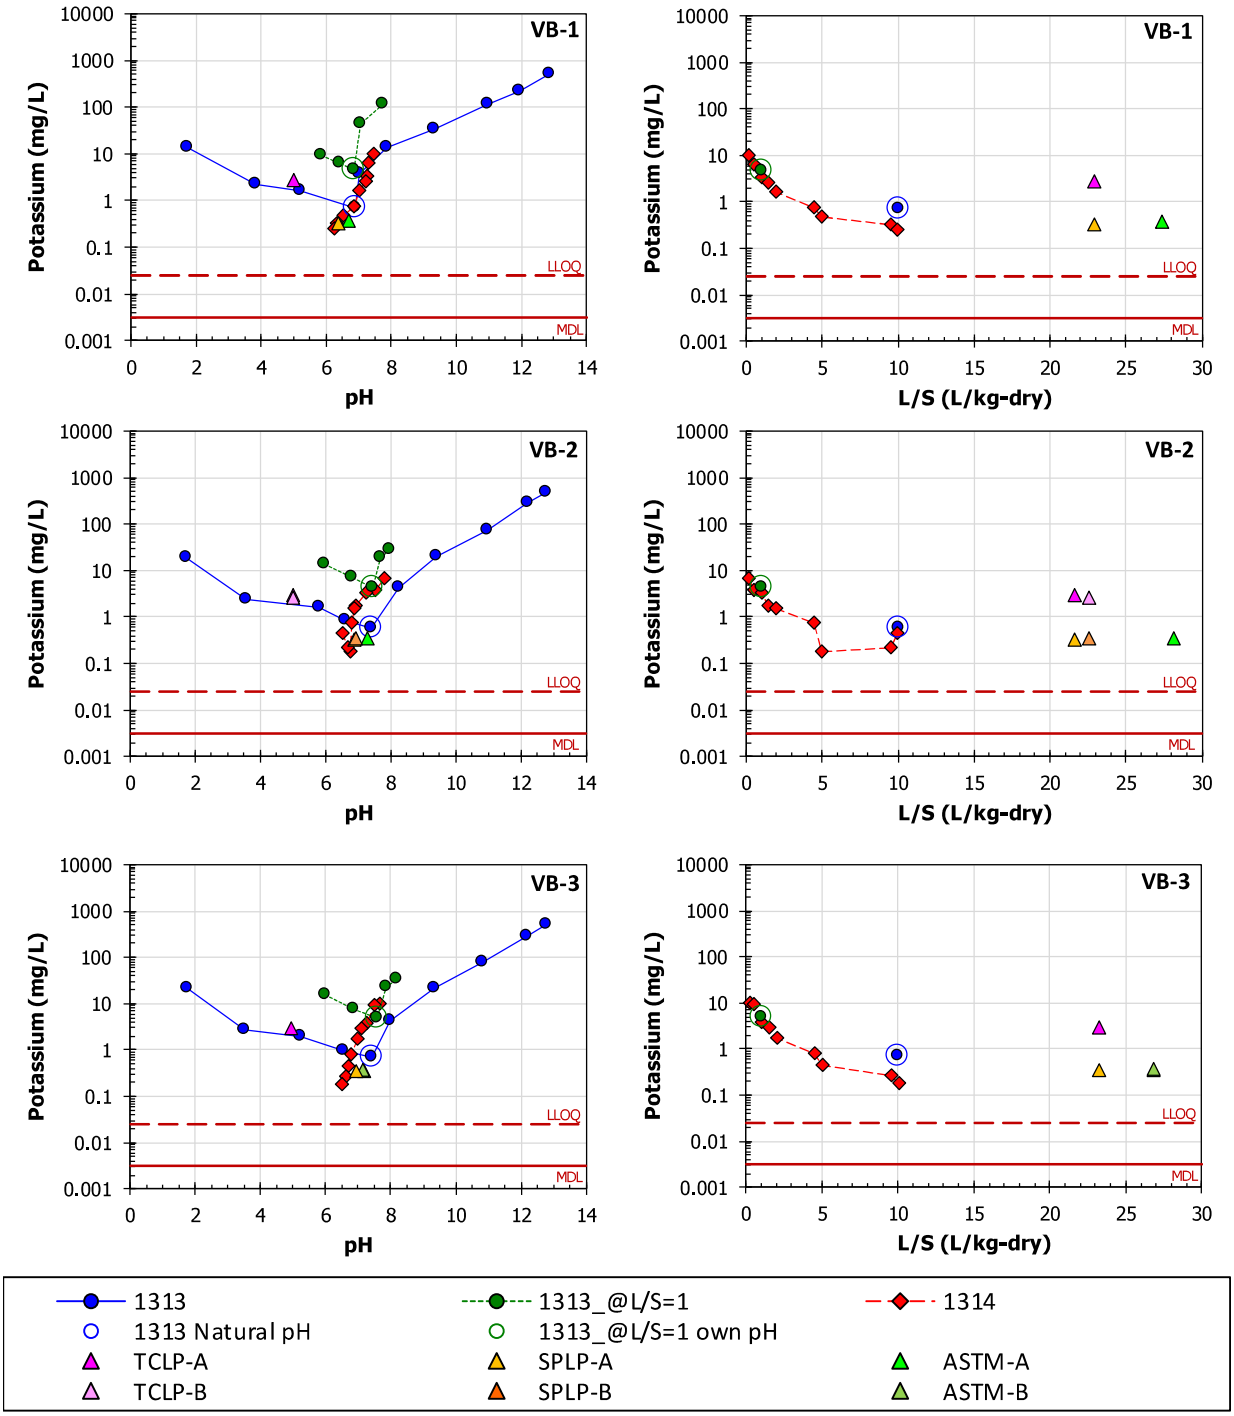

Figure E-27
Potassium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

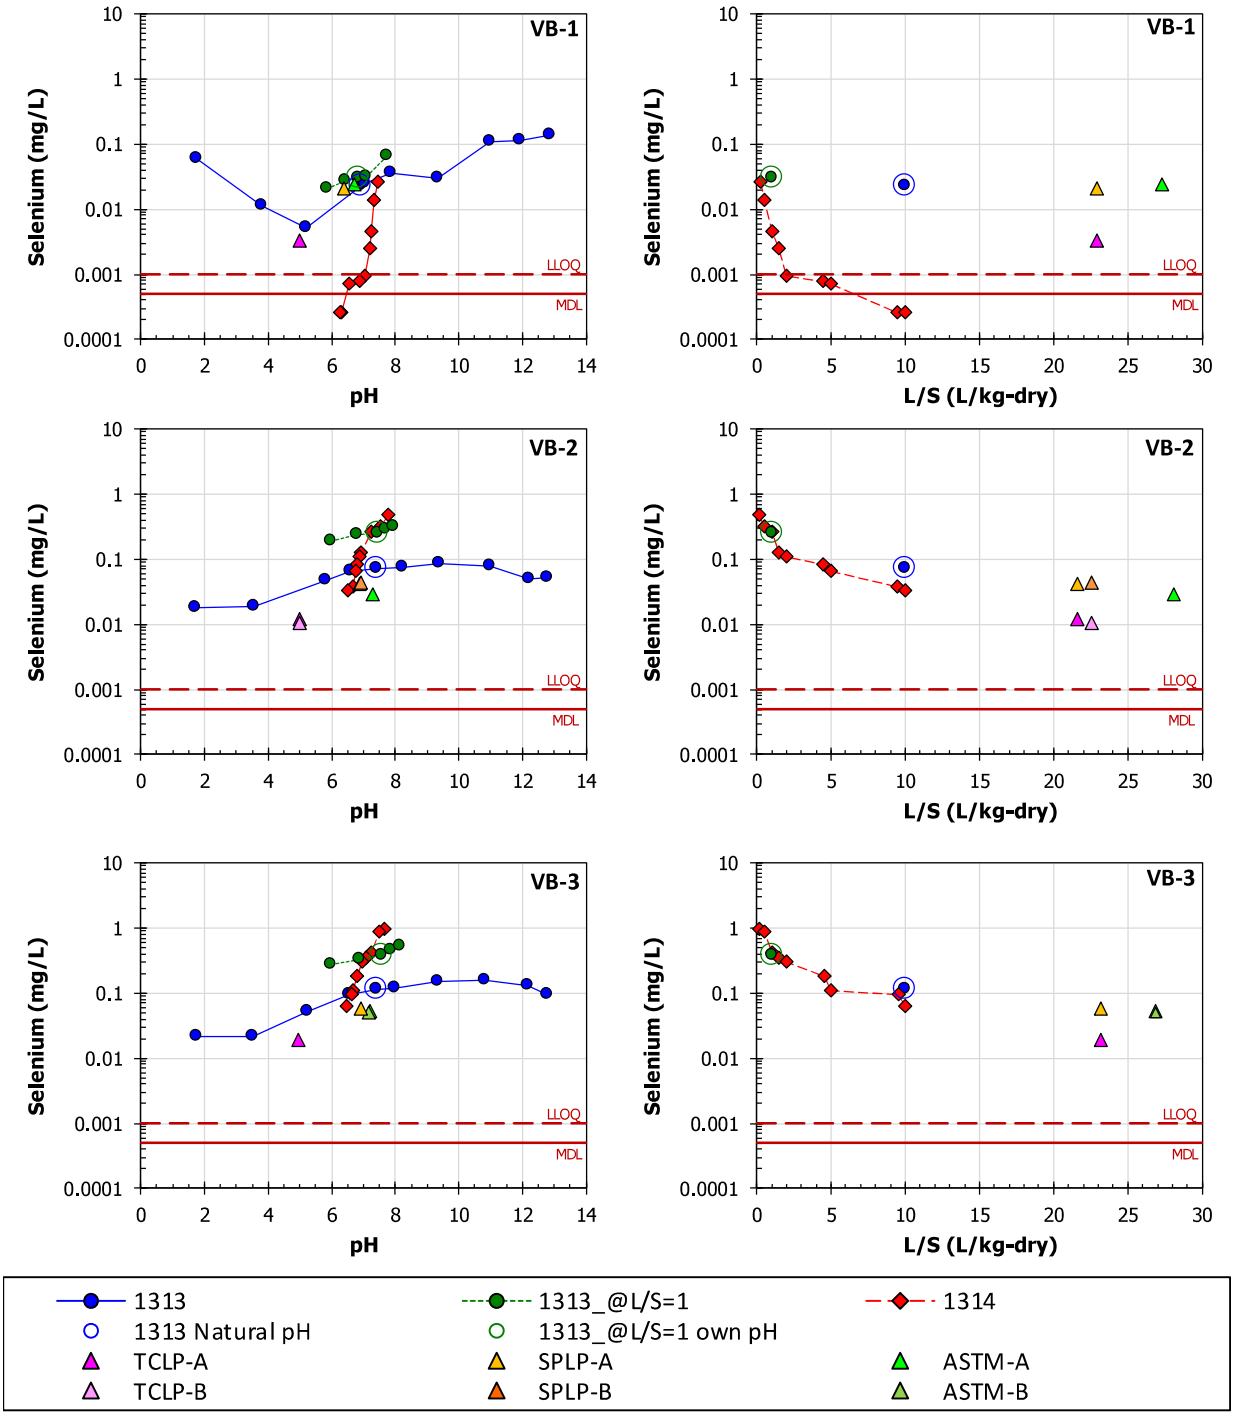

Figure E-28
Selenium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

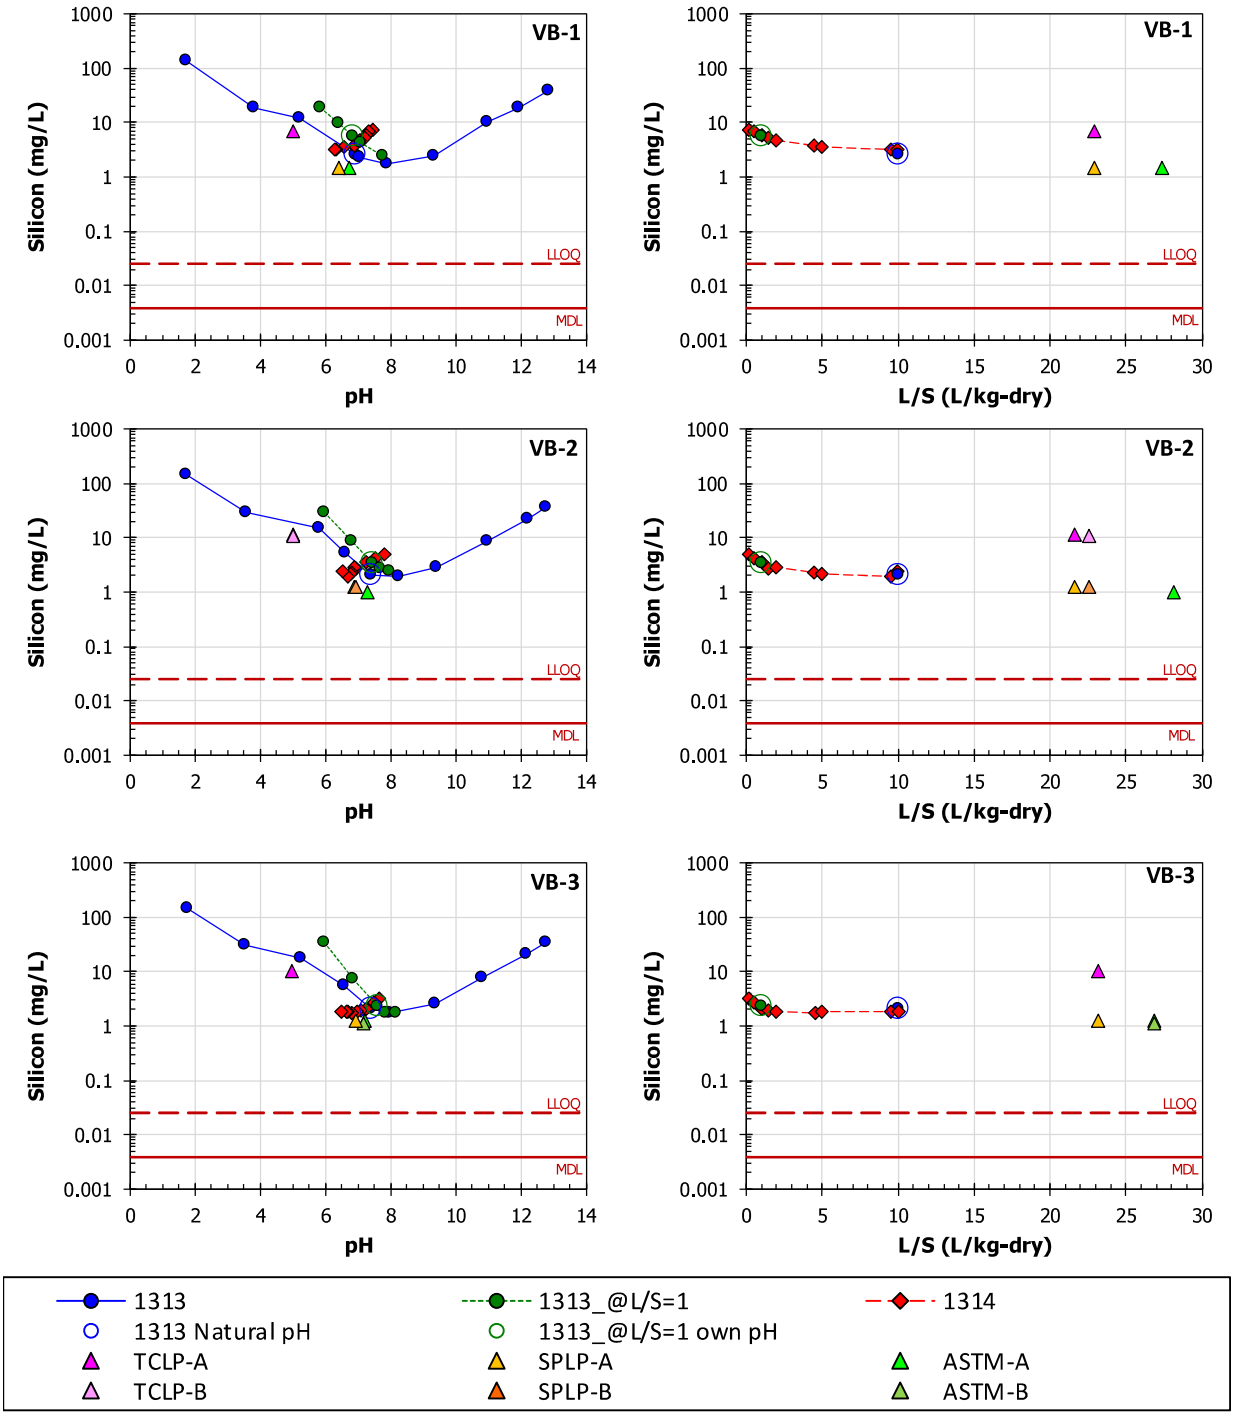

Figure E-29
Silicon concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

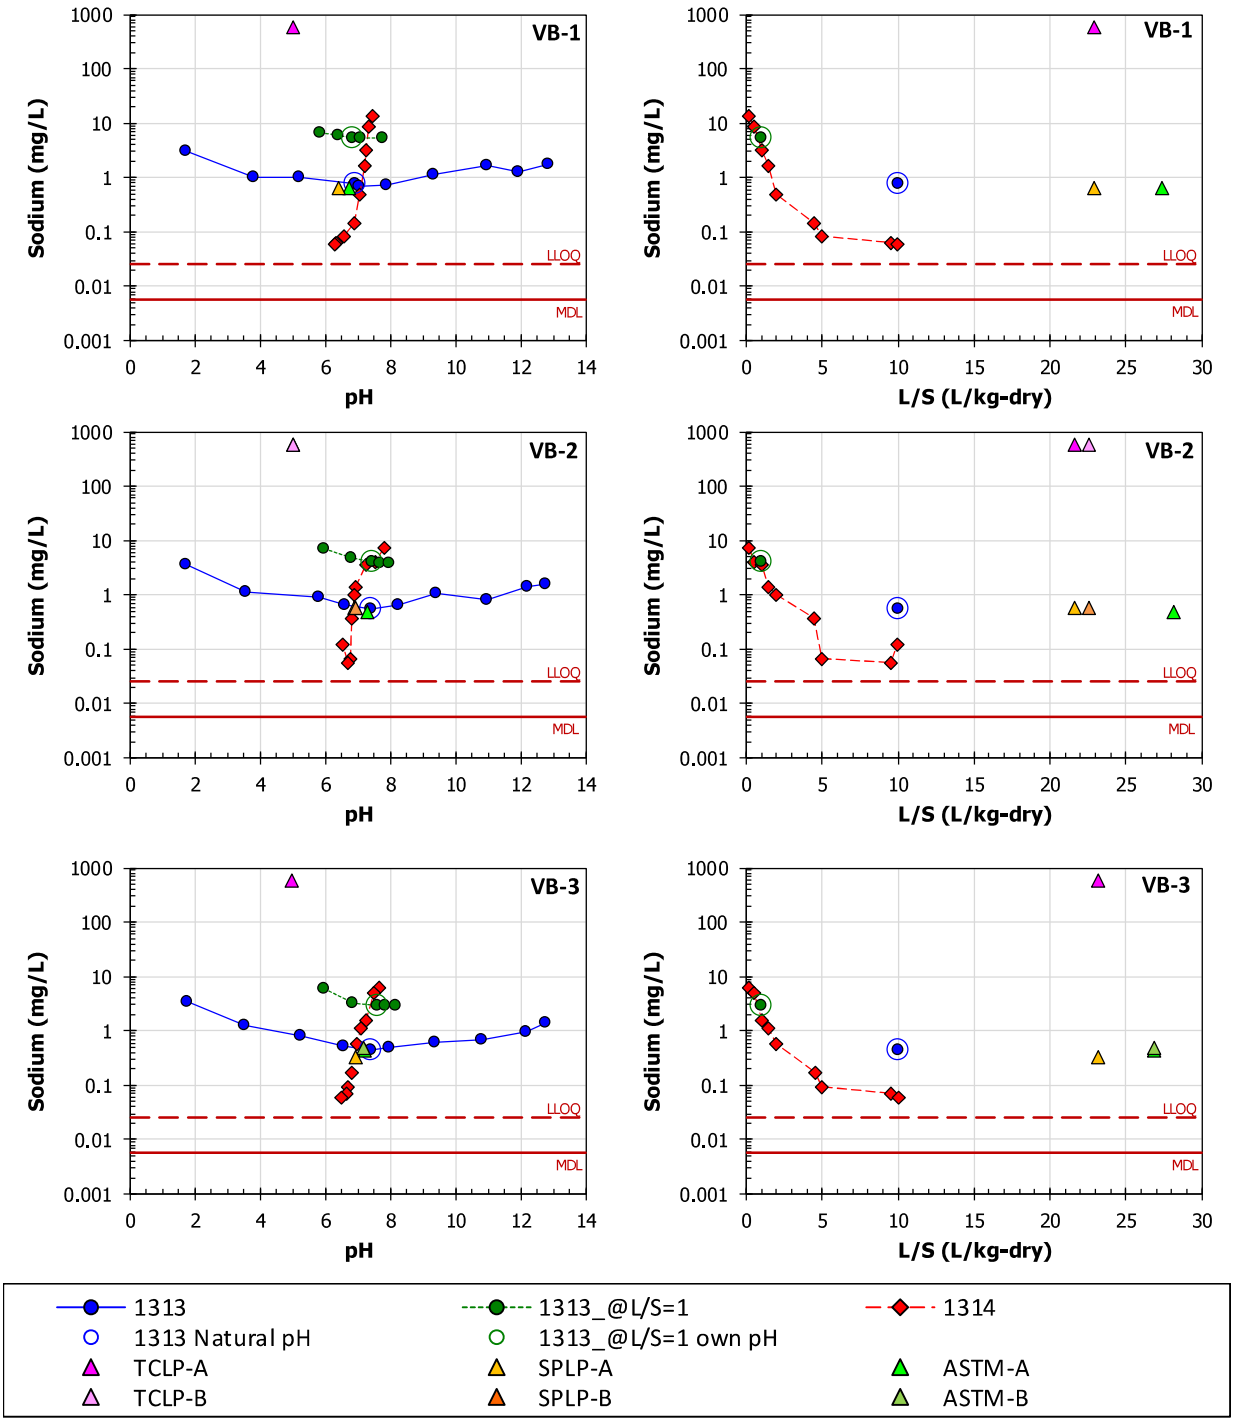

Figure E-30
Sodium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

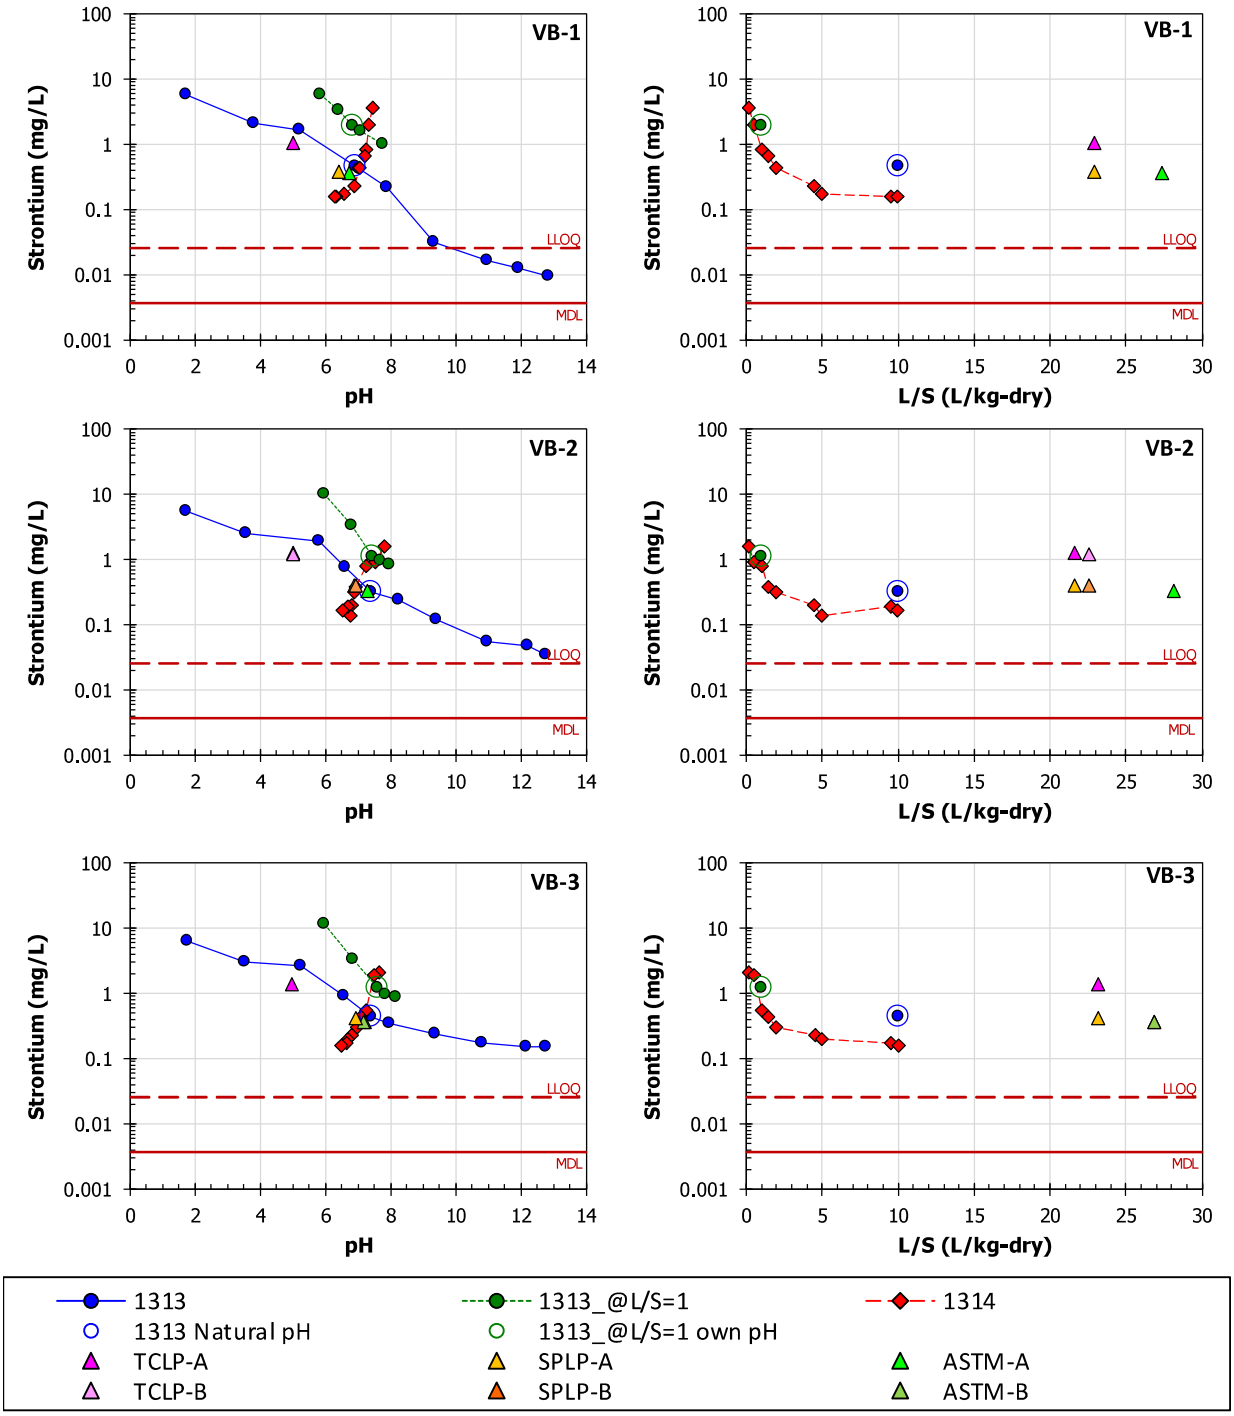

Figure E-31
Strontium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

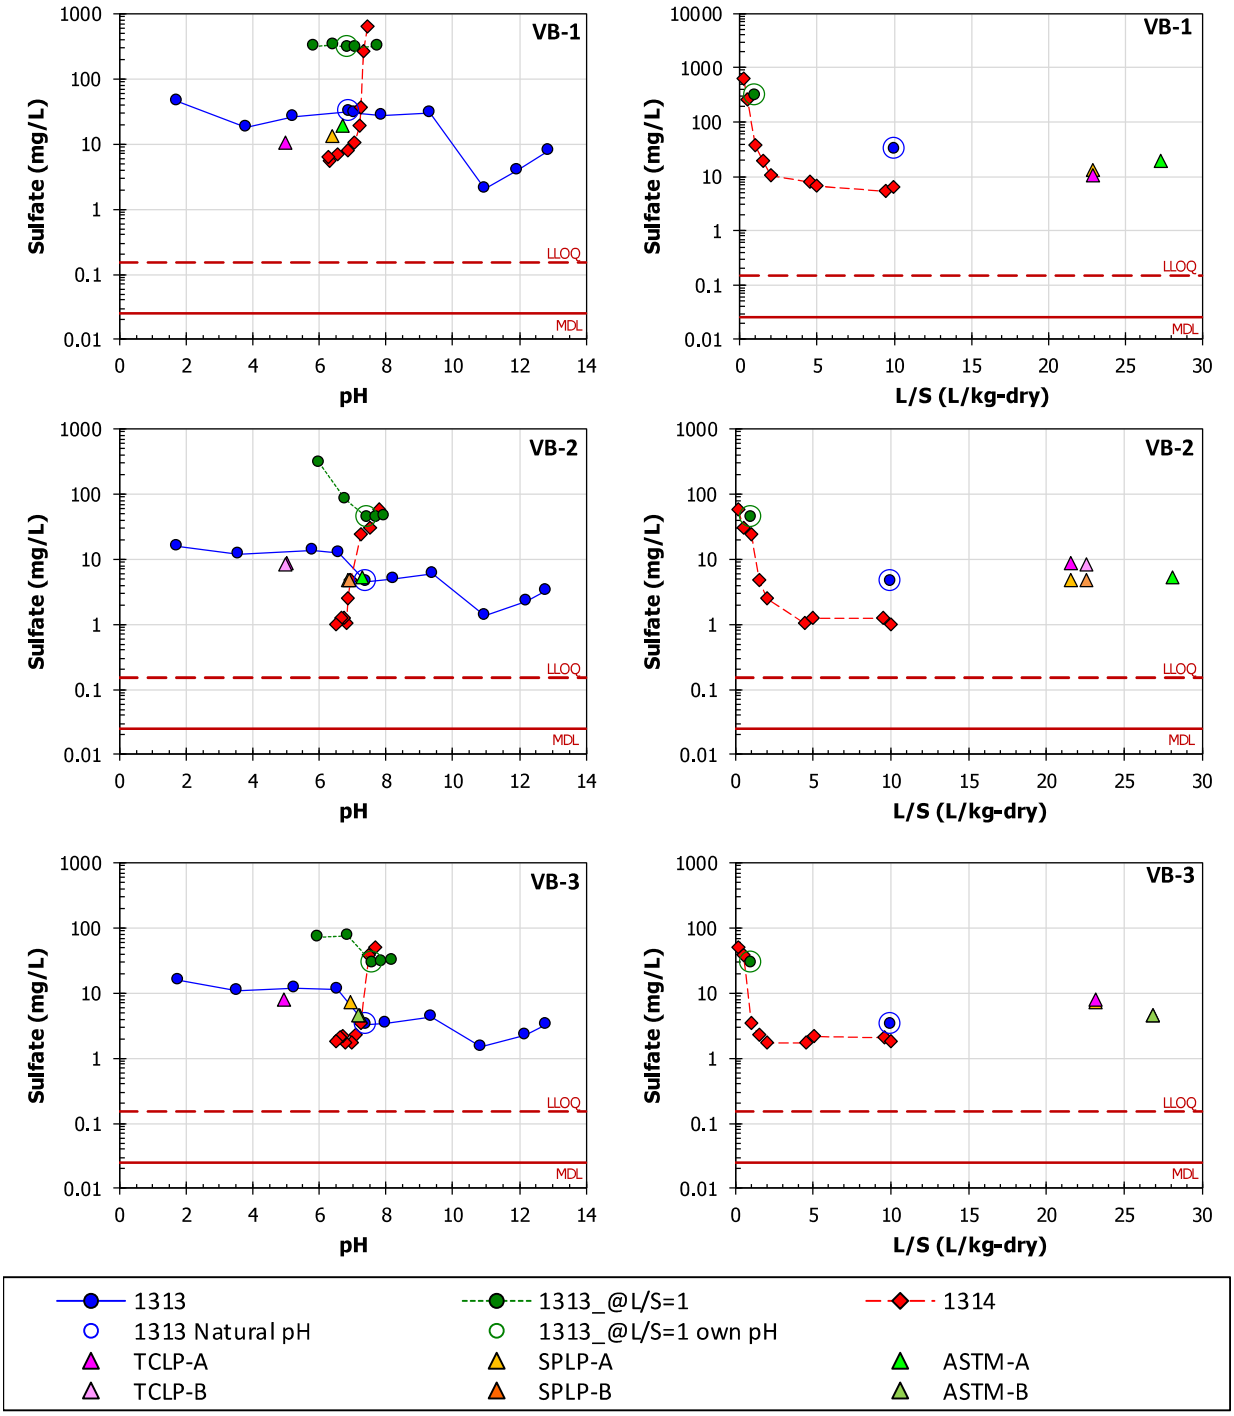

Figure E-32
Sulfate concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

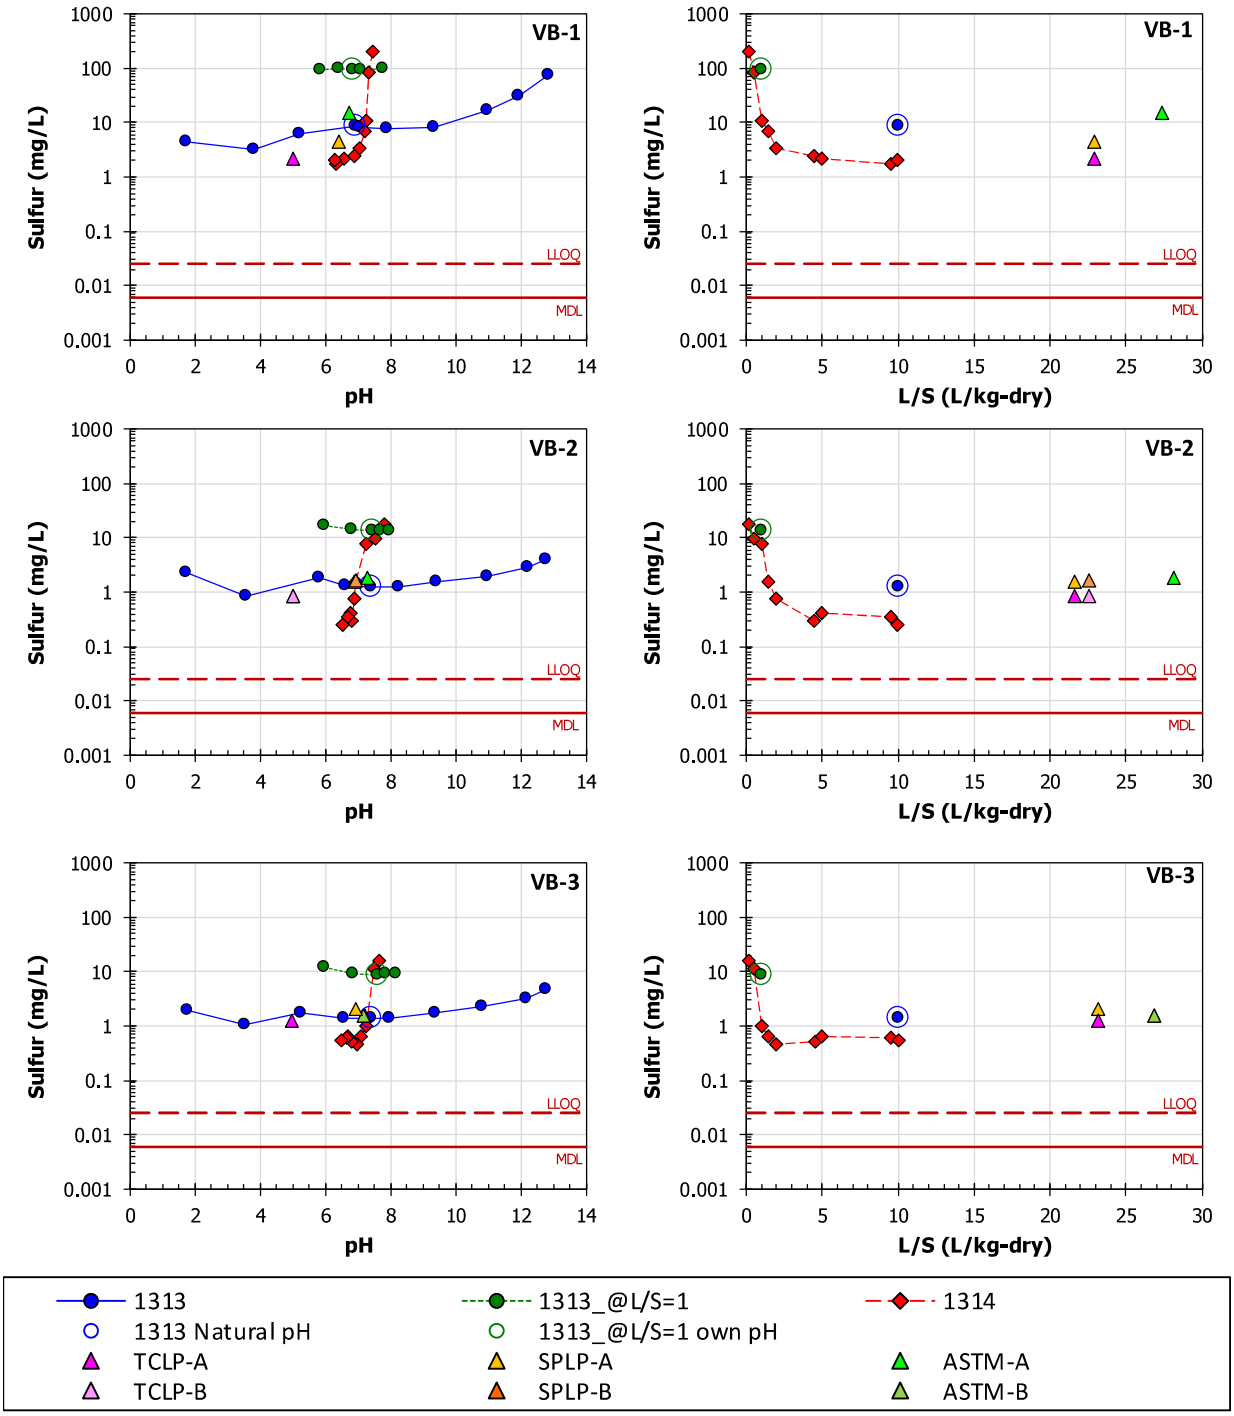

Figure E-33
Sulfur concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

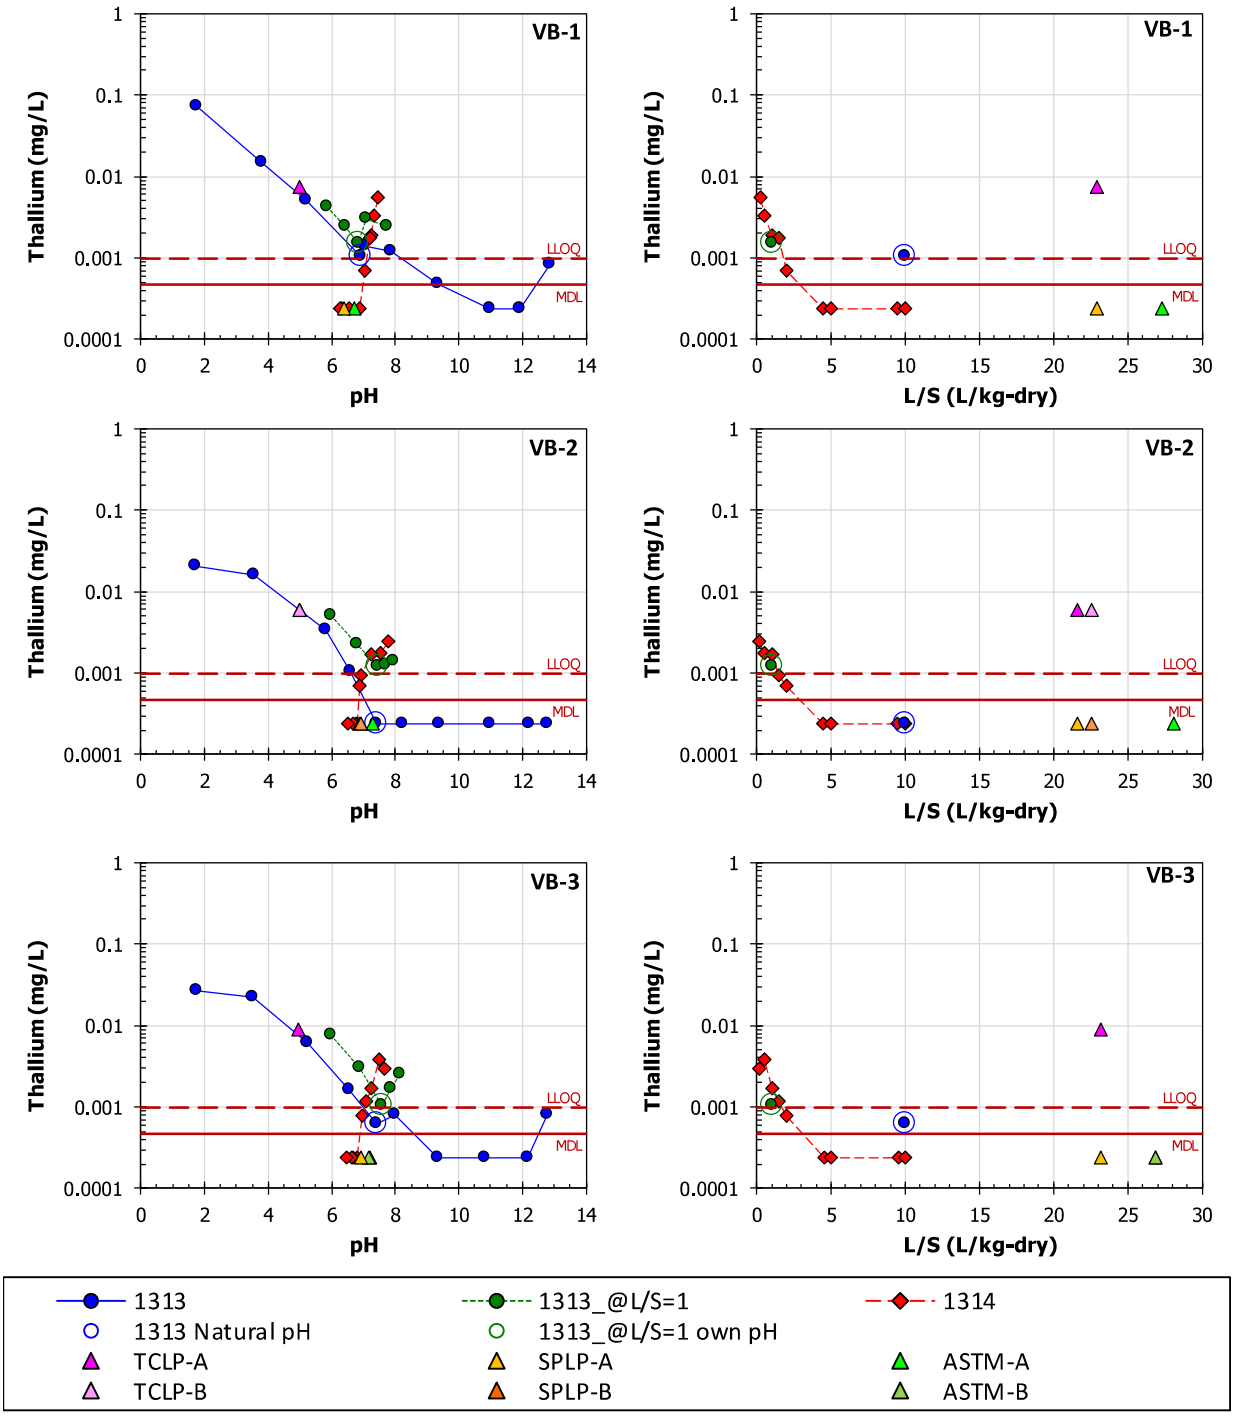

Figure E-34
Thallium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

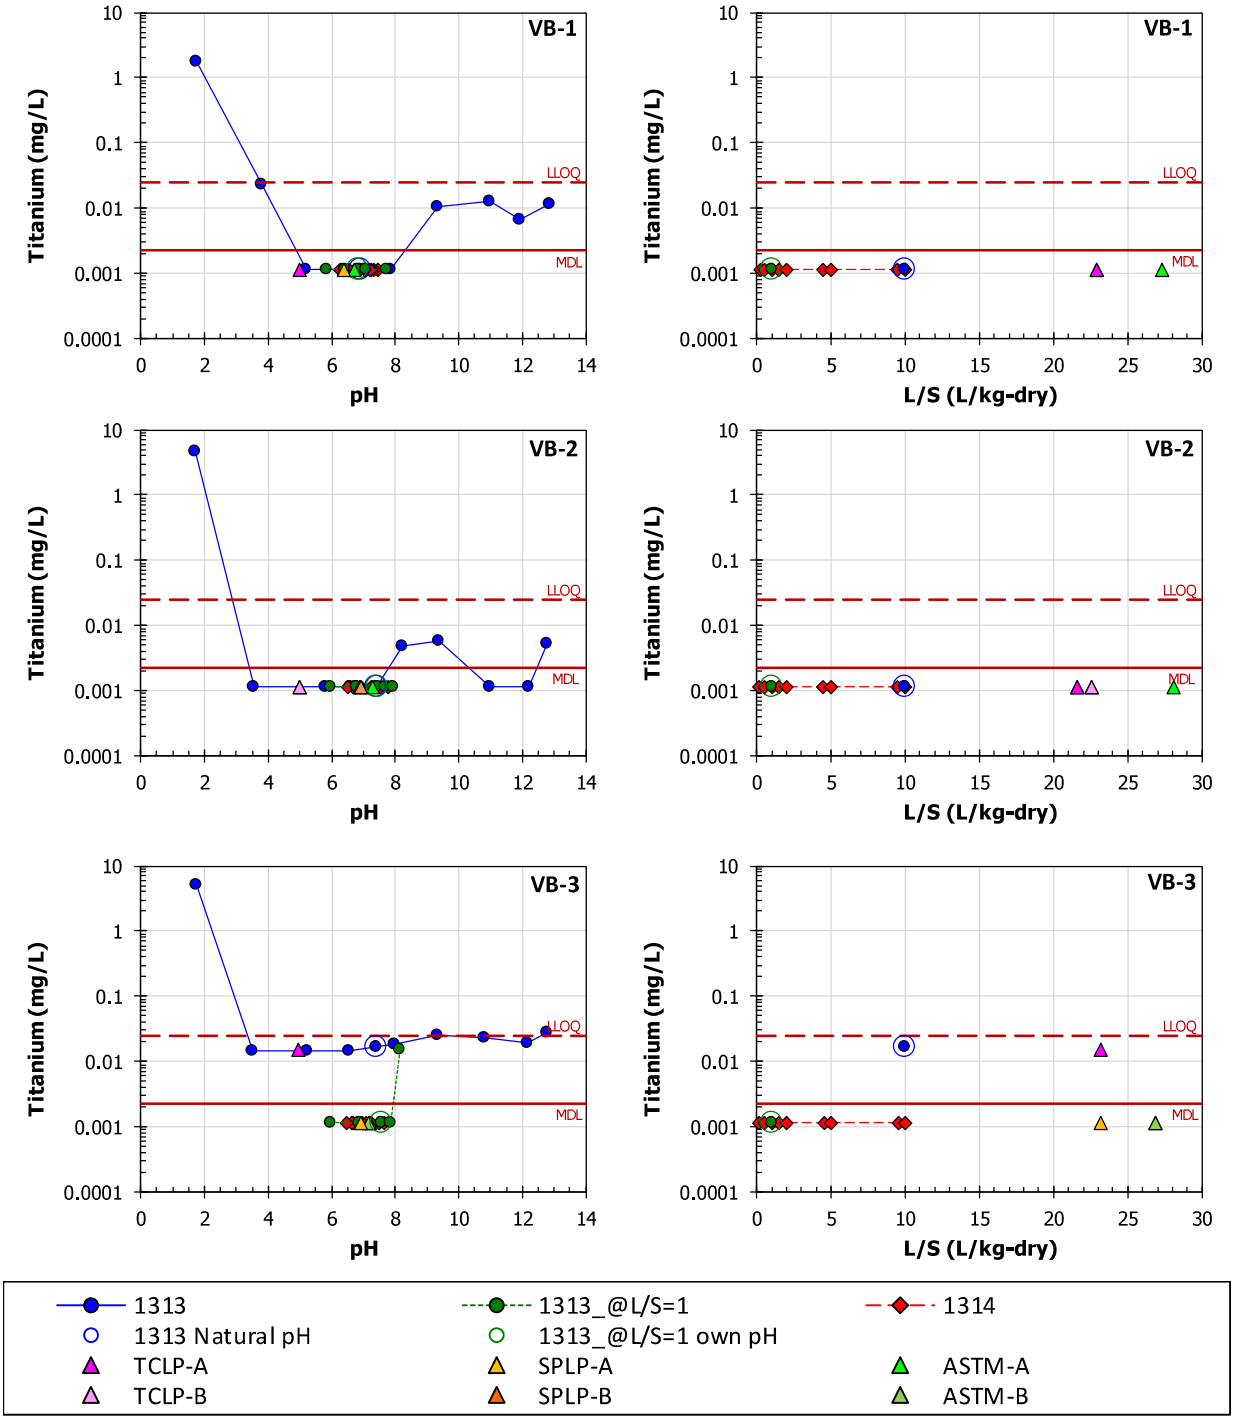

Figure E-35
Titanium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

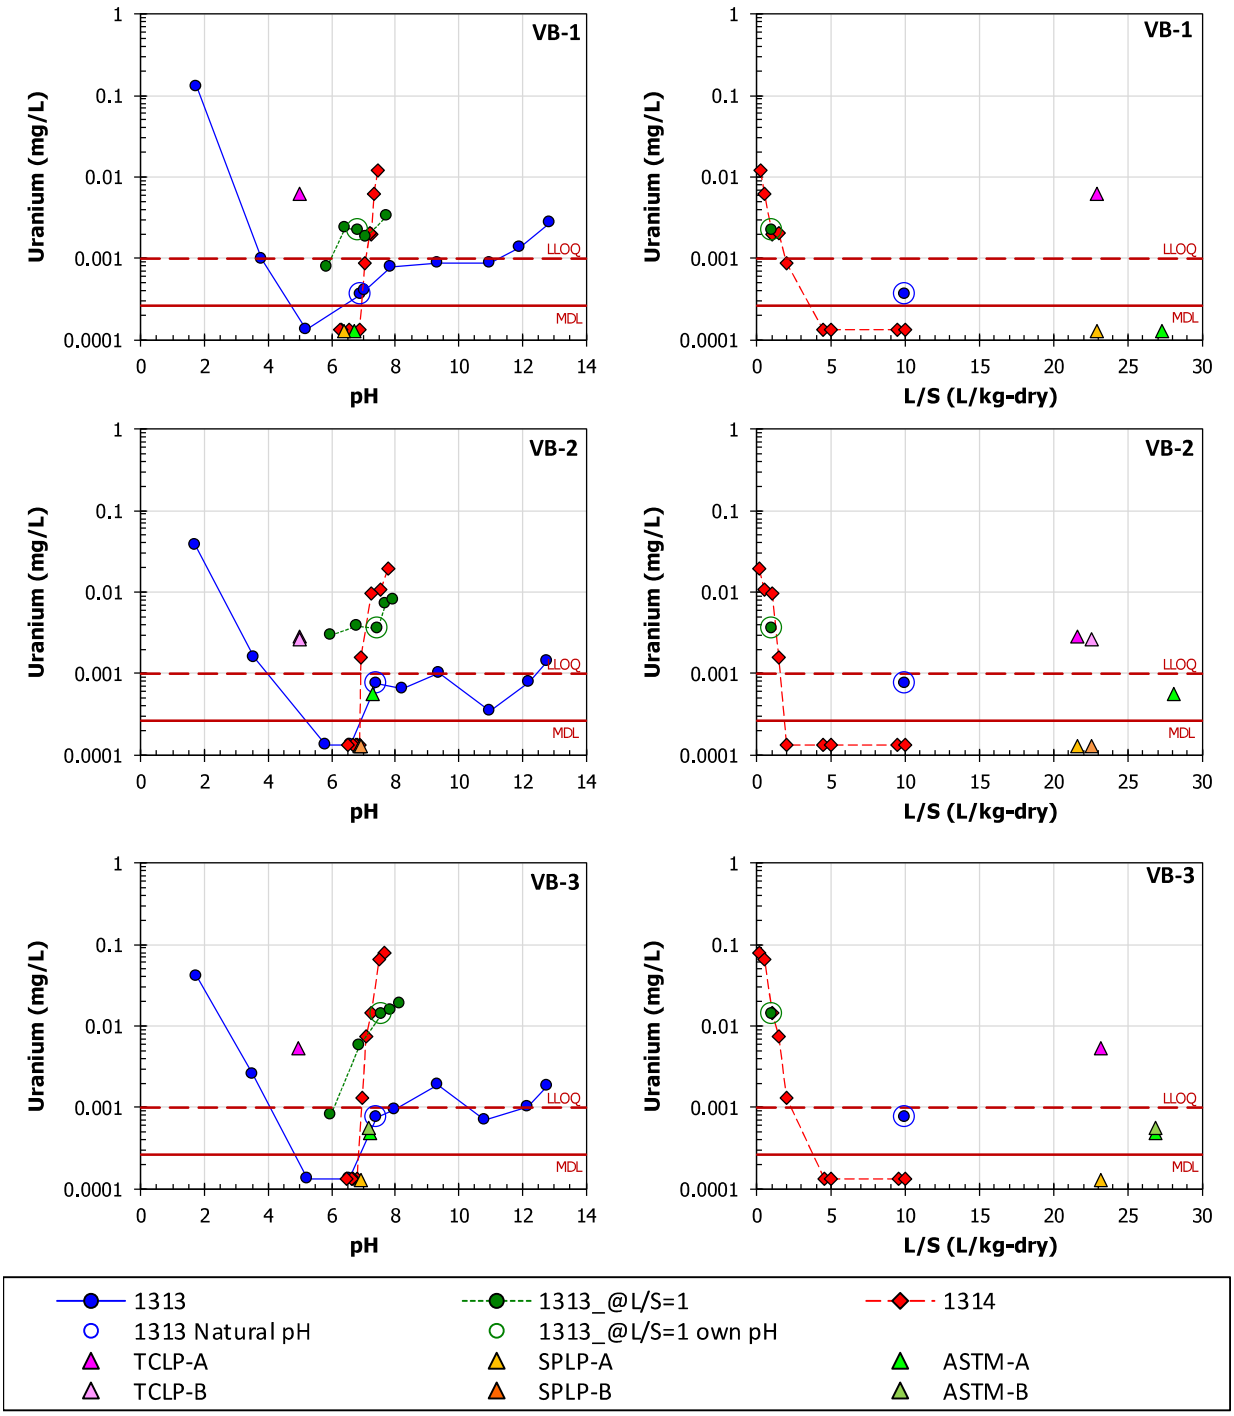

Figure E-36
Uranium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

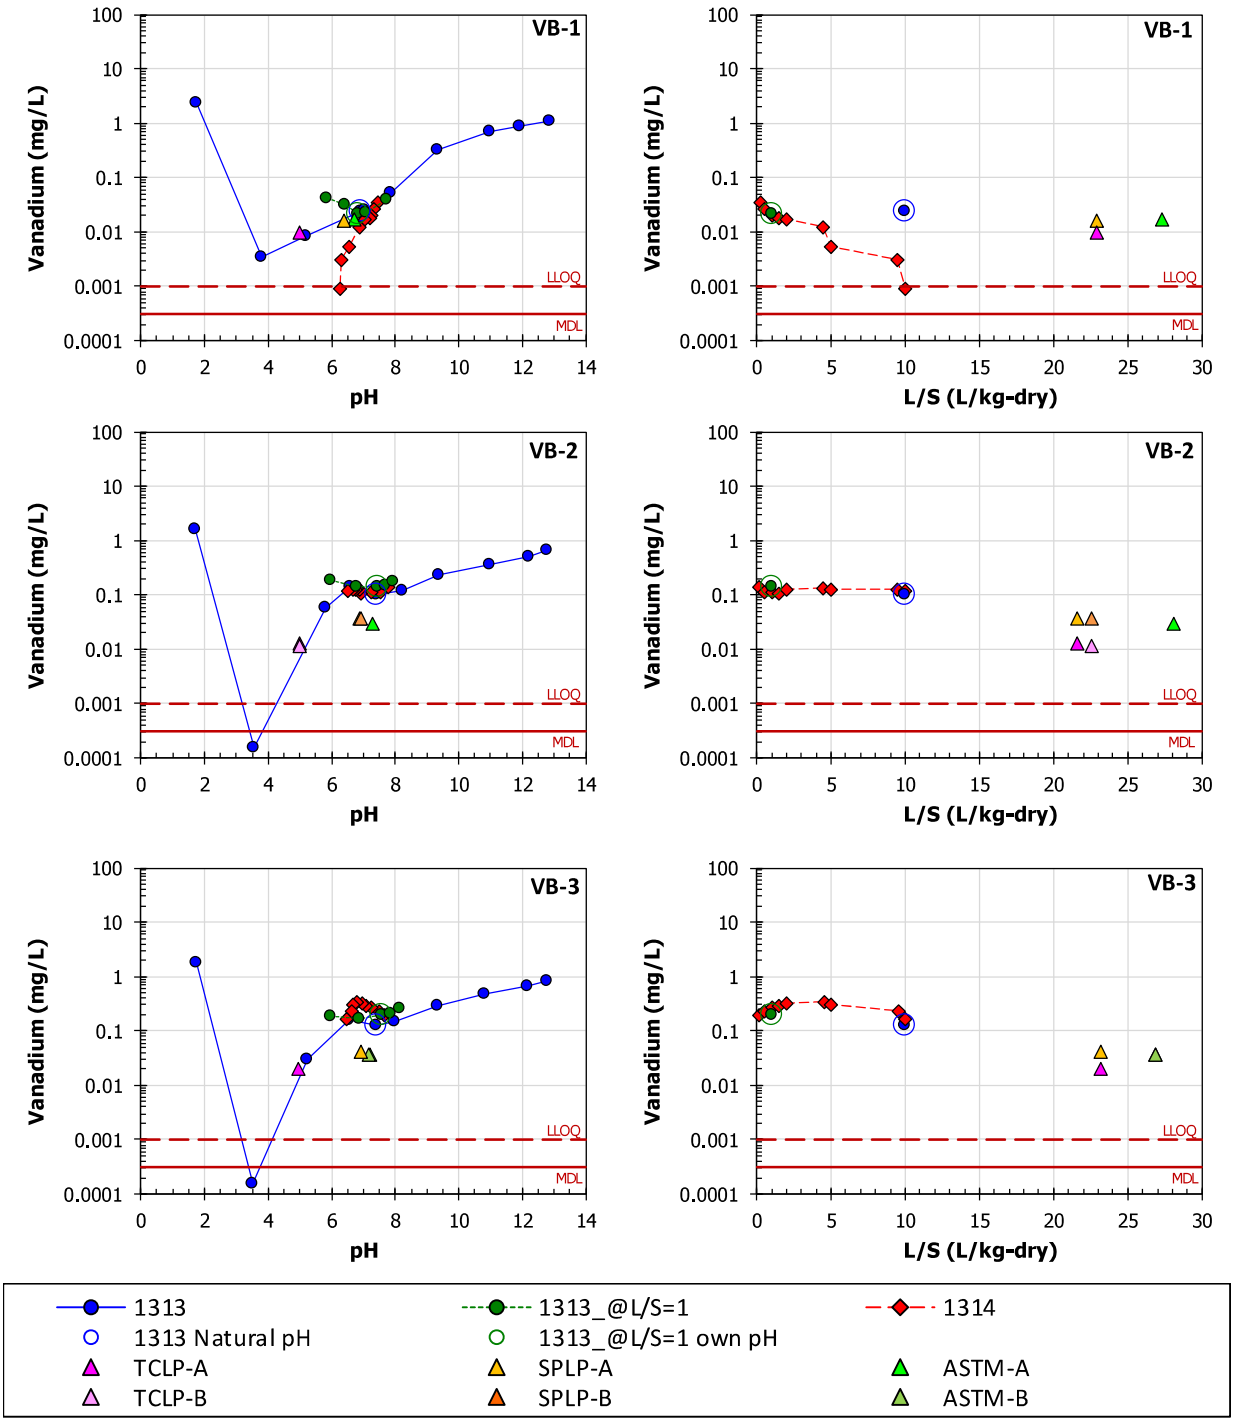

Figure E-37
Vanadium concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

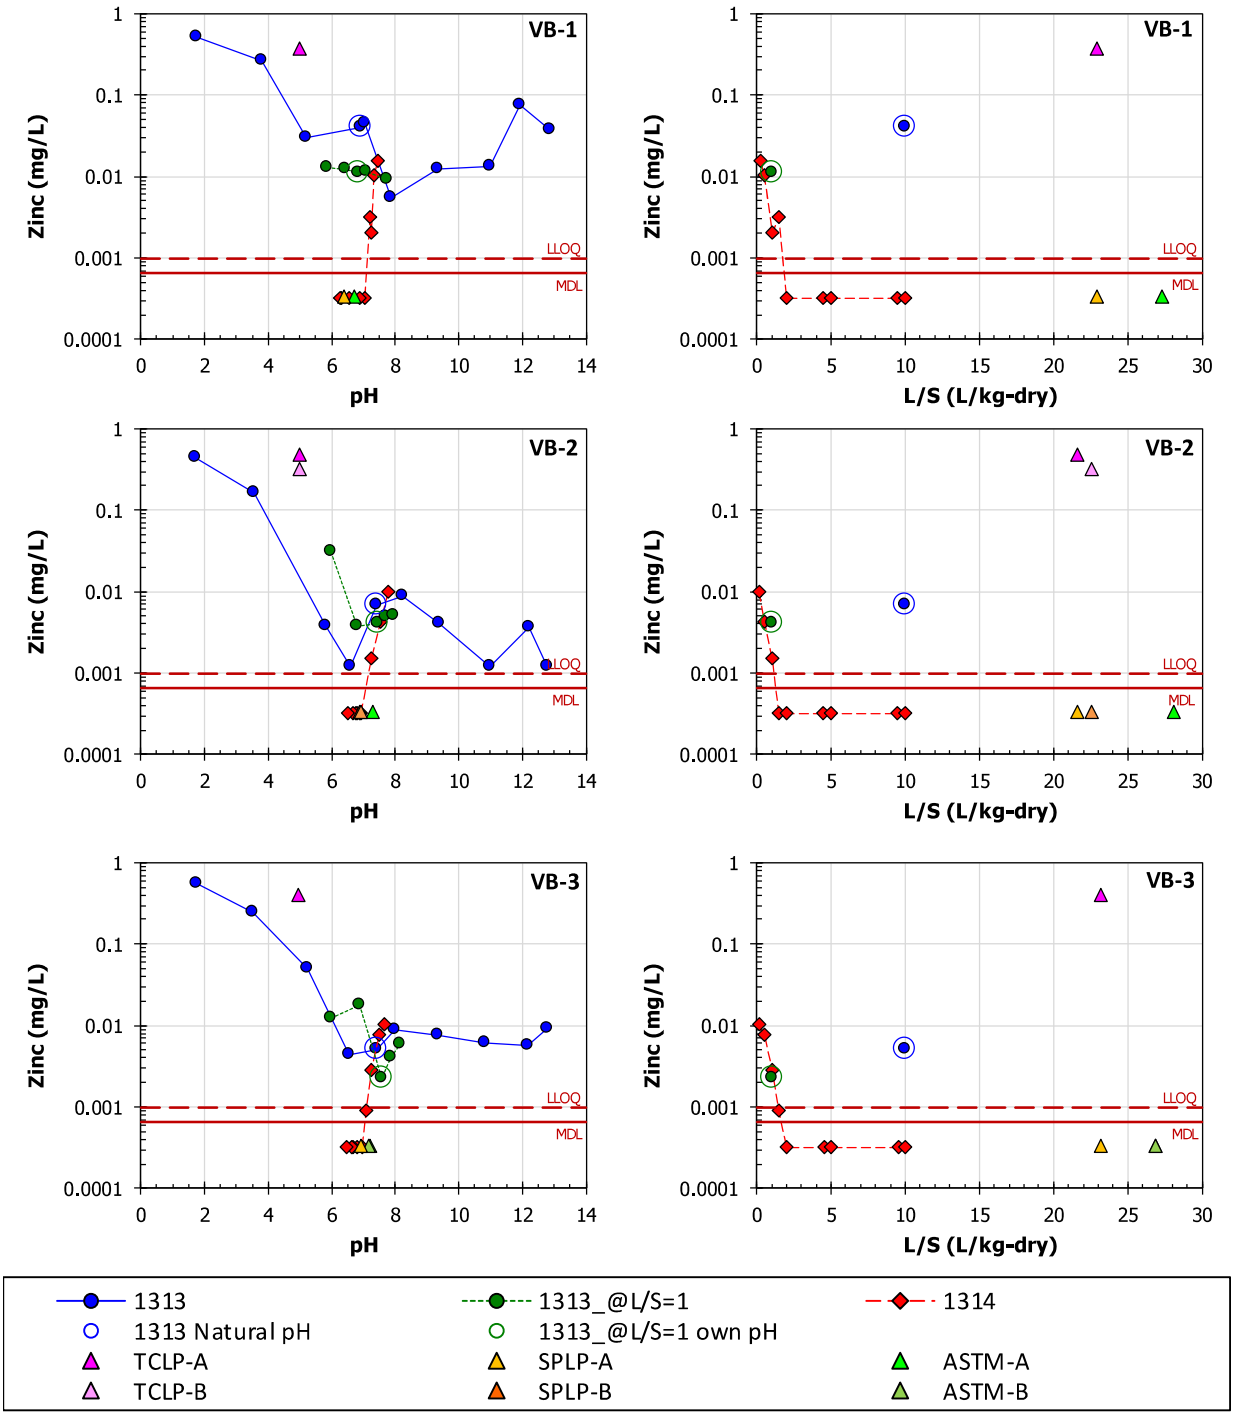

Figure E-38
Zinc concentrations from traditional leaching tests (TCLP, SPLP, and ASTM) compared to LEAF concentrations from composite samples VB-1, VB-2, and VB-3 shown as a function of pH (left) and L/S (right)

F
GROUNDWATER AND POREWATER DATA

Table of Appendices

F.1 Groundwater and Porewater Field and Analytical Data

F.2 Time Series Graphs for Porewater Data

F.3 Subsurface Gas Parameter Tables and Graphs

F.1 Groundwater and Porewater Field Measurement Tables and Graphs

AD1 (upgradient background groundwater well)

	Sep-18	Oct-18	Nov-18	Dec-18	Jan-19	Feb-19	Mar-19
Sampling Date	9/10	10/3	No Sample	12/12	1/14	2/11	3/12

Export Control Restrictions

Access to and use of this EPRI product is granted with the specific understanding and requirement that responsibility for ensuring full compliance with all applicable U.S. and foreign export laws and regulations is being undertaken by you and your company. This includes an obligation to ensure that any individual receiving access hereunder who is not a U.S. citizen or U.S. permanent resident is permitted access under applicable U.S. and foreign export laws and regulations.

In the event you are uncertain whether you or your company may lawfully obtain access to this EPRI product, you acknowledge that it is your obligation to consult with your company's legal counsel to determine whether this access is lawful. Although EPRI may make available on a case by case basis an informal assessment of the applicable U.S. export classification for specific EPRI products, you and your company acknowledge that this assessment is solely for informational purposes and not for reliance purposes.

Your obligations regarding U.S. export control requirements apply during and after you and your company's engagement with EPRI. To be clear, the obligations continue after your retirement or other departure from your company, and include any knowledge retained after gaining access to EPRI products.

You and your company understand and acknowledge your obligations to make a prompt report to EPRI and the appropriate authorities regarding any access to or use of this EPRI product hereunder that may be in violation of applicable U.S. or foreign export laws or regulations.

The Electric Power Research Institute, Inc. (EPRI, www.epri.com) conducts research and development relating to the generation, delivery and use of electricity for the benefit of the public. An independent, nonprofit organization, EPRI brings together its scientists and engineers as well as experts from academia and industry to help address challenges in electricity, including reliability, efficiency, affordability, health, safety and the environment. EPRI also provides technology, policy and economic analyses to drive long-range research and development planning, and supports research in emerging technologies. EPRI members represent 90% of the electricity generated and delivered in the United States with international participation extending to nearly 40 countries. EPRI's principal offices and laboratories are located in Palo Alto, Calif.; Charlotte, N.C.; Knoxville, Tenn.; Dallas, Texas; Lenox, Mass.; and Washington, D.C.

Leaching, Geotechnical, and Hydrologic Characterization of Coal Combustion Products from an Active Coal Ash Management Unit: Plant 42197. EPRI, Palo Alto, CA: 2021. 3002018780.

ABSTRACT

The appropriate selection and use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is highly dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field.

This report presents the results of geotechnical, hydrologic, and leaching characterization of samples of coal ash collected from an active coal ash disposal unit where dry-handled coal ash is placed over a portion of a former sluiced (i.e., wet-handled) coal ash deposit. The hydraulic conductivity of intact cores from the saturated coal ash was measured in context of the distribution of particles in the coal ash samples and the overburden pressure associated with disposal at depth within the facility. The leaching test results for LEAF tests (i.e., EPA Methods 1313 and 1314) were compared to the results for traditional tests (i.e., ASTM, TCLP, SPLP). In addition, porewater estimates derived directly from leaching tests were compared to measured porewater concentrations, and measured porewater concentrations were compared to groundwater concentrations.

Product Type: Technical Report

Product Title: Leaching, Geotechnical, and Hydrologic Characterization of Coal Combustion Products from an Active Coal Ash Management Unit: Plant 42197

PRIMARY AUDIENCE: Electric utility environmental professionals responsible for landfill and impoundment management of CCPs

SECONDARY AUDIENCE: Researchers and regulators interested in CCP leaching and chemistry

KEY RESEARCH QUESTION

The appropriate use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is highly dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field. The objectives of this research were (i) to determine the most appropriate approach for estimating porewater concentrations at CCP disposal facilities, and (ii) to highlight the potential connection between the CCP leaching performance of a disposal facility, based on porewater measurements or leaching tests, and sentinel monitoring of groundwater exterior to the disposed material.

RESEARCH OVERVIEW

The Electric Power Research Institute (EPRI), Vanderbilt University (VU), and University of Virginia (UVA) performed a study to develop relationships between the geochemistry of the disposed CCPs and the measured concentrations for inorganic constituents in the porewater of CCP disposal units. In addition, this study investigates the potential relationship between porewater concentrations and concentration in groundwater measured at adjacent monitoring wells.

CCP materials were collected at four locations from an active CCP disposal unit where coal ash was initially sluiced (wet-handled), and is now dry-handled. During field activities, porewater access points and subsurface gas access points were established for eight monthly sampling events. Collected materials were characterized for leaching and geotechnical/hydrologic properties. The hydraulic conductivity of intact cores from the ash deposit was measured in context of the distribution of particle sizes in the CCP samples and the overburden pressure associated with disposal at depth within the unit. The leaching test results for the Leaching Environmental Assessment Framework (LEAF) (i.e., EPA Methods 1313 and 1314) were compared to those for traditional tests (i.e., ASTM, TCLP, and SPLP). In addition, porewater estimates derived directly from leaching tests were compared to measured porewater concentrations, and measured porewater concentrations were compared to groundwater concentrations.

KEY FINDINGS

- Despite differences in coal ash placement (dry-handled ash in the upper portion and wet-handled ash in the lower portion), there was little observed variability in vertical concentration profiles. This observation suggest that infiltration moving through the unsaturated dry-handled ash (e.g., from precipitation, liquid dumps, water spray for dust management) results in migration of readily dissolved constituents from the dry-handled material into the underlying wet-handled coal ash. Downward movement of soluble constituents results in the pH and porewater composition within the saturated material being similar to the low L/S extraction fractions of composited dry material.
- The ratio of the available content to the total content shows that only a small fraction of total content of most trace constituents is leachable over a broad pH range.
- Suboxic to anoxic conditions are established at relatively shallow depths (> 5 m) below the surface of the dry-handled material.
- The high pH within the porewater of deposited material prevents development of significant microbial activity at depths greater than 5 m below the surface.
- Hydraulic conductivity of the ashes typically was within the range of 10^{-5} to 10^{-6} cm/s. Hydraulic conductivity diminished as the effective stress increased, but only modestly.
- Some parameters in the porewater (e.g., pH, temp, B, Co, Ni, and Zn) exhibited temporal variability due to factors such as seasonal changes or impacts of damage and repair of porewater access points. Other constituents (e.g., Cd, Ca, Cu, Mo, and Se) remained relatively constant within each porewater access point throughout the 8-month monitoring period. Spatial variability was observed for some constituents between porewater access points; however, no consistent pattern was observed.
- The limited data collected from downgradient monitoring wells and porewater access points suggest that porewater concentration alone is an unreliable indicator that a constituent has had an impact on elevated groundwater concentrations or for prediction of downgradient concentrations at this site.
- Traditional leaching tests, such as TCLP, SPLP, and ASTM, are poorer indicators of measured porewater concentrations than LEAF tests. Low liquid-to-solid ratio (L/S) eluates from EPA Method 1314 are better indicators than the traditional tests and EPA Method 1313 for concentrations for available content-limited constituents (e.g., B, Cd, Cl^-, Mo, Se, and SO_4^{-2}) because of the strong L/S-dependence. The data presented here showed that the traditional tests, with an L/S greater than 20 L/kg-dry, and EPA 1313 at L/S=10 L/kg-dry often under-predicted field porewater concentrations by an order of magnitude or more. These results indicate that additional information (e.g., available content and porewater L/S) is needed to provide a reasonable approximation of porewater concentrations. For constituents with solubility-controlled liquid-solid partitioning (e.g., As, Sb, and Tl), EPA 1313 tests at L/S=1 L/kg-dry provide an estimate of porewater concentrations generally within a factor of 2. The combination of pH-dependent leaching data (EPA 1313) with percolation column test results (EPA 1314) provides valuable information for geochemical modeling.

- For field environments that are oxidizing to slightly reducing, leaching test data approximated field porewater concentrations of solubility-controlled constituents within an order of magnitude. Because of the oxic to suboxic subsurface conditions at this site, sampling, laboratory handing, and testing conditions did not appear to significantly influence the redox condition of the field material. This in contrast to impoundments with highly reducing subsurface conditions, where material handling in the presence of oxygen during sampling and laboratory testing can significantly impact test results. The only constituent not well defined by any of the LEAF tests was chromium, the result for which may have been influenced by oxidization of materials during collection from a suboxic environment and testing in an oxic laboratory. The leaching results for chromium indicate that laboratory testing results for redox-sensitive elements (e.g., As, Cr, Sb, Se, V) may not directly reflect the leaching anticipated in porewater when the field environment is reducing, in part due to oxidation incurred during sampling, handling, and testing.

WHY THIS MATTERS

This research provides a unique opportunity to compare a statistically valid field porewater sample set to laboratory leaching test results on samples collected from the same location and depth interval as the porewater sampling point and provides information to guide appropriate use of these tests. It also provides information on, and comparison of, the spatial and temporal/seasonal variability in both porewater quality and laboratory leachate quality at a CCP site. Data collected during this research will inform EPRI physical and geochemical modeling of leaching within coal ash landfills and impoundments.

HOW TO APPLY RESULTS

The results of this research are site-specific, yet when considered with known differences in L/S associated with different leaching tests, and geochemical differences between the field and laboratory environment, they provide information for generalizing the best uses of different leaching tests and porewater data. Companies interested in performing similar comparisons between leaching tests and porewater will be interested in the field and laboratory methodologies described in Sections 2 and 3. Companies and stakeholders interpreting leaching test and porewater results will be interested in the results summarized in Sections 6 and 7.

LEARNING AND ENGAGEMENT OPPORTUNITIES

- A framework using geochemical modeling and porewater data to predict long-term leaching at CCP sites is being developed under EPRI Program 242's hydrogeochemistry project. A series of reports published from 2018 through 2021 describe results of this research. These reports can be accessed by searching epri.com for "Hydrogeochemical Assessment of Long-Term Leaching Characteristics at Coal Combustion Product Sites."
- Stakeholders, including regulatory agencies, reviewing leaching test analyses may be interested in results of this research to understand the relationship between the different leaching tests, and the relationship between leaching tests and porewater within CCPs.

NTU	nephelometric turbidity unit
OD	outer diameter
ORP	oxidation-reduction potential (mV)
O_2	oxygen gas
PAP(s)	porewater access point(s)
pe	electron concentration (-log mol e^-/L)
PSD	particle size distribution
QA/QC	quality assurance/quality control
RCRA	Resource Conservation and Recovery Act of 1986
SAP	sampling and analysis plan
SU	standard unit
TC	total carbon
UVA	University of Virginia (Charlottesville, VA)
VU	Vanderbilt University (Nashville, TN)
wt%	weight percent (percent by mass)
XRF	x-ray fluorescence
ΣL/S	cumulative liquid-to-solid ratio

Groundwater/Porewater Sample Points

VC-1	porewater access point in the CDL landfill
VC-2	porewater access point in the CDL landfill
VC-3	porewater access point in the CDL landfill
VC-4	porewater access point in the CDL landfill
209	downgradient groundwater monitoring well

931	downgradient groundwater monitoring well

Leaching/Extraction Tests

ASTM	ASTM D3987: Practice for Shake Extraction of Solid Waste with Water
1313	EPA Method 1313: Liquid-Solid Partitioning as a Function of Eluate pH Using a Parallel Batch Procedure
1314	EPA Method 1314: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using an Up-Flow Percolation Column Procedure
1313_L/S=1	EPA Method 1313 modified for L/S=1 mL/g-dry and abbreviated to 5 target endpoint pH values about the own pH of the material
SPLP	EPA Method 1312: Synthetic Precipitation Leaching Procedure
TCLP	EPA Method 1311: Toxicity Characteristic Leaching Procedure

Equation and Parameter Variables

AC	available content (mg/kg-dry)
$C_{1313(\max pH\ 2,9,13)}$	max concentration from EPA 1313 at pH 2, 9, or 13 (mg/kg-dry)
F	Faraday constant (23,061 cal/(V mol))
Eh	redox potential (mV)
L/S	liquid-to-solid ratio for fully saturated pores (L/kg-dry)
$(L/S)_{1313}$	liquid-to-solid ratio for EPA 1313 extractions
PW	mean porewater concentration from monthly PAP monitoring (mg/L)
R	1.987 (cal/(K mol))
s	global standard deviation of a profile parameter in all "known ash samples"
T	temperature (K)
WC	water content (%)
x	parameter measurement (e.g., pH, concentration) from the low L/S extraction test
$\bar{x}$	global mean of a profile parameter in all "known ash samples" for all boreholes
z	concentration of a constituent in a leaching test (mg/L)
%D	percentage difference between leaching and porewater concentrations
ρ_{dry}	dry unit density (kg-dry/m^3)
θ_s	saturated water content (m^3_{water}/m^3)

LIST OF FIGURES

Figure 1-1 Schematic representations of the CDL management unit: a) plan view showing boreholes (VC-1 through VC-4) and groundwater monitoring wells; b) cross-section of disposal unit with approximate layer depths 1-4

Figure 2-1 Ash sample collection and field testing for VC-1, VC-2, VC-3, and VC-4 boreholes 2-2

Figure 2-2 Low L/S Field Extraction: a) capped apparatus with sample and b) collected samples stored in pressure vessel prior to purging with argon 2-3

Figure 2-3 Examples of split spoon cores: a) as recovered and photo-documented in the field and b) as a vacuum-sealed bulk sample from borehole VC-3 (CDL_VC-3_16.5'-18') preserved for testing 2-4

Figure 2-4 Porewater and gas access points: a) conceptual design of PAP and GAP installation and b) picture of installed PAP and GAP 2-5

Figure 2-5 Summary of borehole and monitoring well elevations including screened intervals and GAPs. Maximum and minimum water table measurements from monthly measurements (Figure 7-1) are also shown. Figure does not depict horizontal monitoring point placement. 2-7

Figure 3-1 Extrusion of undisturbed coal ash sample from a thin-wall sampling tube conducted at UVA 3-5

Figure 3-2 Hydraulic conductivity test specimen and permeameter setup: a) test specimen (brown, gray cylinder) between two geotextile filter disks (thin black disks) and two porous stones (blue-gray disk on each end); b) test specimen installed in flexible wall permeameter 3-5

Figure 3-3 Subsurface gas monitoring apparatus: a) Ventis Pro 5 meter and b) connected tubing and desiccant syringe 3-14

Figure 4-1 Particle size distribution of coal ash samples on which hydraulic conductivity tests were conducted 4-2

Figure 4-2 Hydraulic conductivity of coal ashes at 20 kPa effective stress as a function of (a) fines content and (b) 2-μm clay content 4-4

Figure 4-3 Hydraulic conductivity of coal ashes as a function of dry unit weight 4-4

Figure 4-4 Hydraulic conductivity of coal ash samples as a function of effective stress 4-5

Figure 5-1 Low L/S Field Extraction concentration profiles within boreholes (VC-1, VC-2, VC-3, and VC-4): pH and arsenic; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL 5-2

Figure 5-2 Low L/S Field Extraction concentration profiles within boreholes (VC-1, VC-2, VC-3, and VC-4): chromium and selenium; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL 5-3

Figure 5-3 Standardized Low L/S Field Extraction profiles within boreholes (VC-1, VC-2, VC-3, and VC-4) standardized to the global mean and standard deviation of known ash samples: pH and arsenic; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL 5-6
Figure 5-4 Standardized Low L/S Field Extraction profiles within boreholes (VC-1, VC-2, VC-3, and VC-4) standardized to the global mean and standard deviation of known ash samples: chromium and selenium; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL 5-7
Figure 5-5 Comparison of standardized mass release profiles for Low L/S Field Extractions and L/S ≈ 1 Field Extractions of major constituents from VC-1 and VC-2: pH+pE, aluminum, iron, and sulfur; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL 5-9
Figure 5-6 Comparison of standardized mass release profiles for Low L/S Field Extractions and L/S ≈ 1 Field Extractions of trace constituents from VC-1 and VC-2: antimony, arsenic, boron, and selenium; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL 5-10
Figure 6-1 Titration curves from EPA 1313 test results from five composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) 6-4
Figure 6-2 Example LSP behaviors from composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) showing applicable pH range (8 ≤ pH ≤ 12) for alkaline materials 6-5
Figure 6-3 Example mass release from composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) showing available content (dashed horizontal lines) 6-9
Figure 6-4 Evolution of pH in column eluates (EPA 1314) from five composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) compared to natural pH (EPA 1313), own pH (EPA 1313_L/S1), and range of porewater pH measurements 6-11
Figure 6-5 Example 1314 test results from VC-1 showing a solubility-controlled constituent (antimony) and depletion of the available content (cobalt) and wash-off of a soluble constituent fraction without depletion (selenium). The gray dot-dashed line indicates prototypical solubility-controlled release fitted to the first EPA 1314 data point. 6-13
Figure 6-6 Examples of EPA 1313 and EPA 1314 data showing solubility-controlled LSP (antimony); available content-limited LSP (molybdenum); wash-off of soluble fraction leading to depletion (magnesium); and wash-off followed by solubility-controlled LSP (selenium) 6-15
Figure 6-7 Comparison of L/S-dependent (EPA 1314) data showing influence of dry-handled ash (Dry composite) on eluate concentrations of wet-handled ash (VC-1, VC-2, VC-3, and VC-4) 6-17
Figure 6-8 Comparison of molybdenum concentration (left) and mass release (right) using traditional (TCLP, SPLP, and ASTM) and LEAF tests (1313, 1313_L/S=1, and 1314); replicates indicated by “-A” and “-B” 6-22
Figure 7-1 Groundwater and porewater field parameters from monthly sampling: water table elevation, pH, and EC 7-2
Figure 7-2 Groundwater and porewater field parameters from monthly sampling: water temperature, ORP, and DO 7-3

Figure 7-3 Groundwater and porewater monitoring from monthly sampling showing lower concentrations in coal ash porewater (VC-1, VC-2, VC-3, and VC-4) than in downgradient groundwater wells (209 and 931); concentrations plotted on a logarithmic axis 7-6
Figure 7-4 Groundwater and porewater monitoring from monthly sampling showing significantly higher concentrations in coal ash porewater (VC-1, VC-2, VB-3, and VC-4) than in groundwater from the downgradient wells (209 and 931); concentrations plotted on a logarithmic axis 7-7
Figure 7-5 Example temporal porewater data showing seasonal or other variability: elevation, temperature, and pH+pE 7-9
Figure 7-6 Example temporal porewater data showing relatively constant conditions: arsenic, boron, and molybdenum 7-10
Figure 7-7 Concentration (%) of oxygen (O_2) from GAPs at boreholes VC-1, VC-2, VC-3, and VC-4 in the subsurface of the dry-handled landfill 7-12
Figure 7-8 Concentration (%) of carbon dioxide (CO_2) from GAPs at boreholes VC-1, VC-2, VC-3, and VC-4 in the subsurface of the dry-handled landfill 7-13
Figure 7-9 Concentration (ppm) of methane (CH_4) from GAPs at borehole VC-1, VC-2, VC-3, and VC-4 in the subsurface of the dry-handled landfill 7-14
Figure 7-10 Boron concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right) 7-16
Figure 7-11 Chromium concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right); crosshatched ratio results indicate estimates based on at least one MDL value 7-18
Figure 7-12 Arsenic concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right) 7-19
Figure B-1 Concentration profiles from in-field low L/S extractions: pH and liquid-to-solid ratio (L/S) B-2

1
INTRODUCTION

The appropriate use of laboratory leaching tests to describe the leaching characteristics of disposed or beneficially used coal combustion products (CCPs) is an ongoing concern. Leaching tests can provide information to estimate the release of inorganic constituents for (i) comparison of the effects of environmental conditions on leaching characteristics of a material, (ii) evaluation of the effects that chemical changes over time may have on leaching, and (iii) comparison of leaching characteristics between different materials. However, the ability of leaching test results as a tool or input used to predict field porewater concentrations is dependent on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field. For example, traditional leaching tests, including EPA Method 1311: Toxicity Characteristic Leaching Procedures (TCLP), EPA Method 1312: Synthetic Precipitation Leaching Procedure (SPLP), and ASTM D3987: Shake Extraction of Solid Waste with Water (ASTM), provide only a snapshot of leaching performance under conditions that often deviate substantially from current or anticipated future field conditions.

In 2012, the United States Environmental Protection Agency (EPA) published four leaching methods from the Leaching Environmental Assessment Framework (LEAF) as draft methods available for use. The four methods have since been validated (Garrabrants et al., 2012a; 2012b) and incorporated as final methods into the Agency's compendium of laboratory methods for solid wastes (SW-846, 2019). The four LEAF methods are:

- EPA Method 1313: Liquid-Solid Partitioning as a Function of Eluate pH Using a Parallel Batch Procedure
- EPA Method 1314: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using an Up-Flow Percolation Column Procedure
- EPA Method 1315: Mass Transport Rates of Constituents in Solid Materials Using a Tank Leaching Procedure
- EPA Method 1316: Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using a Parallel Batch Procedure

The LEAF approach differs from traditional leaching assessment methodologies in that the leaching tests are designed to provide a series of eluates characteristic of leaching behavior dependent on one or more controlling factors rather than a single eluate that is representative of field leachate from a designed scenario. The EPA has provided a guide for how LEAF tests may be incorporated into common leaching assessment practices (EPA, 2019; Garrabrants et al., 2020a; 2020b).

There remains uncertainty as to the selection of specific test methods and interpretation of testing results to represent (i) the range of pH and liquid-to-solid ratio (L/S) within a waste mass and (ii)

the current and long-term geochemical conditions of the porewater of CCP impoundments and landfills. Thus, leaching tests have been widely applied, but often without consideration of their inherent limitations for providing information suitable for evaluation of long-term leaching performance. In addition, little information is available that directly compares measured field porewater concentrations at CCP disposal sites to the results of various leaching test results.

The Electric Power Research Institute (EPRI), Vanderbilt University (VU), and University of Virginia (UVA) initiated a study to develop relationships between the geochemistry of the disposed CCPs and the measured and predicted concentrations for inorganic constituents in the porewater of CCP disposal units. In addition, this study investigates the potential relationship between porewater concentrations and the concentrations in groundwater measured at adjacent downgradient monitoring wells; although this evaluation was limited because there were no upgradient or background monitoring wells that could be used for comparison. This research was accomplished by collecting CCP materials from an active disposal unit where dry-handled coal ash overlies wet-handled ash. During field activities, subsurface materials were collected during borings, and porewater access and subsurface gas access points were installed and sampled for eight monthly monitoring events. Collected materials were characterized for leaching and geotechnical/hydrologic properties. A framework for integrating these data is being developed under a separate EPRI project. This report provides the methodology for sampling and characterization of disposed CCPs collected from an ash management unit at Plant 42197, also referred to as "CDL." The report summarizes the results of characterization CCP samples, including leaching tests and geotechnical/hydrologic data, and monitoring data with respect to groundwater and coal ash porewater collected at the facility as well as vadose-zone subsurface gas concentrations monitored within the coal ash deposit.

Project Goals and Objectives

The goals of this research are (i) to determine the most appropriate approach for estimating porewater concentrations at CCP disposal facilities, and (ii) to highlight the potential connection between the CCP leaching performance of a disposal facility and monitoring of groundwater exterior to the disposed material, based on porewater measurements and leaching tests.

The specific objectives of this project include:

- Collecting field materials to qualify the spatial variability of materials disposed in the management unit and measurements of spatial and temporal variability of porewater and pore gas composition, and to allow for characterization of leaching and geotechnical/hydrologic properties;
- Characterizing the hydraulic properties of coal ash for use in hydrologic/reactive transport modeling of CCP impoundments and landfills;
- Establishing the relationships between the characterization of leaching from bulk samples using traditional leaching tests (i.e., TCLP, SPLP, and ASTM) and LEAF pH- or L/S-dependence leaching tests with measured porewater concentrations monitored at the site;
- Assessing the ability of leaching tests (traditional or LEAF tests) to directly estimate coal ash porewater concentrations; and

- Identifying the relationship, if any, between porewater concentrations within the saturated zone of the management unit and downgradient groundwater concentrations.

Site Description

The active landfill at Plant 42197 covers a 110-acre area that was part of a larger 300-acre CCP management unit constructed around 1970 and used to collect storm water and process water from the plant. Starting in the mid-1990s, the unit was divided into sections for sluicing/consolidation of bottom ash, storage of gypsum, and landfilling of dry-handled fly and bottom ash. A 5-ft layer of bottom ash with a permeable geomembrane was laid as a capillary break over the lower wet-handled coal ash deposit to separate this older material from the landfill. Fly ash is collected in a dry state and conditioned with moisture prior to spreading and compacting the ash on the landfill. Bottom ash from the bottom ash settling area is deposited and compacted into the unit primarily to provide surface stability for transport and construction equipment. Starting in October 2019, approximately one-quarter of the surface area of the landfill was covered with 1-2 feet of topsoil and seeded for final cover.

Sampling and Testing Approach

Fieldwork for this project included: (i) advancement of boreholes into the coal ash deposit to improve the understanding of the ash stratigraphy and to obtain samples of the unsaturated and saturated ash layers; (ii) installation of porewater access points (PAPs) within the saturated ash layer and subsurface gas access points (GAPs) within the unsaturated ash; and (iii) sampling of groundwater and porewater and subsurface gas on a monthly basis.

Figure 1-1 shows the relative locations of four boreholes (VC-1, VC-2, VC-3, and VC-4) drilled into the coal ash for material sampling at the site and for installation of PAPs. Additionally, the figure indicates the locations of two groundwater monitoring wells (209 and 931) that allow for sampling of downgradient groundwater in the alluvium that extends beneath the management unit. No upgradient groundwater monitoring well was identified that would provide data on the condition of groundwater prior to reaching the disposal facility. At each of the four borehole locations, bulk ash samples were collected at approximately 10-foot intervals by split spoon sampling. This material was tested in the field and in the laboratory to evaluate the homogeneity of material in the disposal facility and to characterize the leaching properties of the collected ash. In parallel, intact ash cores were collected by tube sampling to determine geotechnical characteristics and hydraulic conductivity of the disposed ash. On a monthly basis for eight months following the completion of the initial fieldwork, samples were collected from each PAP and from the two downgradient groundwater monitoring wells to provide points of comparison to PAP porewater samples. During monthly sampling, the composition of subsurface gas was monitored.

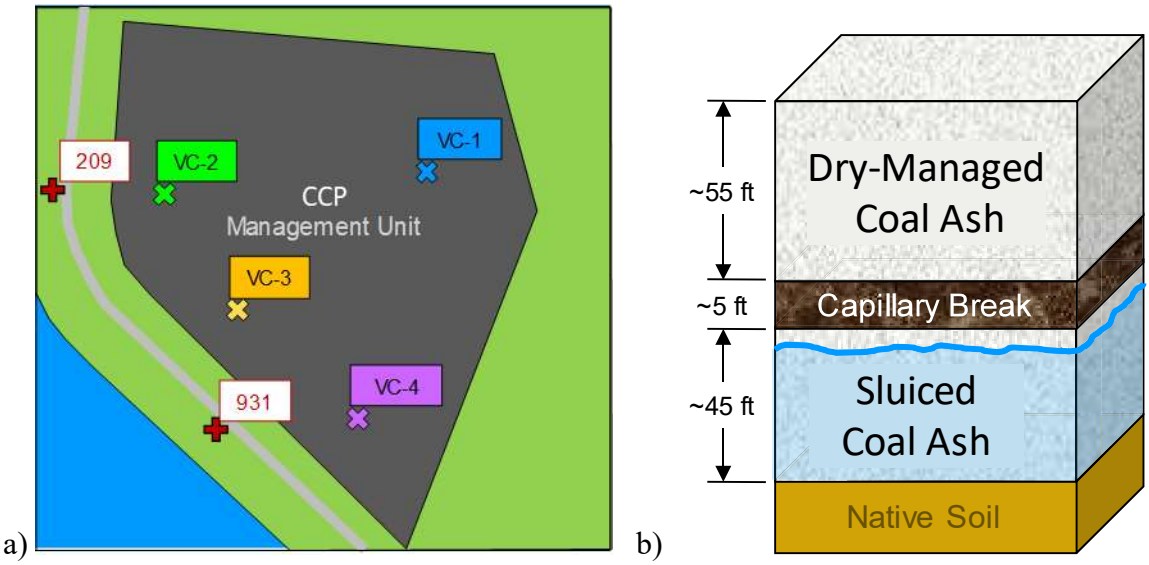

Figure 1-1
Schematic representations of the CDL management unit: a) plan view showing boreholes (VC-1 through VC-4) and groundwater monitoring wells; b) cross-section of disposal unit with approximate layer depths

Bulk samples of collected ash were shipped to the Department of Civil and Environmental Engineering at VU for characterization of leaching properties using the following tests:

- EPA Method 1313 to determine leaching behavior as a function of eluate pH at L/S values of 10 and 1 mL/g-dry,
- EPA Method 1314 to evaluate L/S-dependent leaching from a percolation column, and
- A trio of single-batch extraction tests (i.e., TCLP, SPLP, and ASTM) commonly used to estimate leaching concentrations.

The eluate pH for all leaching tests was measured and recorded so that comparisons could be made between leaching evaluations. The reported constituents include most of those found in the Code of Federal Regulations, Title 40, Section 257 (40 CFR 257), Appendix III for detection monitoring and Appendix IV for assessment monitoring, as well as several additional constituents. Although listed in 40 CFR 257 App III and IV, radium and total dissolved solids were not analyzed. Approximately 40 constituents were quantified in leachates and porewater/groundwater samples to provide a comprehensive basis for geochemical modeling of leaching test results.

The geotechnical and hydrologic properties of intact core samples were determined at the School of Engineering at UVA. Hydraulic conductivity of intact samples was measured using flexible-wall permeameters following the methods in ASTM D5084. Tests were conducted over a range of effective stresses to evaluate how hydraulic conductivity varies with packing configuration and overburden found at depth. Particle size analysis was conducted on each sample using the methods in ASTM D6913 to understand how the hydraulic conductivity varies with the composition of the ash.

2
COLLECTION OF FIELD MATERIALS

The locations of the four boreholes (VC-1, VC-2, VC-3, and VC-4) shown in Figure 1-1 were selected to be within the footprint of the saturated ash deposits, but out of the way of active ash placement. Thus, materials obtained from these boreholes were considered to capture the vertical and horizontal heterogeneity of ash materials above and below the water table. Prior to the 1990s, coal ash was sluiced from the main plant using process water to an outfall near the location of VC-1. Records indicate that the wet-handled ash is approximately 45-feet deep, covered by a 5-foot thick bottom ash capillary break, and, at the time of field sampling, approximately 55 feet of unsaturated dry-handled material consisting of fly ash mixed with bottom ash. The description of historical ash placement in this unit, and the lack of any significant known spatial variations in material types within the unit, indicated that the four locations would be representative of materials across the 110-acre disposal facility.

Initial Site Sampling

Field sampling included collection and testing of bulk ash samples from two to three consecutive split spoons interspersed with thin-wall tube sampling to obtain samples of undisturbed ash. This sequence was repeated at 10-foot intervals starting at five feet below ground surface (BGS). All drilling operations were conducted by a contracted drilling/engineering company. Boreholes were advanced using an 8.25-inch internal diameter (ID) hollow-stem auger (HSA) drilling a 13-inch diameter hole. Collected samples included small samples used in field-testing, bulk material preserved for leaching characterization at VU, and core samples for hydraulic property testing at UVA. Figure 2-1 shows a schematic of the samples collected at depth along with a summary of the number and type of samples collected at each borehole. In this figure, the depths BGS for each sample recorded during collection have been converted to elevations in feet above mean sea level (AMSL) after surveying of the PAP casings and ground elevations. An inventory of the collected samples is provided in Appendix A.

When the borehole depth reached a target level below the water table, prepacked PVC well screen was set in a sand layer for porewater recovery, and the borehole was sealed with bentonite pellets and then backfilled with bentonite chips to the target level for GAP placement. GAPs were set within a 1-foot interval of round river stone and sealed with a wetted and expanded bentonite cap (bentonite pellets) above and below the GAP layer. After the completion of initial site sampling (i.e., advancing borings and installation of monitoring points), the PAP wells were developed and readied for sampling. The finalized bore logs are maintained as electronic files available upon request.

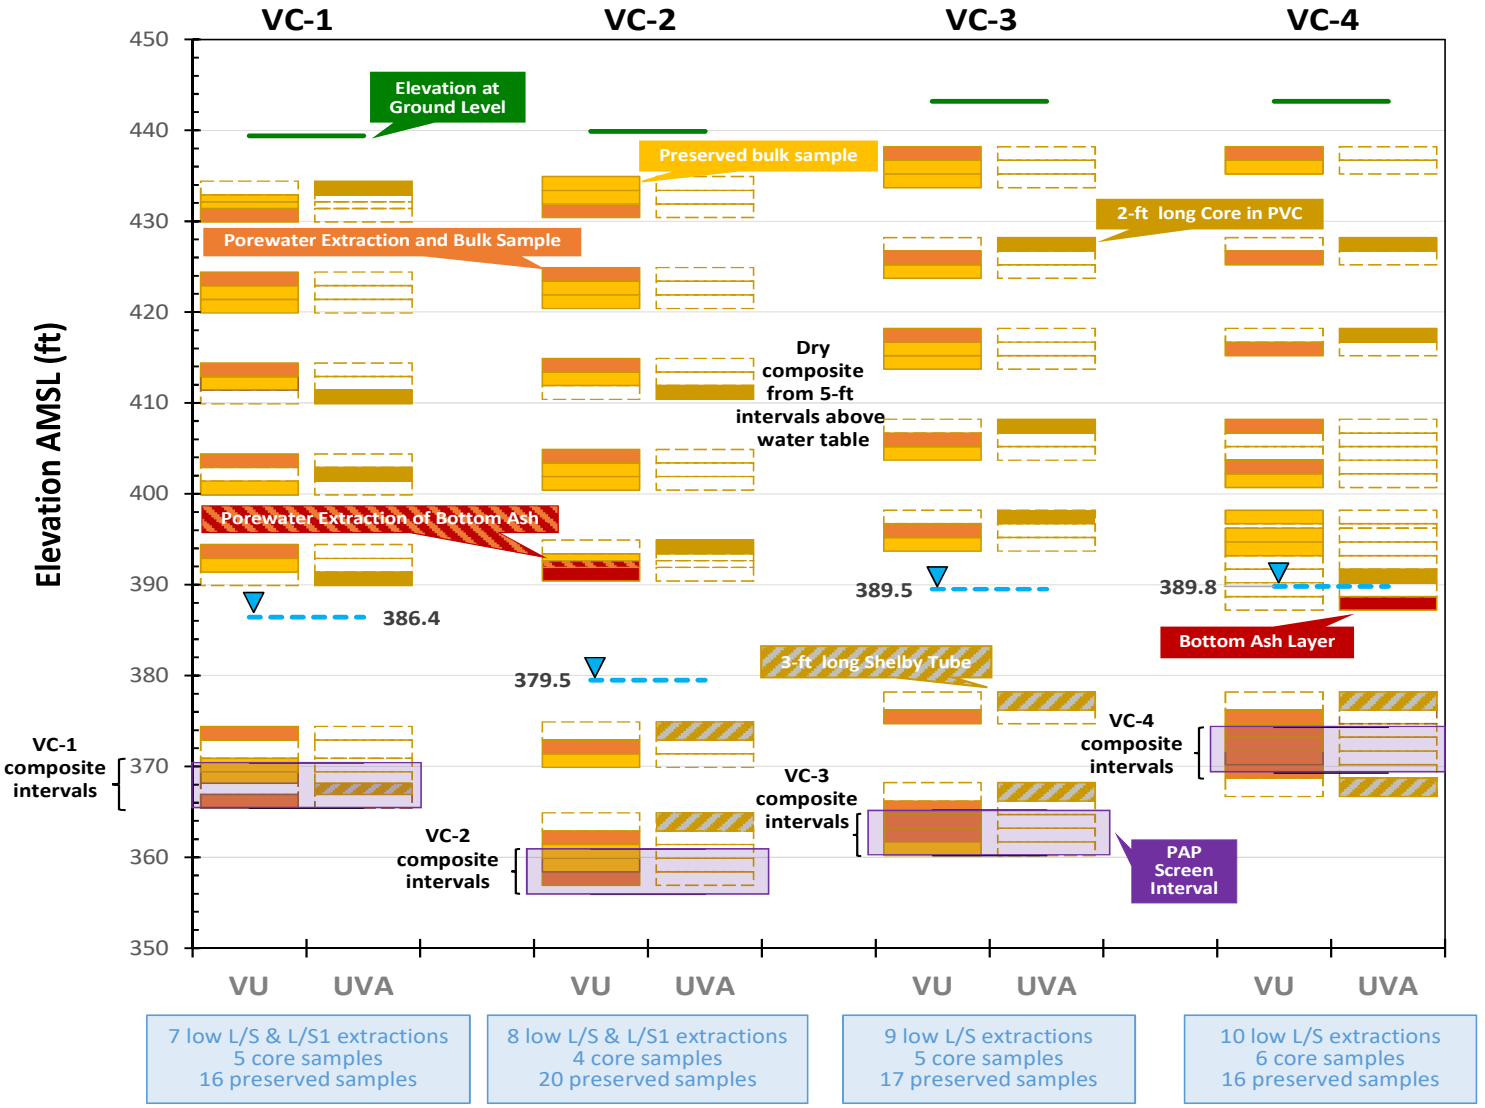

Figure 2-1
Ash sample collection and field testing for VC-1, VC-2, VC-3, and VC-4 boreholes

Bulk Material (Split Spoon Samples)

At each borehole location, 3-inch OD x 24-inch long split spoon samplers were advanced into the coal ash starting at 5 feet BGS (Figure 2-1). Upon retrieval by the drilling contractor, each split spoon sample was opened, recorded, and examined by a licensed geologist prior to release to VU for sample packaging, distribution, and laboratory analysis. VU field activities included preparation of samples for the following:

- Low L/S Field Extractions: Approximately 120 grams of ash from a split spoon was moderately packed into a 3.8-cm ID x 11-cm long acrylic cylinder equipped with a filtration stage and a 0.45-m polypropylene filtration membrane (Figure 2-2a). To ensure extractable moisture in visually dry samples, 10 to 20 mL of de-oxygenated, deionized water (DIW) was added to the cylinder prior to capping, sealing, and storage under an argon blanket (Figure 2-2b). In the laboratory, these samples were centrifuged at 1,000 revolutions-per-minute (rpm) for 5 minutes to extract the pore solution for analysis. During field operations, the porewater extraction tubes were stored in a pressure vessel that was purged with argon gas immediately after each sampling session. This unique field sampling and extraction technique was specifically designed for this project to optimize control of L/S ratio and maintenance of field reduction-oxidization (redox) conditions based on previous field sampling experience (EPRI, 2020).

a) b)

Figure 2-2
Low L/S Field Extraction: a) capped apparatus with sample and b) collected samples stored in pressure vessel prior to purging with argon

- Moisture Content Samples: In parallel to porewater testing, a known mass of ash (~20 g) was collected in a certified, pre-tared 125-mL high-density polyethylene (HDPE) bottle (Nalgene I-Chem #N311-0125) for moisture content analysis at VU.
- L/S≈1 Extractions: A known mass of ash (~150 g) from VC-1 and VC-2 split spoons was placed into a certified, pre-tared 50-mL HDPE DigiTube (SCP Science #010-500-253). The bottle was filled with de-oxygenated DIW and weighed to record the mass of added water. In the laboratory, these tubes were tumbled for 24 hours followed by filtration through 0.45-µm HDPE membrane and analysis of extracted fluid.

- Bulk Ash Collection: Remaining ash from each split spoon was vacuum-sealed in plastic bags (Figure 2-3) with oxygen scavenger packets (zero-valent iron) to preserve the redox conditions of the material. The preserved bulk material was maintained in its original cylindrical shape with the top and bottom of the core marked on the vacuum bag. Bulk samples were stored in coolers for shipment to VU.

Labels used for samples included "CDL" as a site identifier, the borehole number (VC-1, VC-2, VC-3, or VB-4), and the depth BGS from which the samples were taken. For example, the sample labeled "CDL_VC-3_16.5-18" in Figure 2-3 was collected from the split spoon at 16.5 to 18 feet BGS at borehole VC-3. For split spoons that penetrated an interface (e.g., between ash with visually different properties), the separate materials were collected as separate bulk samples in two vacuum-sealed bags. The upper portion was labeled with an "A" extension, while the lower portion was labeled with "B" at the same split spoon interval. All samples were stored at <5 °C and transported to the VU lab within 48 hours of collection, where they were stored in an environmentally controlled room at 5 °C prior to processing for leaching tests.

a)

b)

Figure 2-3
Examples of split spoon cores: a) as recovered and photo-documented in the field and b) as a vacuum-sealed bulk sample from borehole VC-3 (CDL_VC-3_16.5'-18') preserved for testing

Intact Cores (Tube Samples)

Thin-walled tube sampling of unsaturated ash was attempted, but the tubes would not penetrate the compacted unsaturated material without crumpling. Therefore, split spoon samples of unsaturated ash were extruded into 2-inch OD diameter x 24-inch long PVC tubes, maintaining the sample orientation, so that materials could be consolidated at UVA for testing. Oxygen scavenger packets were included within the tubes, and PVC endcaps were sealed to the tube with duct tape.

Below the water table, in the wet-handled ash, 3-inch OD by 36-inch long thin-wall tube samplers were pushed into the ash layer to obtain intact cores at locations targeted to collect samples near the PAP elevations. Each recovered thin-walled tube was sealed at both ends using plastic expanding inserts, capped with plastic endcaps, and sealed with duct tape. Oxygen scavenger packets were included in each thin-walled tube before sealing. Sample identification was based on the interval BGS from which the samples were recovered (e.g., the tube sampler recovered from the interval from 65 to 67 feet BGS at borehole VC-2 was labeled "CDL_VC-2_65-67").

Porewater Access Points

Once the 8.25-inch ID HSA was advanced to the target depth for placement of a PAP, a 2-inch OD Schedule 40 PVC pipe was installed through the HSA. At each well location, the contractor installed pre-packed, 5-foot screened section in agreement of the field team leads for VU, EPRI, and CDL. Each 13-inch diameter borehole was backfilled with 1 foot of clean sand before the well screen was set, and after setting the screen, was backfilled with sand to 2 feet above the top of the well screen. The sand pack was sealed with bentonite clay pellets, and bentonite chips were used to backfill the borehole to within ½ foot of the GAP depth.

Subsurface Gas Access Points

GAPs were established for monthly monitoring of subsurface gas at nominally 5-, 15-, and 50-feet BGS (50-foot deep GAPs were established at VC-1 and VC-3 only). Each GAP consisted of a ¼-inch diameter stainless steel tube set at depth within a 1-foot thick layer of round river rock and sealed from above and below with a 1-foot thick layer of expanded bentonite clay. The lower end of the GAP tubing was protected from rock, ash, and clay debris with an inverted steel cup. The stainless steel tubing was zip-tied to the PVC well and finished with a 2-way shut-off valve. The bed of river rock, nominal size of between ¾ inch and ¼ inch, ensures sufficient subsurface gas volume for measurement. A detail of the conceptual design of an installed GAP is illustrated in Figure 2-4.

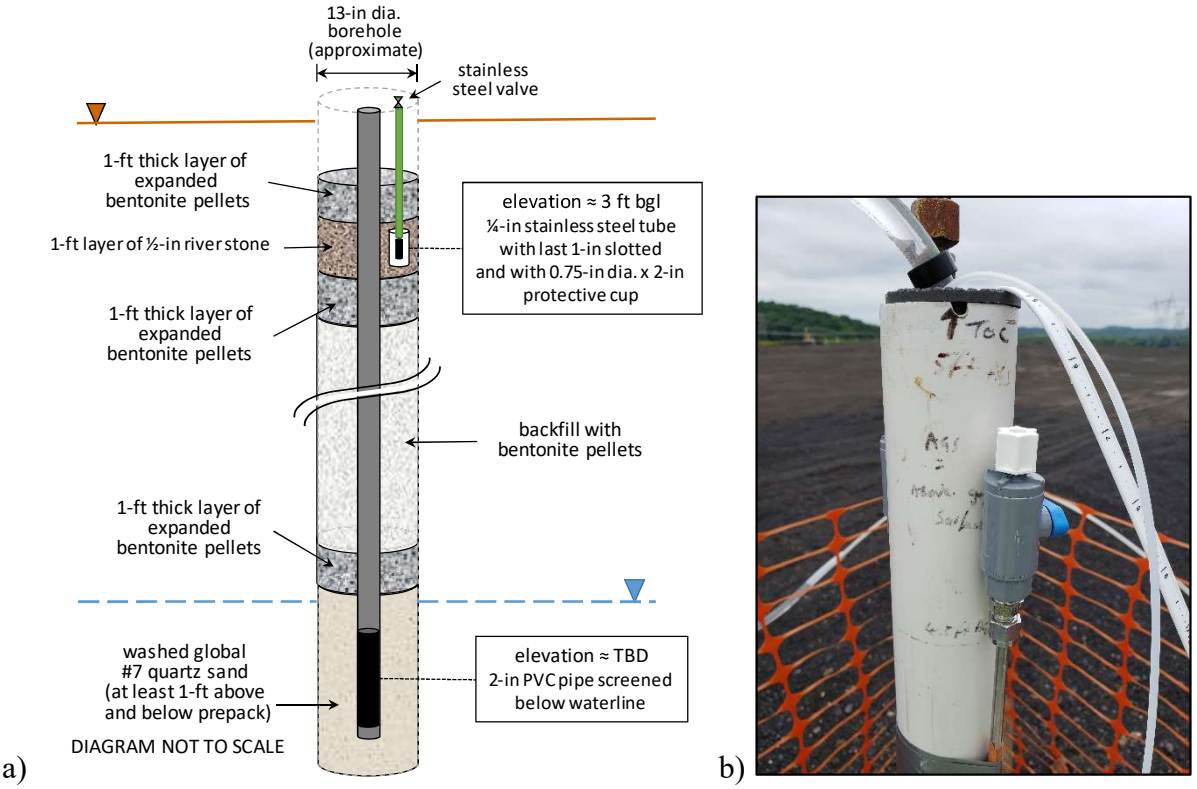

Figure 2-4
Porewater and gas access points: a) conceptual design of PAP and GAP installation and b) picture of installed PAP and GAP

Summary of Borehole and PAP/GAP Elevations

Within two weeks of field sampling, the drilling contractor installed dedicated pumps, developed the wells, and protected the borehole locations with a construction mesh. The horizontal location of the PAP and the elevations of the PVC tubing and ground surface level were surveyed by a professional land surveyor. A summary of the elevation survey results and elevation of pertinent sampling locations for the VC-1, VC-2, VC-3, and VC-4 boreholes is tabulated in Table 2-1. Figure 2-5 graphically shows the elevation relationships between the boreholes and the two downgradient monitoring wells (209 and 931), as well as porewater and groundwater elevations measured during the field study.

Table 2-1
Elevations Above Mean Sea Level (AMSL) for CDL Boreholes

	Elevations AMSL (ft)			
	VC-1	**VC-2**	**VC-3**	**VC-4**
Top of Well Casing	444.46	445.06	448.92	447.63
Ground Surface	439.4	439.9	443.2	443.2
GAP #1 (green)	434.4	435.0	438.4	438.1

Note: (-) indicates that no GAP was placed adjacent to the water table at VC-2 or VC-4.

* water level measured on the date of well construction. Monthly water table elevations are provided in Figure 7-1.

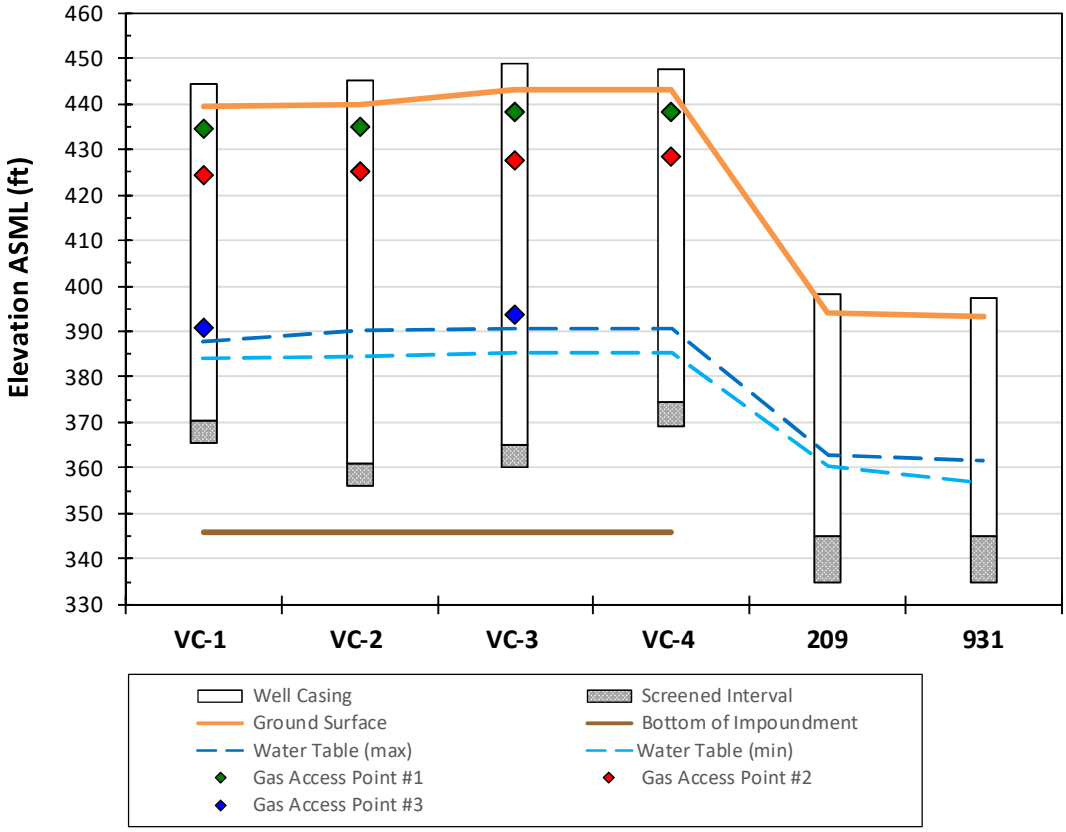

Figure 2-5
Summary of borehole and monitoring well elevations including screened intervals and GAPs. Maximum and minimum water table measurements from monthly measurements (Figure 7-1) are also shown. Figure does not depict horizontal monitoring point placement.

Monthly Field Monitoring

Porewater and subsurface gases were monitored monthly at each borehole location over eight months from June 2019 through January 2020. In addition, groundwater samples from monitoring wells 209 and 931 downgradient of the CCP landfill were collected.

Collection of Groundwater and Porewater

The relative locations of the four installed PAPs (VC-1, VC-2, VC-3, and VC-4) and the two existing groundwater sampling wells were shown previously in Figure 1-1. CDL field personnel accessed each well, stabilized the well using low-flow sampling techniques according to company standard operating procedures, and allowed VU field team access to the effluent line for collection of groundwater and porewater samples. At no time did the site owners' personnel retain custody of any samples used for this analysis.

The sampling flow rates for porewater and groundwater wells were approximately 150 mL/min and 50 mL/min, respectively. At 5-minute intervals, the pH, dissolved oxygen (DO), electrical conductivity (EC), oxidation-reduction potential (ORP), temperature, and turbidity of the sampled water were monitored using a flow-through multi-parameter sonde and separate

turbidity meter while water level was measured with a portable electronic water level meter. The criteria used to determine well stability were (i) turbidity less than 10 NTUs and (ii) pH stable within 0.1 standard unit over three consecutive 5-minute readings.

Groundwater and porewater samples were collected in 50-mL Digitubes including duplicate samples collected for anion analysis via ion chromatograph (IC) and duplicate samples collected for metals and other cation analysis via inductively coupled plasma (ICP) techniques (see *Chemical Analysis of Eluates, Groundwater, and Porewater* in Section 3 for details). Samples for ICP analysis were preserved in the field by addition of 1.5 mL of Tracemetal® grade nitric acid (3% total acid addition) using a 100-1000 µL Oxford Benchmate manual pipette and disposable tips. A set of four samples was collected unfiltered followed by a set of samples passed through a QuickFilter 609 cm^2, 0.45-mm inline filter. In total, eight 50-mL Digitubes were collected at each sampling location. All liquid samples were stored in a cooler of ice with an Elitech RC-5 USB temperature data logger to record the temperature within the cooler. Samples were transported by the field team to VU for immediate storage at 5 ºC prior to analysis. Analysis of the sample results showed negligible differences between the filtered and unfiltered samples, and the results from the unfiltered samples are used in the following analysis.

Subsurface Gas Monitoring

A description of the monitoring process for subsurface gas and a picture of gas monitoring apparatus are provided in Section 3.

3
MATERIALS AND METHODS

The following sections include brief descriptions of the test methods and analytical methods used in this study. Also described are the quality assurance/quality control (QA/QC) samples and criteria for each analytical method.

Collected Materials

Materials recovered during initial sample collection included bulk samples from split spoons and intact cores contained in PVC tubes or thin-wall stainless steel tubes. Laboratory processing of bulk material for leaching tests included (i) homogenization within each split spoon sample, (ii) compositing saturated ash samples from each borehole from materials collected near the screening level, and (iii) compositing unsaturated ash into one sample across the disposal facility.

Homogenization of Bulk Samples

Each recovered split spoon sample was crushed with a rolling pin and homogenized by hand through the plastic bag until the contents were well mixed. From this homogenized split spoon material, composite samples were created.

Material Composites

For each of four boreholes (VC-1, VC-2, VC-3, and VC-4), saturated ash homogenized from split spoons collected at the PAP screen elevation was used to develop a composite test material representative of the bulk ash deposited at the PAP. Table 3-1 shows the specific homogenized split spoon materials used to create each composite sample for the four boreholes. In addition, a fifth composite material of unsaturated ash was created by blending homogenized material above the water table from all boreholes collected; however, the intervals used in this composite, hereafter referred to as "Dry," varied with the intervals of unsaturated ash at each borehole.[1]

The composite material was created by mixing equal dry mass equivalents (i.e., the mass of "as received" material that equates to a prescribed mass of dry material) from each homogenized split spoon in a plastic bag under a N_2-purged environment in a Coy chamber (an anoxic glove box) to minimize air exposure. The composite material was homogenized by hand through the plastic bag until well mixed. This composited sample was used for total content analysis and characterization using LEAF leaching tests and traditional leaching tests (i.e., ASTM, TCLP, and SPLP).

[1] In other words, five composites are discussed in Section 4 – composites VC-1, VC-2, VC-3, and VC-4, which represent the lower wet-handled coal ash deposit and have corresponding PAP porewater samples, and the composite referred to as Dry, which represents the upper dry-managed coal ash deposit and does not have corresponding porewater samples.

Table 3-1

Material Properties

Total Content by EPA Method 3052

The total elemental content of composite samples was determined by acid digestion following EPA Method 3052, with subsequent analysis of the digestate by Eurofins TestAmerica (Knoxville, TN). According to the Method 3052, a solid sample of up to 0.5 g (wet) is digested in 9 mL of nitric acid and 3 mL of hydrofluoric acid for 15 minutes in a microwave to accelerate the digestion reactions. Additional acid and reagent combinations, including hydrochloric acid and hydrogen peroxide, are added to ensure that the solid is dissolved. The microwave temperature profile includes reaching 180±5 ºC in approximately less than 5.5 minutes and remaining at 180±5 ºC for 9.5 minutes for the completion of specific reactions. After cooling, the vessel contents were centrifuged and decanted. The small volume of remaining digestate was diluted to a volume of 100 mL and chemically analyzed. Inductively coupled plasma–optical emission spectrometry (ICP-OES) following EPA Method 6010A was used to determine digestate concentrations for 26 constituents (i.e., Al, Sb, As, Ba, Be, Cd, Ca, Cr, Co, Cu, Fe, Pb, Li, Mg, Mn, Hg, Mo, Ni, K, Se, Ag, Na, Sr, Tl, V, and Zn). Boron was not included in this total content analysis because metaborate is added to the digestion process for Method 3052. Mercury concentrations in the digestate were measured by using cold vapor atomic absorption following EPA Method 7470A. The total content (mg/kg) is calculated by multiplying the concentration measured in the digestate (mg/L) by the L/S of the extraction procedure (L/kg). For this study, the resultant total content is effectively on a dry mass basis (mg/kg-dry) because the material submitted to the laboratory for testing was oven-dried prior to submission to the laboratory.

X-Ray Fluorescence Analysis

The elemental composition of coal ash samples was determined at UVA using x-ray fluorescence (XRF) quantitative analysis on an Epsilon 3X energy-dispersive XRF spectrometer (PANalytical, Malvern, UK) with a silver anode X-ray tube and 50-micron beryllium window.

Five-gram subsamples of coal ash were taken from the undisturbed core samples, air-dried for 24 hours at room temperature, and ground by hand to less than 0.075 mm using an agate mortar and pestle. For analysis, ground samples were packed into an 18-mL sample cup (28 mm ID x 30 mm). Each subsample was analyzed in duplicate following ASTM D8064 (2016) for the XRF analytical method of silicate rocks.

Loss on Ignition

Loss on ignition (LOI) was measured at UVA for subsamples of undisturbed coal ash material to quantify total organic matter content. LOI was conducted in accordance with ASTM D2974-14 by heating a pre-weighed sample at 550 °C using a Lindberg/Blue M 1200 °C Box Furnace (ThermoFisher Scientific, Waltham, MA).

Moisture Content

As part of the leaching test characterization using the LEAF methods, the moisture content of each study material was determined following the ASTM D2216 (2010). Moisture content on a dry mass basis was calculated as the difference in the mass of a "wet" subsample compared to the sample after oven drying to constant mass at 105±5 °C. The solids content is defined as the mass of solid material in an "as-tested" or "wet" subsample, measured on a "wet" basis. The determination of moisture content and solids content provides uniform bases for reporting of total content and leaching behavior results, allowing for comparison between moist and dry materials.

Porosity or Saturated Volumetric Water Content

Dry density and porosity of each material were determined at UVA using weight-volume computations, following the procedure in ASTM D7263 (2018). Under saturated conditions (i.e., when all voids are filled with water), the saturated volumetric water content equals the porosity.

Particle Size Distribution

Particle size distribution (PSD) of each CCP sample was determined at UVA by a combination of mechanical analysis following ASTM D6913-17 and sedimentation analysis following ASTM D7928-17. For mechanical analysis, a 100-g sample was oven-dried at 110±5 °C and passed through a series of US standard sieves: No. 10 (2 mm), No. 20 (0.85 mm), No. 60 (0.25 mm), No. 100 (0.15 mm), and No. 200 (0.075 mm). The fraction of the 100-g mass retained on each sieve was measured gravimetrically. Particle size distribution of the fraction coarser than the No. 200 sieve (0.075 mm) was calculated as the weight of solid retained on each sieve.

For sedimentation analysis, 50 g of dry solid that had passed the No. 200 (0.075 mm) sieve was soaked in 4% sodium metaphosphate, $(NaPO_3)_6$, solution for 12 hours and then transferred to a 1-L graduated cylinder. The graduated cylinder was capped, then agitated end-over-end for 60 seconds, and then settling of particles was monitored using a hydrometer. Stokes law was used to compute the PSD from the hydrometer data for the fraction of particles finer than the No. 200 sieve.

Saturated Hydraulic Conductivity

Hydraulic conductivity tests were conducted in flexible-wall permeameters following the methods in ASTM D5084-16. Sections of undisturbed coal ash were extruded from thin-wall sampling tubes (Figure 3-1) and cut into 76-mm long specimens. Non-woven geotextile disks and porous stones were placed on both ends of each coal ash specimen (Figure 3-2a) to ensure uniform flow distribution and to retain particles. Specimens were wrapped in a latex membrane and placed into a flexible-wall permeameter (Figure 3-2b).

In lieu of the more traditional tap water or 0.01 M $CaCl_2$ solution suggested in ASTM D5084, DIW was used as the permeant solution to ensure that the water entering the specimen had no ionic species that might alter the hydraulic conductivity or the leachable constituents in the coal ash. Effluent from the permeameter was collected following the procedure in ASTM D7100-11. Effluent samples were collected from the tests, stored in Teflon® sample bottles with minimal headspace, and shipped under chain of custody to VU for chemical analysis.

The falling headwater-constant tailwater method was used with an average hydraulic gradient of 15. No backpressure was applied to simulate field conditions and to minimize alterations in geochemistry. All tests were conducted at an initial effective stress of 20 kPa and continued until the hydraulic conductivity reached hydraulic equilibrium as defined in ASTM D5084 (steady hydraulic conductivity, incremental outflow divided by steady inflow within 1.0±0.25). At the conclusion of the test, weight-volume calculations were conducted to confirm that all specimens were saturated during testing.

After testing at 20 kPa was complete, three specimens, representing higher, lower, and intermediate hydraulic conductivity, were consolidated to an effective stress of 100 kPa and permeated again until hydraulic equilibrium was established (steady hydraulic conductivity, steady flow ratio 1.0±0.25). This procedure was repeated at effective stresses of 250, 400, and 500 kPa. The initial stress (20 kPa) was selected to replicate the stress condition of shallow coal ash in the basin. The higher stresses represent conditions at greater depths. Effluent samples from the higher-stress tests were not collected for chemical analysis.

Traditional Extraction Tests

EPA Method 1311 – Toxicity Characteristic Leaching Procedure

EPA Method 1311, or TCLP, is a single-point batch leaching test used to determine the toxicity characteristic of a material and the disposal options for a material under the Resource

Conservation and Recovery Act of 1986 (RCRA). TCLP was designed to simulate eluate concentrations for a plausible mismanagement scenario where hazardous waste is disposed in a municipal solid waste landfill. Thus, a solution of acetic acid in DIW is the extraction fluid to represent the primary acidity in municipal solid waste landfill leachate. Based on a pretest of the buffering capacity of test sample for acetic acid, either Extraction Fluid #1 (dilute acetic acid with a NaOH buffer at a pH of 4.93±0.05) or Extraction Fluid #2 (dilute acetic acid at a pH of 2.88±0.05) is selected for the test. Since the method allows for analysis of samples with filterable water (e.g., slurries), the specified L/S of 20 mL/g is based on the mass of moist sample recovered from pressure filtration at 15 lb/in^2 (103 kPa). The filtrate from pressure filtration was preserved and chemically analyzed in parallel to TCLP extracts. Therefore, the final dry-basis extraction L/S is typically greater than 20 mL/g-dry when filterable water is considered.

For TCLP analysis, 100 g of solid was pressure-filtered and the moist solid was mixed with Extraction Fluid #1 at an L/S of 20 mL/g-dry. The mixture was tumbled at 28±2 rpm for 18±2 hours. Although not specified in the method, the pH of the final eluate was measured and recorded so that test results could be compared to other leaching methods. The eluate from the extraction was pressure-filtered through a 0.22-µm borosilicate glass fiber filter and preserved for analysis. Filtrate from pressure filtration and the extraction eluate were analyzed separately, and an "effective" extraction concentration was calculated for each constituent as a volume-weighted average concentration of the two liquids. For QA/QC purposes, a method blank, with the filter paper and extraction fluid only, and duplicate samples for the composite at VC-3 were conducted in parallel using the same reagents.

EPA Method 1312 – Synthetic Precipitation Leaching Procedure

EPA Method 1312, or SPLP, is a single-batch leaching test used to evaluate the leaching behavior of a waste material in contact with acidic rain. The test is performed in the same manner as the TCLP, but with extraction fluids of 60/40 weight percent (wt%) sulfuric acid (H_2SO_4) and nitric acid (HNO_3) in DIW (Extraction Fluids #1 and #2) or DIW (Extraction Fluid #3). The selection of extraction fluid depends on the location of the site under investigation and the constituents being tested. Extraction Fluid #1 is used for sites east of the Mississippi River, Extraction Fluid #2 is used for sites west of the Mississippi River, and Extraction Fluid #3 is used only when cyanides or volatiles are to be analyzed.

Approximately 100 g of ash was pressure-filtered and the moist solid was mixed with Extraction Fluid #1 at an L/S of 20 mL/g. The mixture was tumbled at 28±2 rpm for 18±2 hours. Although not specified in the method, the pH of the final eluate was measured and recorded so that test results could be compared to other leaching methods. The eluate from the extraction was pressure-filtered through a 0.22-µm borosilicate glass fiber filter and preserved for analysis. Filtrate from pressure filtration and the extraction eluate were analyzed separately and an "effective" extraction concentration for each constituent was calculated as a volume-weighted average of the two liquids. A method blank, extraction fluid with no solid carried through test process, and duplicate samples for the composite at VC-4 were analyzed.

ASTM D3987 – Shake Extraction of Solid Waste with Water

ASTM D3987, or ASTM, is a single-point extraction test that is used to estimate leaching concentrations when no acid or base is added to the extraction. Since the method is patterned

after TCLP, the procedure is similar to the EPA method; however, DIW is used as the extraction fluid. A subsample of ash (70±0.1 g) was tumbled at 28±0.2 rpm with DIW at an L/S of 20 mL/g for 18±0.25 hours. After tumbling, the extract was separated from the solid by vacuum filtration through a 0.45-µm polypropylene membrane and the pH of the final eluate was measured and recorded. Reagent blanks, method blanks, and duplicate samples for the composite at VC-2 were analyzed.

Leaching Environmental Assessment Framework (LEAF) Methods

EPA Method 1313 – Liquid-Solid Partitioning as a Function of Eluate pH Using a Batch Extraction Procedure

EPA 1313 (SW-846, 2019) is a standardized, parallel batch extraction method used to evaluate the liquid-solid partitioning (LSP) of inorganic constituents as a function of eluate pH. The general procedure consists of nine batch extractions of a particle-size reduced subsample material contacted with leaching solution at an L/S of 10 mL/g-dry material and tumbled end-over-end over a specified contact interval. The leaching solution is DIW with additions of HNO_3 or potassium hydroxide (KOH) to adjust the final pH of the eluate to a target of nine specific pH values (i.e., pH values of 2, 4, 5.5, 7, 8, 9, 10.5, 12, and 13). An additional extraction without addition of acid or base was carried out to measure constituent leaching at the natural pH of the material.[2] After 24 hours of tumbling, the contact time associated with a sample particle size of 85 wt% less than 300 µm, the solid and liquid phases were separated by settling or centrifugation, and the pH, EC, and ORP of the clarified eluate were measured. The remaining slurry was vacuum-filtered through 0.45-µm pore size membranes prior to chemical analysis by ICP-OES, IC, and carbon analysis.

EPA 1313 provides (i) a titration curve of the pH response to additions of acid or base, (ii) the available content of constituents in the solid material, and (iii) the LSP curve for constituents over the tested pH range. Furthermore, the results of EPA Method 1313 are suitable for use in geochemical speciation modeling for the estimation of the solid-phase mineralogy and surface chemistry that controls constituent release.

Variants of EPA 1313 Methods

In this program, the full EPA 1313 method and variants of EPA 1313 were carried out on ash materials for different purposes:

- Full EPA 1313 was conducted on all composite samples (i.e., saturated ash composite from each borehole plus the site-wide unsaturated composite). The procedure was modified slightly to include an extra extraction filling the gap in pH between pH < 2.0 and pH = 4.
- For all composite materials, a variant of EPA 1313 was carried out using an L/S of 1 mL/g-dry and abbreviated to the natural pH and four other pH target values distributed over the range of pH 6 to 13 (i.e., five pH values in total). This modified 1313 test, referred to as

[2] The "natural pH," sometimes referred to as "own pH," is defined as the eluate pH in response to extraction in deionized water (i.e., no acid or base added) at an L/S of 10 mL/g-dry. To distinguish the natural pH at L/S=10 mL/g-dry (Method 1313 or 1313_3pt) from the pH response to DIW at L/S of 1 mL/g-dry measured using 1313_L/S=1, the former will continue to be called with "natural pH," while latter will be referred to as "own pH."

1313_L/S=1, was used to evaluate how changes in L/S may influence LSP concentrations and to provide verification data for development of geochemical speciation models.

EPA Method 1314 – Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio using a Percolation Column Procedure

EPA 1314 (SW-846, 2019) is a standardized, up-flow column procedure used to evaluate release of inorganic constituents from percolating solid materials as a function of cumulative L/S (i.e., the volume of liquid that passes through the column relative to the dry mass of material in the column). In this study, EPA 1314 was used to characterize the L/S-dependent leaching of constituents in 250-400 g-dry composited ash samples (e.g., VC-1, VC-2, VC-3, VC-4, and Dry). A 5-cm diameter by 30-cm glass column was packed with coal ash in a series of five lifts with moderate tamping between lifts. DIW was used as the eluent solution since the coal ash had relatively low organic carbon and clay contents compared to soils. The eluent was pumped at a flowrate of 0.75±0.25 L/S per day through the material in an up-flow direction to minimize air entrapment and flow channeling. Eluates were collected at predetermined cumulative L/S values (i.e., 0.2, 0.5, 1.0, 1.5, 2.0, 4.5, 5.0, 9.5, and 10 mL/g-dry). For each eluate fraction, the pH and conductivity were recorded prior to filtration and preservation for chemical analysis. To present the results, the eluate pH, and concentrations of constituents in the eluates (mg/L), and the cumulative release through the end of each eluate fraction (mg/kg-dry) were plotted as functions of L/S in separate graphs.

Comparison of Leaching Test Parameters and Conditions

All leaching tests conducted for this program are designed to measure the LSP of constituent release from a material under the specified test conditions shown in Table 3-2. TCLP, SPLP, and ASTM are single-batch leaching tests that yield only one result; thus, test duplicates were conducted as shown in the table to ensure the quality of test results. The EPA 1313 test and its variants are batch procedures, but with parallel extractions to provide data over a range of test conditions. These batch tests, however, differ in the chemical makeup of extraction fluid as well as in the specified L/S. Moving from left to right in Table 3-2, the leaching test conditions are presented in order of increasing L/S. In the last column are the test conditions for EPA 1314, designed to measure LSP as a function of cumulative L/S.

Table 3-2
Leaching Test Parameters and Test Conditions

Parameter	TCLP	SPLP	ASTM	1313	1313_L/S=1	1314
Method Type	Single-batch	Single-batch	Single-batch	Parallel batch	Parallel batch	Column
Number of Eluates	1	1	1	11**	5	9

Note: * indicates the TCLP and SPLP extraction fluids used for these tests.
** the 1313 procedure calls for 9 pH extractions + natural pH. An additional extraction at pH 3 was performed for this testing.

Chemical Analysis of Eluates, Groundwater, and Porewater

For each eluate from a leaching test, the following parameters were measured.

Eluate pH

Eluate pH was measured on all aqueous extracts following EPA 9040C (SW-846, 2019) using an Accumet XL20 meter and a combined pH electrode on approximately 5 mL of eluate. Prior to testing, the electrode was calibrated with two National Institute of Standards and Technology (NIST) traceable pH buffer solutions that bounded the anticipated range of pH to be measured. A third mid-range NIST buffer was used to verify the calibration.

Specific Conductance

Specific conductance, or EC, is a measure of the ability of an aqueous solution to carry an electrical current. The property is dependent on (i) the presence of ions; (ii) total concentration, mobility, and variance of ions in solutions; and (iii) the temperature of the measurement. Conductivity of all leaching test eluates was determined following EPA Method 9050A (SW-846, 2019) using a standard conductivity probe calibrated to an appropriate standard conductivity solution for the conductivity range of concern.

Oxidation-Reduction Potential

ORP is a voltage differential related to the redox state of a solid-liquid solution and its effect on chemical composition (e.g., reduced/oxidized iron, dissolved oxygen, biological activity). ORP voltage of all eluate solutions was measured with a probe, consisting of a platinum electrode and a reference electrode, placed in contact with the soil solution. In laboratory tests, the ORP voltage reading was converted to redox potential (Eh) by addition of a probe-specific correction factor of 228 mV at 25 °C. In field measurements, however, the probe correction factor was automatically compensated for by the instrument to produce output as Eh values.

Since redox reactions vary with pH and the mineral species present, redox is parameterized in geochemical modeling as the pH+pE, where pE is the negative logarithm of the free electron concentration, or –log([e^-]). The corrected Eh values of leachates and eluates were converted to a pE value using the following equation:

$$pE = \frac{F}{2.303RT}(Eh/1000)$$

where F is the Faraday constant (23,061 cal/(V mol)),
Eh is the redox potential of the solution (mV),
2.303 is a conversion (ln[e^-]/2.303 log[e^-]),
R is the gas constant (1.987 cal/(K mol)),
T is the temperature (K), and
1000 is a units conversion (1,000 mV = 1 V).

Inductively Coupled Plasma Spectrometry

The eluate concentrations of trace elements and material major species (e.g., Al, Ca, Si) were determined using a combination of ICP-OES and inductively coupled plasma–mass spectrometry (ICP-MS). The choice of instrumentation was determined based on detection limits, expected concentrations, and environmental threshold values. Table 3-3 provides the method detection limits (MDLs) and lower limits of quantitation (LLOQs) used in this project.

Major species and trace elements present at higher concentrations were determined using a Varian Model 720-ES ICP-OES (Agilent Technologies, Santa Clara, CA) following EPA Method 6010D (SW-846, 2019). The ICP-OES was calibrated to a 5-point standard curve with an analytical range of 25 to 25,000 µg/L. For some high-concentration trace elements, the standard curve was extended up to 500,000 µg/L using a 7-point standard curve. For low-level trace analysis, concentrations were determined by ICP-MS using a Perkin Elmer Elan DRC II (Perkin Elmer, Waltham, MA) following EPA Method 6020A (SW-846, 2019). The ICP-MS was calibrated to a 5-point standard curve with range between approximately 1 and 250 µg/L and extended with a 7-point calibration curve to 1,000 µg/L for some constituents.

Analytical QA/QC included initial and continuing calibration checks and blanks, matrix spikes, and method blanks. Calibration check standards and matrix blanks were evaluated every 10 to 20 samples with the requirements that check standards were within 15% of the specified value and blanks were below LLOQs. Matrix spikes were required to have recoveries within 20% of the calculated concentration considering the spiked mass. Initial and continuing calibration check standards for ICP-OES and ICP-MS were 0.5 mg/L and 0.050 mg/L, respectively. Analyte concentrations measured at less than the MDL were reported as <MDL and graphed at one-half the MDL values to indicate that the measurement was conducted. Analytical results measured at less than the LLOQ but greater than the MDL are estimated values.

Table 3-3
Methods, MDLs, and LLOQs for Analysis of Eluates by ICP-OES and ICP-MS

Analyte	Symbol	Method	MDL (mg/L)	LLOQ (mg/L)
Aluminum	Al	ICP-OES	0.0034	0.025

Ion Chromatography

The concentrations of anions in leaching test eluates were determined by IC using a Metrohm 881 Compact IC Pro (Metrohm USA, Riverview, FL) with a Metrosep A Supp 5 column and a conductivity detector following EPA Method 9056A (SW-846, 2019). A seven-anion calibration standard was diluted to form a 5-point calibration curve with the MDLs and LLOQs shown in Table 3-4. Since the calibration standards are diluted from a bulk multi-analyte standard, the calibration range differs for each analyte (e.g., 0.050-50 mg/L for Cl^- and 0.150-150 mg/L for SO_4^{-2}). Calibration check standards were required to be within 15% of the specified value, while acceptable analytical blanks were measured below the quantitation limits.

Table 3-4
MDLs and LLOQs for Analysis of Eluates by IC

Analyte	Symbol	MDL (mg/L)	LLOQ (mg/L)
Bromide	Br^-	0.0064	0.025
Chloride	Cl^-	0.0101	0.05
Fluoride	F^-	0.0063	0.02
Nitrate	NO_3^-	0.0112	0.1
Nitrite	NO_2^-	0.0108	0.05
Phosphate	PO_4^{-3}	0.0247	0.15
Sulfate	SO_4^{-2}	0.0254	0.15

Carbon Analysis

Carbon analysis for eluate samples included analyses for dissolved inorganic carbon (DIC) and dissolved organic carbon (DOC). Carbon analysis was conducted using a Shimadzu TOC-V CPH/CPN (Shimadzu Scientific Instruments, Inc., Columbia, MD) by catalytic oxidation/non-dispersive infrared detection (NDIR) following EPA Method 9060A. Total carbon (TC) in the eluate is converted to carbon dioxide via oxidation or decomposition, carried by a zero-CO_2 air stream into the NDIR. For analysis of DIC, liquid samples are acidified with 2-molar hydrochloric acid to liberate carbonates and other forms of inorganic carbon from solution as carbon dioxide, which is sparged from the liquid sample into the NDIR by the zero-CO_2 carrier gas. DOC is determined by measuring the TC of a sample after purging of inorganic carbon. The instrument was calibrated using sodium hydrogen carbonate and potassium hydrogen phthalate over a 5-point calibration curve for DIC and DOC, respectively. The resultant analytical range was between 0.1 and 100 mg/L, with MDL and LLOQ values shown in Table 3-5. Checks on QA/QC at a frequency of every 10 analytical samples included calibration checks with a required recovery within 15% of the specific value, and method blanks with a requirement that the concentration was less than quantifiable limits.

Table 3-5
MDLs and LLOQs for Eluate Analysis for Carbon

Analyte	Symbol	MDL (mg/L)	LLOQ (mg/L)
Inorganic carbon	DIC	0.15	0.5
Organic carbon	DOC	0.18	0.5

Subsurface Gas Analysis

The composition of subsurface gas was monitored monthly from June 2019 through January 2020. Subsurface gas was monitored for oxygen (O_2), carbon dioxide (CO_2), methane (CH_4), ammonia (NH_3), and hydrogen sulfide (H_2S) using a Ventis Pro 5 meter (Figure 3-3a) rented monthly from Industrial Scientific, Pittsburgh, PA. Table 3-6 shows the measurement units and calibration ranges for the five gases. To avoid any moisture from subsurface gas fouling the vacuum pump, the subsurface gas was drawn through a 250-mL syringe filled with desiccant (Figure 3-3b).

a) b)

Figure 3-3
Subsurface gas monitoring apparatus: a) Ventis Pro 5 meter and b) connected tubing and desiccant syringe

Table 3-6
Calibration Ranges for Subsurface Gas Monitoring

Analyte	Symbol	Units	Calibration Range	
Ammonia	NH_3	ppm	0	500
Hydrogen sulfide	H_2S	ppm	0	500
Carbon dioxide	CO_2	%	0	5
Methane	CH_4	%	0	5
Oxygen	O_2	%	0	30

Data Management with LeachXS™

Laboratory and analytical information for leaching tests was recorded by the laboratory technician in Microsoft Excel® spreadsheets specifically designed for each test for use as templates for data collection and archiving. Analytical data documenting concentrations of constituents from each leaching test were entered into the same spreadsheets. These data templates were used as the interface for loading laboratory and analytical data into LeachXS™ (VU, 2019), a database-driven data management and reporting software program. LeachXS was used to (i) archive the laboratory and analytical data from leaching tests; (ii) compare test results between composite materials (e.g., VC-1, VC-2, VC-3, or VC-4) and between test types (e.g., TCLP, SPLP, ASTM, and LEAF); and (iii) generate the Excel plots used for this report. These data have also been added to EPRI's CPInfo database.

4
PHYSICAL AND HYDRAULIC PROPERTIES

Physical properties of the fly ash samples used for measurement of hydraulic properties are summarized in Table 4-1, composition of the solids is summarized in Table 4-2, and the hydraulic conductivities are summarized in Table 4-3.

Particle size distributions of the coal ash samples are shown in Figure 4-1. All of the ashes contained a broad range of particle sizes ranging from coarse-to-fine sand, silt, and clay-size (<2 μm) particles. Fines is the predominant fraction for all of the samples. Each has a broadly graded particle size distribution. The fines content (i.e., particles finer than 75 μm) ranges from 61.5% to 96.8%, and the clay-size (i.e., finer than 2 μm) ranges from 7.0% to 19.4%. No particles coarser than sand-size were observed.

Table 4-1
Physical Properties of Coal Ash Samples Used for Hydraulic Conductivity Testing

Sample ID	Sample Elevation at Top (ft AMSL)	Sample Elevation at Bottom (ft AMSL)	Water Content (%)	Dry Unit Weight (kg/m^3)	Pore L/S of Intact Cores (L/kg-dry)	Particle Size Fractions			
						% Gravel	% Sand	% Fines	% Clay
CDL-VC2-65	374.9	371.9	39.5	1,090	0.36	0	12.1	87.9	13.1
CDL-VC2-75	364.9	361.9	35.4	1,110	0.32	0	38.5	61.5	7.3
CDL-VC3-65	378.2	375.2	35.7	1,390	0.26	0	3.2	96.8	14.3
CDL-VC3-75	368.2	365.2	41.5	1,150	0.36	0	7.8	92.2	7.0
CDL-VC4-65	378.2	375.2	39.8	1,150	0.35	0	23.3	76.7	19.4
CDL-VC4-75	368.2	365.2	36.6	1,290	0.28	0	6.2	93.8	11.6

An estimate of the pore L/S ratio of intact cores was made from the water content and the dry unit density assuming a fully saturated 1 m^3 volume of ash:

$$L/S = \frac{WC/100}{\rho_{dry}} \times 1000$$

where L/S is the liquid-to-solid ratio for fully saturated pores (L/kg-dry);
WC is the water content (%) from Table 4-1;
ρ_{dry} is the dry unit density (kg-dry/m^3) from Table 4-1; and,
1000 is a unit conversion factor for volume (1000 L = 1 m^3).

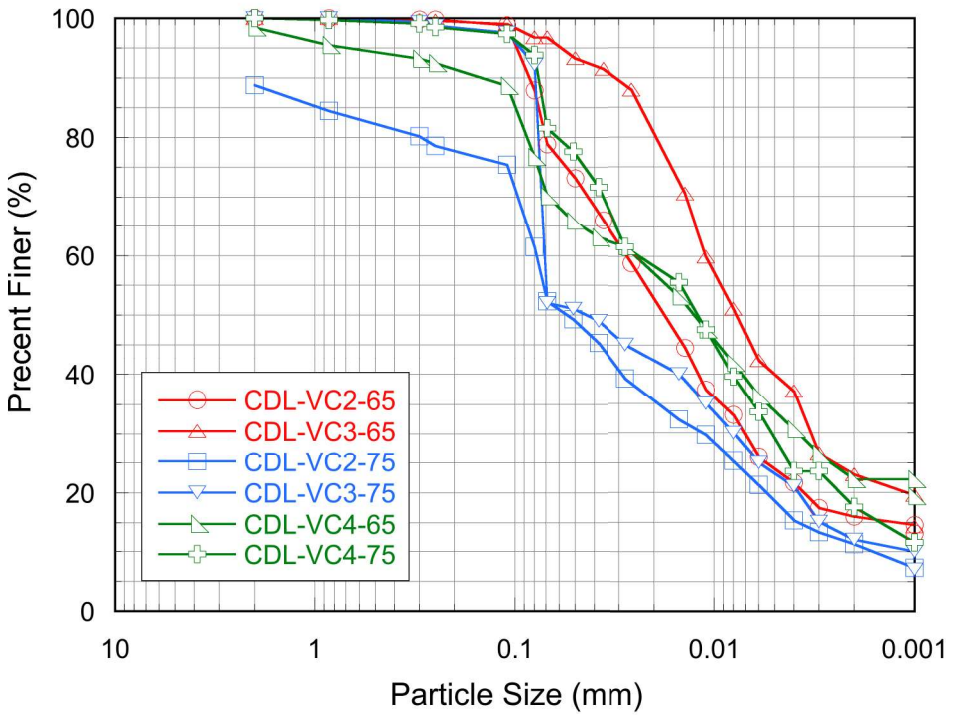

Figure 4-1
Particle size distribution of coal ash samples on which hydraulic conductivity tests were conducted

Table 4-2 indicates that all of the ash samples are predominantly composed of Al, Fe, and Si oxides, which reflects the predominant alumino-silicate mineral structure of the particulate. All samples contain modest amounts of Ca, K, and Ti. The LOI varies considerably, from 1.9% to 13.1%, with all but one sample having an LOI > 3.3%. The variability in composition of major elements appears to reflect the nature of the deposited ash as layers of fly ash and bottom ash.

Table 4-2
Composition of Solids (%) from LOI and XRF of Coal Ash Samples Used for Hydraulic Conductivity Assessment (elements exceeding 1.0%). Measurements were not conducted for CDL-VC3-65.

Composition	VC-2		VC-3		VC-4	
	65	75	65	75	65	75
LOI	2.0	2.7	-	1.9	13.1	3.3
Al_2O_3	15.8	16.1	-	17.2	15.6	17.5
CaO	7.9	8.9	-	6.6	8.4	5.3
Fe_2O_3	32.6	29.0	-	27.5	32.6	31.0
K_2O	3.7	4.2	-	4.5	3.7	4.0
SiO_2	35.2	36.4	-	39.2	34.6	37.3
TiO_2	1.3	1.3	-	1.4	1.2	1.4

The hydraulic conductivities fall into two groups (Table 4-3): more permeable samples (CDL-VC2-65, CDL-VC2-75, and CDL-VC3-75) and less permeable samples (CDL-VC3-65, CDL-VC4-65, and CDL-VC4-75). The more permeable ashes have hydraulic conductivities in the range of 10^{-5} cm/s, whereas the less permeable ashes have hydraulic conductivities in the range

of 10^{-6} cm/s. The differences in hydraulic conductivity between these groups cannot be attributed to particle size characteristics such as fines content or 2 -μm clay content (Figure 4-2). However, the less permeable ashes have higher dry density, and therefore lower void ratio (Figure 4-3).

Table 4-3
Hydraulic Conductivity of Coal Ash Samples

Sample ID	Effective Stress (kPa)	Hydraulic Conductivity (cm/s)
CDL-VC2-65	20	4.18×10^{-5}
	100	2.40×10^{-5}
	250	2.02×10^{-5}
	400	1.82×10^{-5}
	500	1.81×10^{-5}
CDL-VC2-75	20	2.43×10^{-5}
	100	1.90×10^{-5}
CDL-VC3-65	20	8.28×10^{-6}
	100	6.22×10^{-6}
	250	4.83×10^{-6}
	400	4.32×10^{-6}
	500	3.75×10^{-6}
CDL-VC3-75	20	1.54×10^{-5}
	100	1.26×10^{-5}
	250	1.09×10^{-5}
	400	8.15×10^{-6}
CDL-VC4-65	20	4.98×10^{-6}
	100	4.47×10^{-6}
CDL-VC4-75	20	2.07×10^{-6}
	100	1.96×10^{-6}

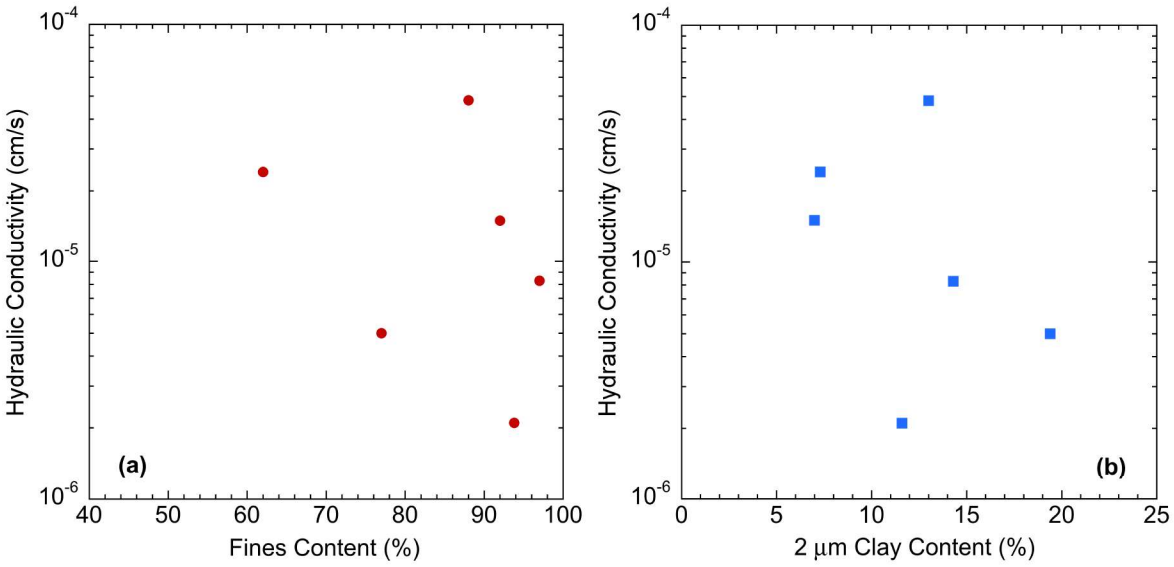

Figure 4-2
Hydraulic conductivity of coal ashes at 20 kPa effective stress as a function of (a) fines content and (b) 2-µm clay content

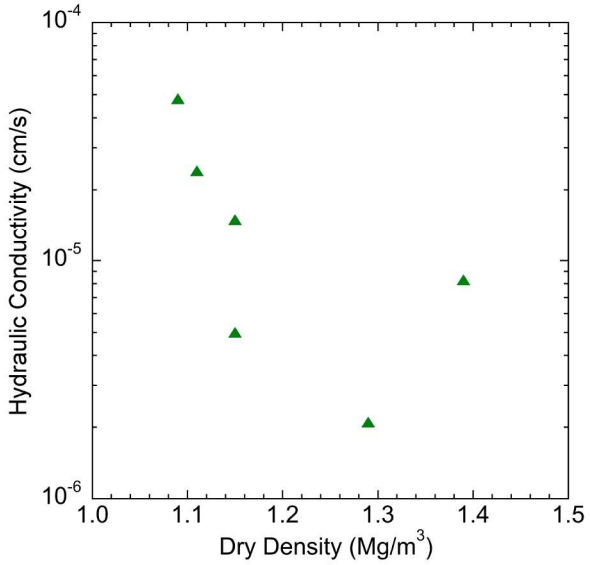

Figure 4-3
Hydraulic conductivity of coal ashes as a function of dry unit weight

Hydraulic conductivity of the coal ash samples as a function of confining stress is shown in Figure 4-4. The hydraulic conductivity diminishes only modestly with increasing stress, decreasing approximately by a factor of 2 as the effective stress is increased from 20 to 500 kPa. The insensitivity to stress is most likely due to the ash being predominantly comprised of silt-size and sand-size particles.

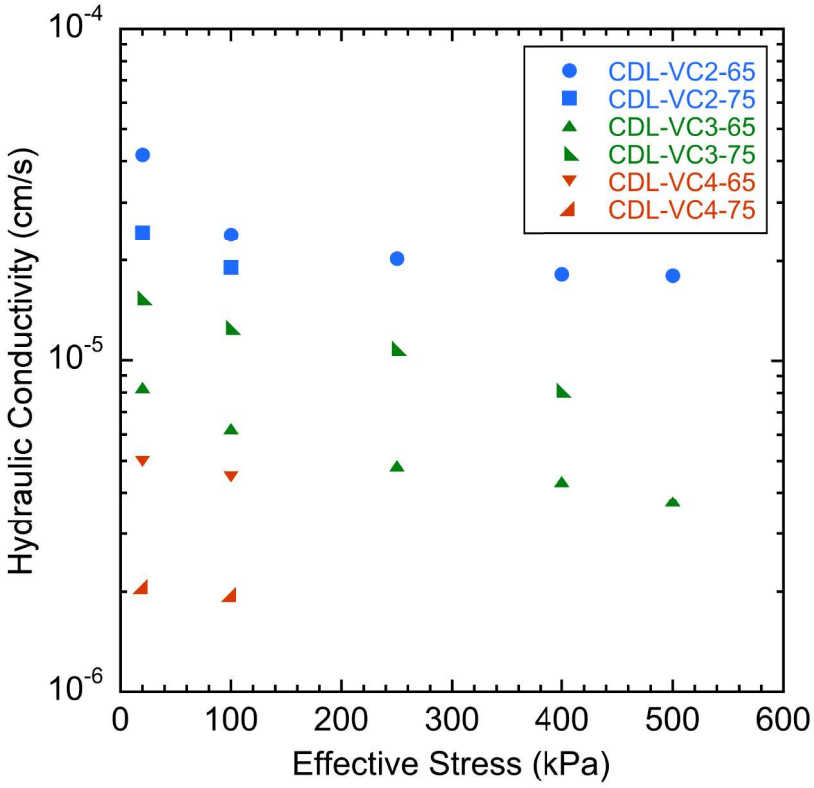

Figure 4-4
Hydraulic conductivity of coal ash samples as a function of effective stress

5
INDIVIDUAL SPLIT SPOON SAMPLE TESTING

Evaluation of Field Extractions (Low L/S and L/S ≈ 1)

During field sampling, grab samples of ash from each split spoon were extracted by centrifugation of the moisture content (i.e., Low L/S Field Extractions). Because the moisture content of the unsaturated split spoon material varied with depth and texture, a small amount of DIW was added to each extraction to ensure that a sufficient amount of liquid could be recovered and analyzed. The resultant L/S of Low L/S Field Extractions varied between 0.28 and 0.67 mL/g-dry, consistent with the L/S of porewater from intact core samples (Table 4-1).

Vertical Heterogeneity Within and Between Boreholes

Profile Plots of Field and Laboratory Extraction Data

After surveying of the borehole and PAP locations and elevations, depths BGS measured during sample recovery were converted to elevations ASML. The concentration from Low L/S Field Extractions of individual split spoon materials was plotted as a function of elevation to provide a visual indication of material heterogeneity with depth within a borehole. Examples of these borehole profile plots are presented in Figure 5-1 and Figure 5-2.

Each figure represents the concentration profiles for a measured constituent in the Low L/S Field Extractions for VC-1 (blue), VC-2 (green), VC-3 (orange), and VC-4 (purple). The constituent concentration is plotted along the x-axis, while the elevation for the center of the split spoon is plotted on the y-axis. The red horizontal line shows the surface elevation at the time of drilling. The 5-foot wide shaded area indicates the screening interval for the PAP in each borehole. The light-colored data points in each profile indicate the intervals from which material was taken to create the composite ash sample for each borehole used in detailed characterizations.

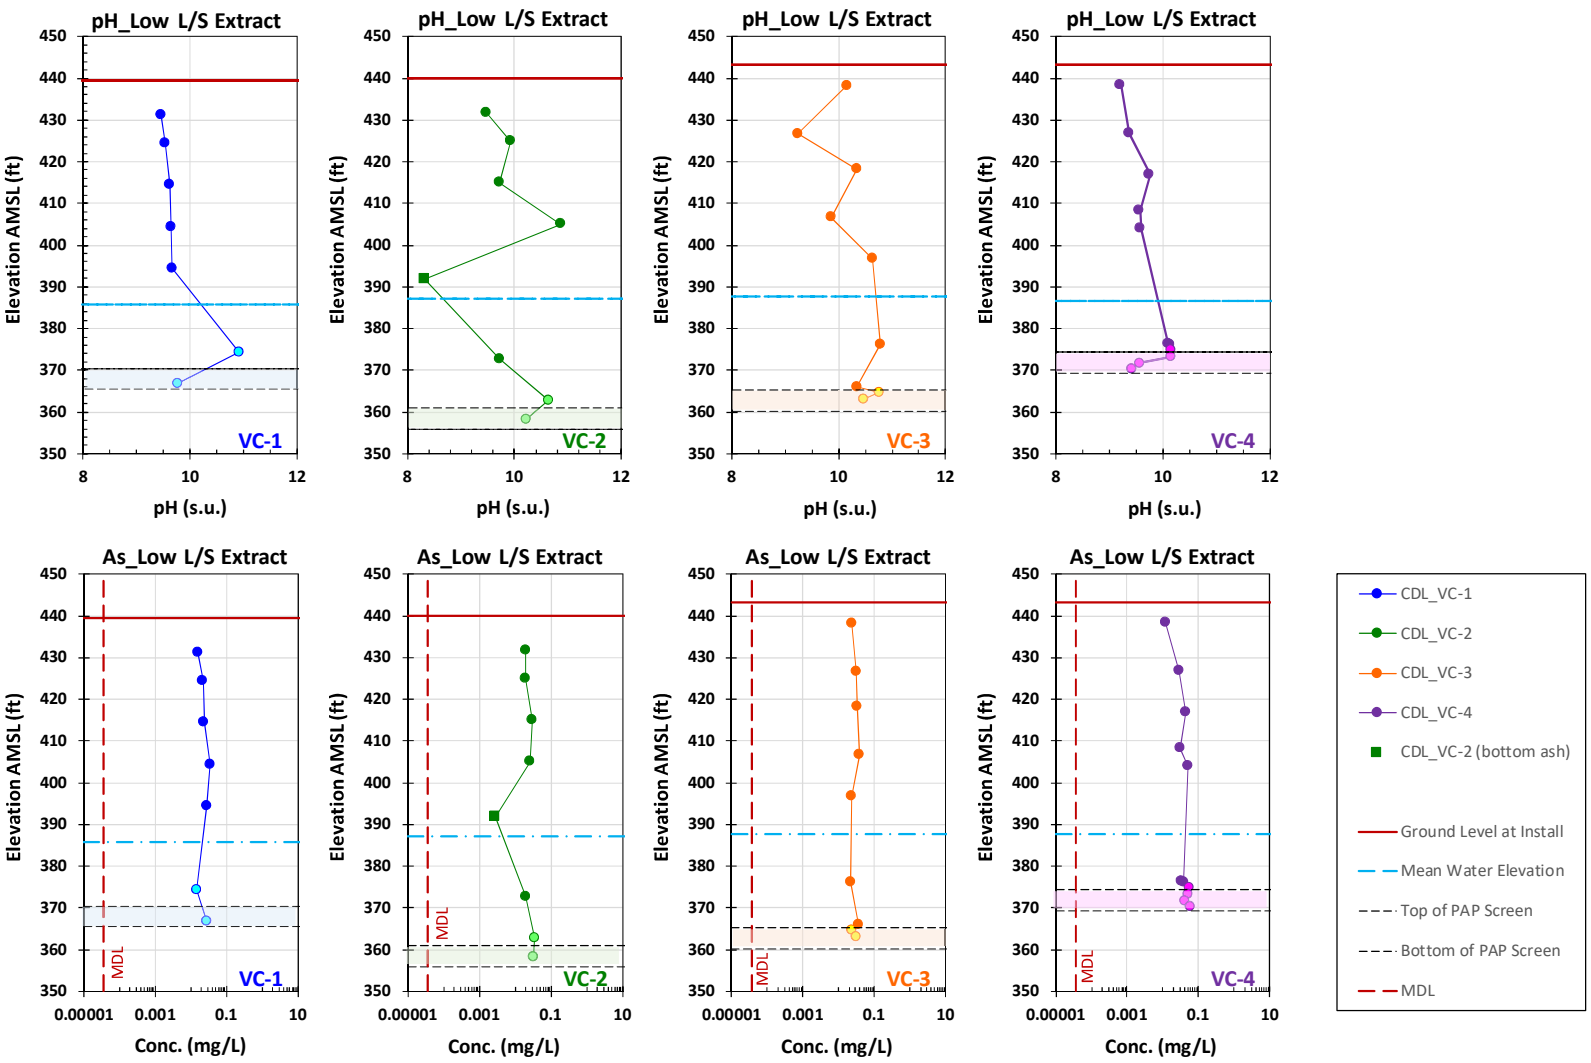

Figure 5-1
Low L/S Field Extraction concentration profiles within boreholes (VC-1, VC-2, VC-3, and VC-4): pH and arsenic; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL

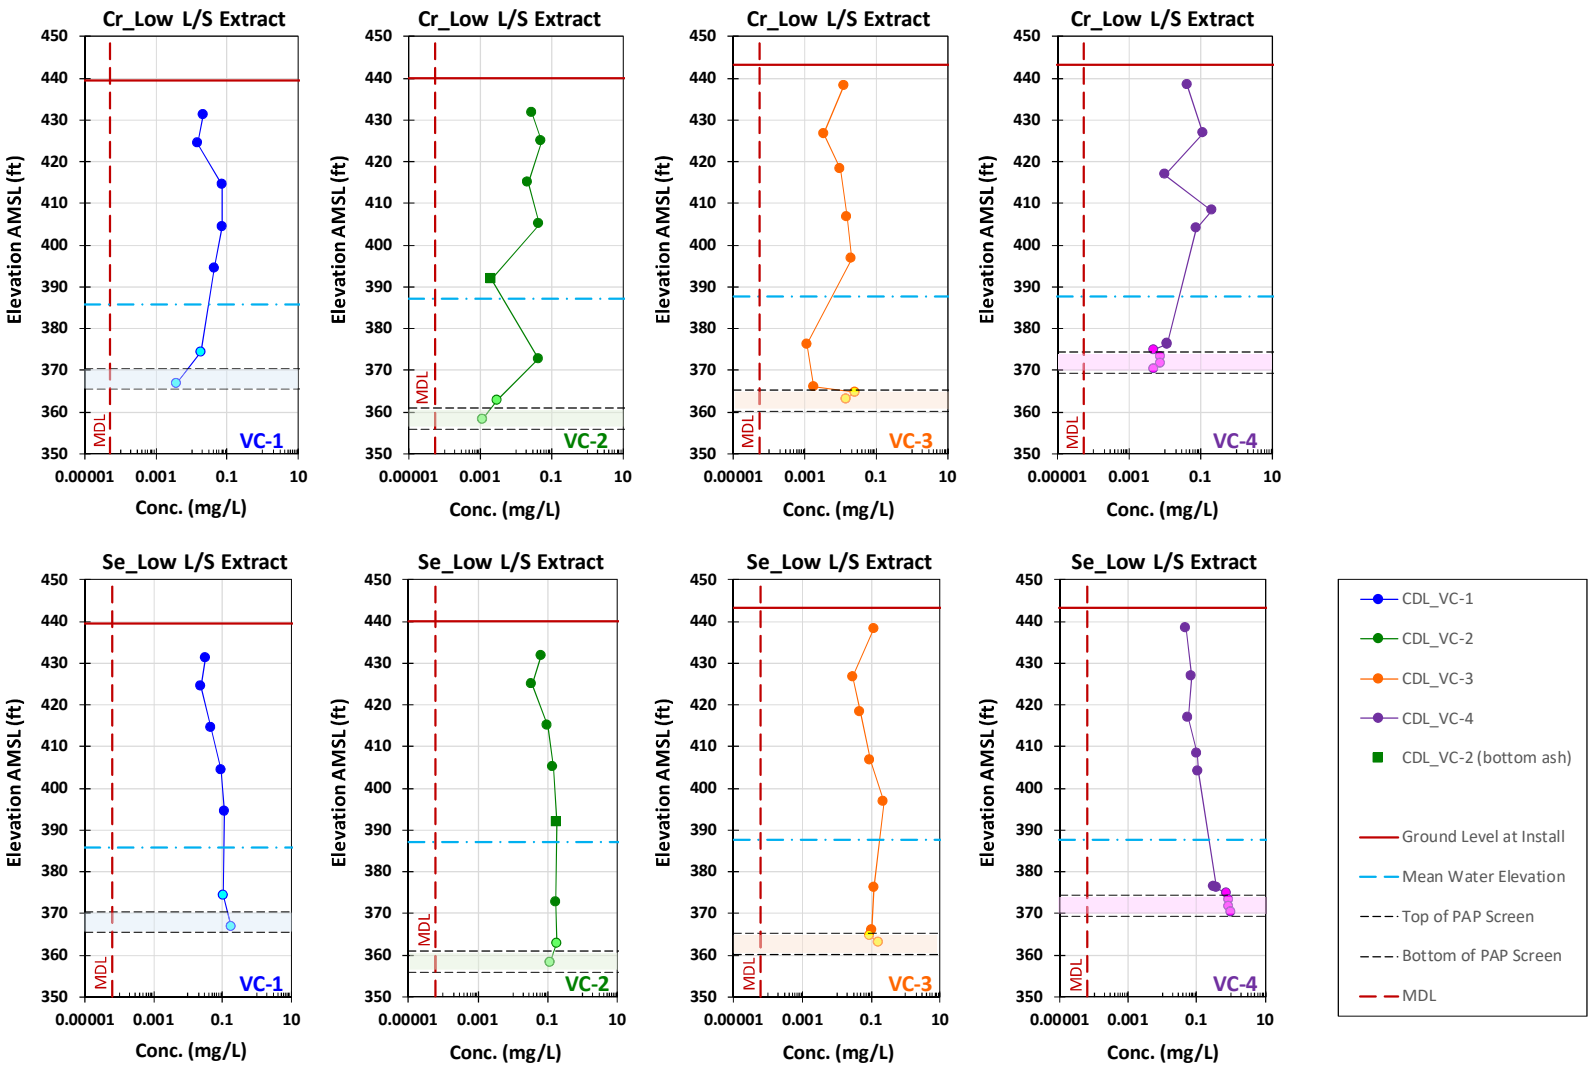

Figure 5-2
Low L/S Field Extraction concentration profiles within boreholes (VC-1, VC-2, VC-3, and VC-4): chromium and selenium; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL

Standardized Borehole Profiles of Low L/S Field Extractions

The concentration data for Low L/S Field Extractions were converted to standardized profile plots using the global mean and standard deviation for "known ash samples" in all boreholes as characterized by the geologist notes. The standardized concentration is calculated as:

$$\frac{x - \bar{x}}{s}$$

where x is the parameter (e.g., pH, concentration) from the extraction test,
$\bar{x}$ is the global mean of all "known ash samples" for all boreholes, and
s is the global standard deviation of all "known ash samples."

The global mean and standard deviation for all constituents are tabulated in Table 5-1. The standardized concentration provides a measure of the difference between the measured concentration and the mean as a number of standard deviations from the mean concentration. A homogenous material, for example, may have measurements within 2 standard deviations of the mean, while measurements greater than 4 standard deviations may have more than random variations such as influence from cover or underlying material. Justification for use of ash sample global statistics, rather than within-borehole statistics, was based on the results of t-test for pairwise comparisons assuming unequal variances, which showed no statistical difference in means between boreholes. In addition, the use of global statistics in standardized concentration profiles allows for comparison between boreholes on the same basis.

The standardized borehole profiles for the example constituents presented in Figure 5-1 and Figure 5-2 are presented in Figure 5-3 and Figure 5-4. The standardized profiles for all constituents are presented Appendix B-2. In general, the concentration profiles for most constituents are vertically consistent within the ash deposit and show no evidence of difference between the upper dry-handled coal ash and lower wet-handled coal ash.

Table 5-1
Global Mean and Standard Deviation of Laboratory Extractions (L/S=1) Concentrations

		Global "Ash" Statistics		
Analyte	**Units**	**Mean**	**Std. Dev**	**Coefficient of Variation**
Moisture Content	g_{H2O}/g	0.24	0.07	29%
EC	mS/cm	4.29	1.48	35%
pH	S.U.	9.96	0.49	4.9%
ORP	mV	78.4	23.3	30%
pH+pE	-	15.14	0.32	2.1%

Chromium	mg/L	0.31	0.04	13%
Cobalt	mg/L	0.0006	0.0002	33%
Copper	mg/L	0.011	0.001	9.1%
Iron	mg/L	0.01	0.02	200%
Lead	mg/L	ND	-	-
Lithium	mg/L	1.4	1.0	71%
Magnesium	mg/L	0.96	1.0	100%
Manganese	mg/L	0.0017	0.0011	65%
Molybdenum	mg/L	10.4	8.6	83%
Nickel	mg/L	0.0047	0.0012	26%
Phosphorus	mg/L	ND	-	-
Potassium	mg/L	300	88	29%
Selenium	mg/L	0.21	0.26	120%
Silicon	mg/L	4.1	2.2	54%
Silver	mg/L	ND	-	-
Sodium	mg/L	280	130	46%
Strontium	mg/L	3.2	2.0	63%
Sulfur	mg/L	590	280	48%
Thallium	mg/L	0.02	0.02	100%
Vanadium	mg/L	1.8	1.1	61%
Zinc	mg/L	0.01	0.01	100%

Notes: ND = all or most of the L/S=1 concentrations were less than the MDL

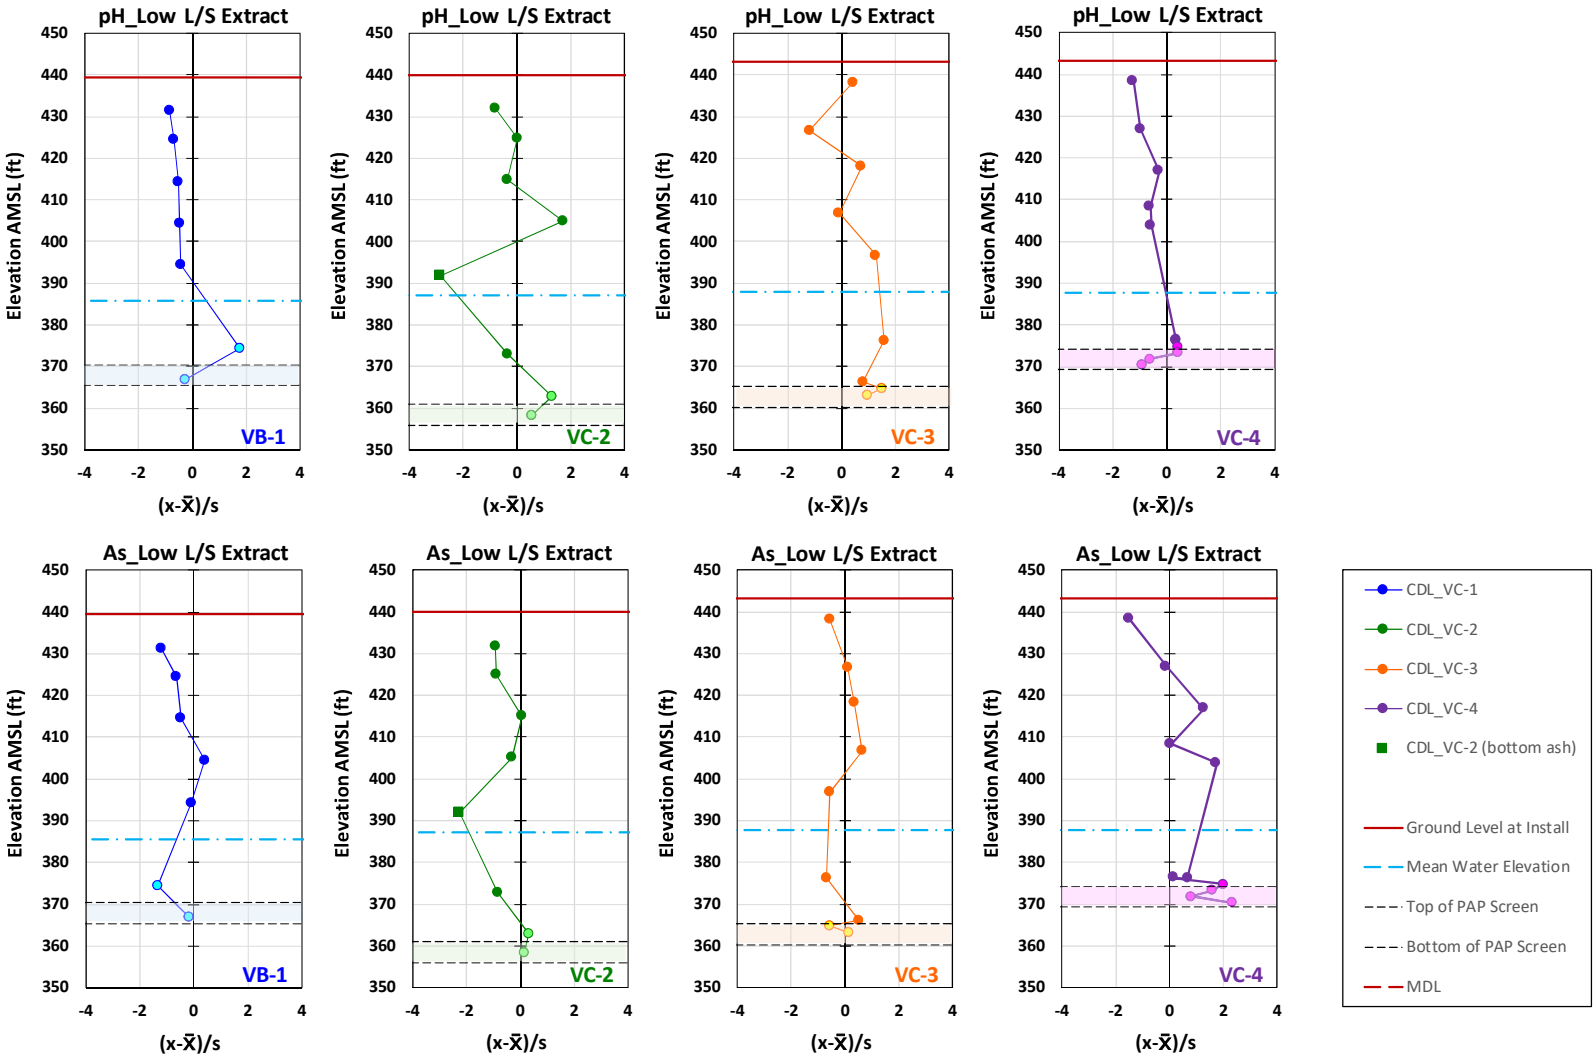

Figure 5-3
Standardized Low L/S Field Extraction profiles within boreholes (VC-1, VC-2, VC-3, and VC-4) standardized to the global mean (X̄) and standard deviation (s) of known ash samples: pH and arsenic; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL

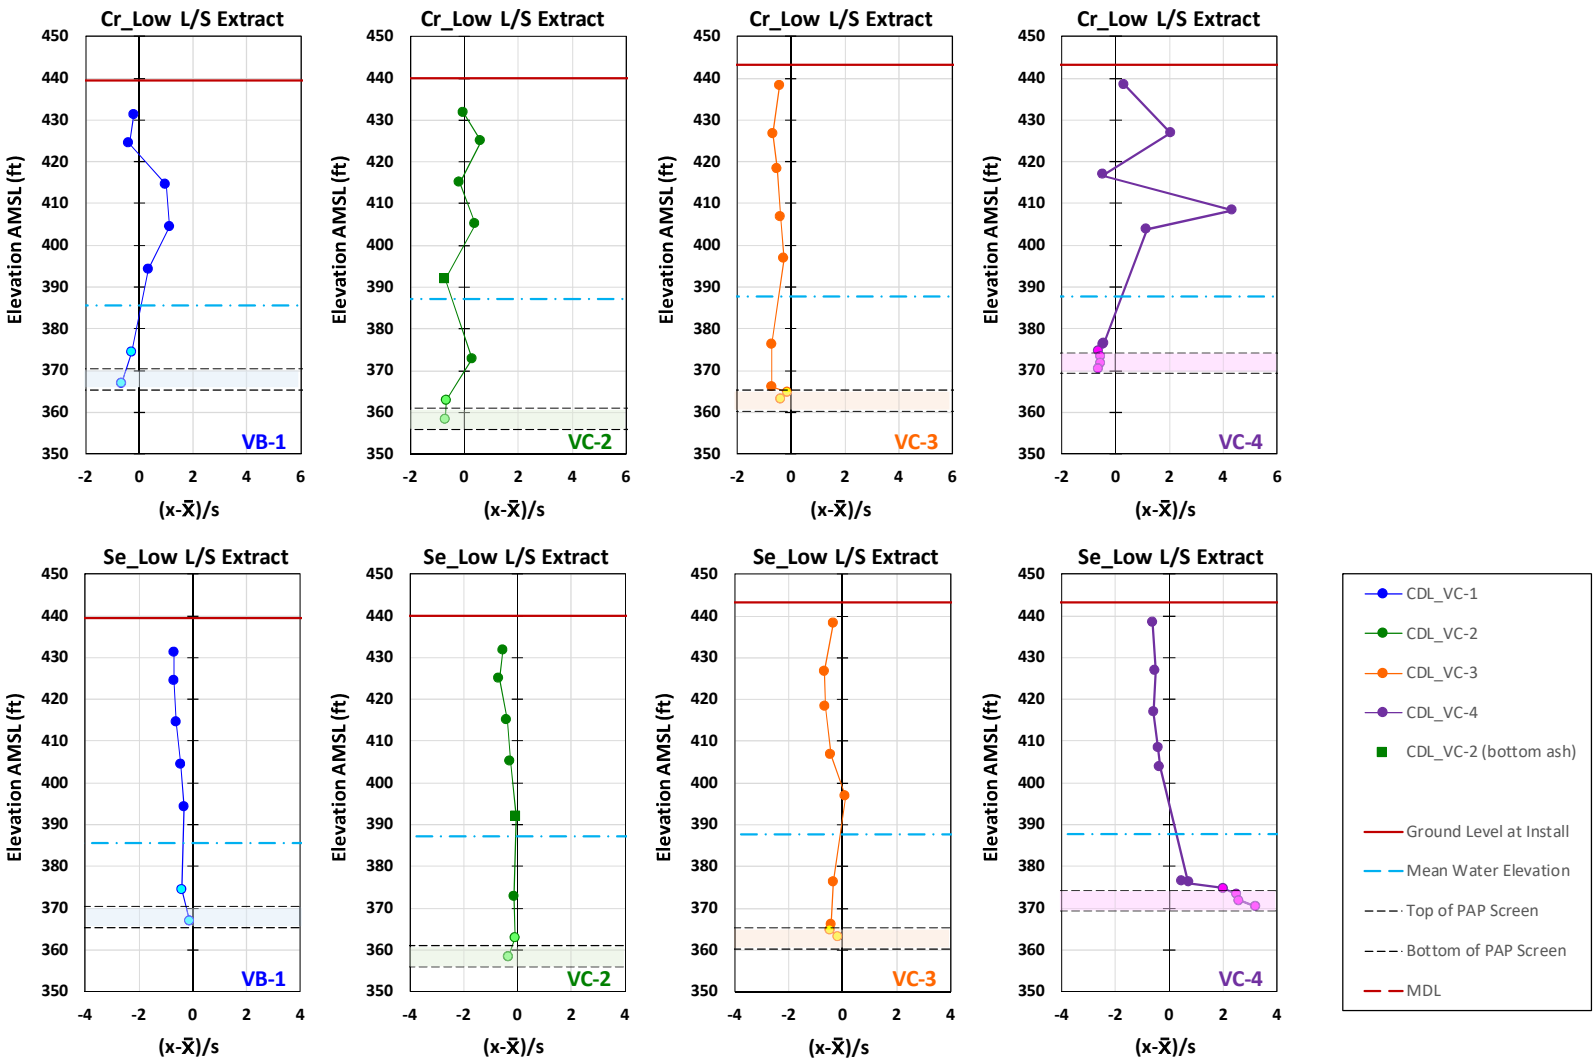

Figure 5-4
Standardized Low L/S Field Extraction profiles within boreholes (VC-1, VC-2, VC-3, and VC-4) standardized to the global mean (x̄) and standard deviation (s) of known ash samples: chromium and selenium; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL

Comparison of Standardized Borehole Profiles for Low L/S and L/S≈1 Field Extractions Based on Mass Release (mg/kg)

For boreholes VC-1 and VC-2, L/S≈1 Field Extractions were conducted as a comparator to the unique Low L/S Field Extractions. Example comparisons of standardized borehole variability graphs are presented in Figure 5-5 and Figure 5-6, while the complete results for all measured constituents are presented in Appendix B-3. In general, the variability between field extraction methods is negligible; however, the unique Low L/S Field Extraction technique provided data that are somewhat less variable than the L/S≈1 Field Extractions. The Low L/S extractions are considered to provide better control of redox conditions and L/S values that are more consistent with porewater values.

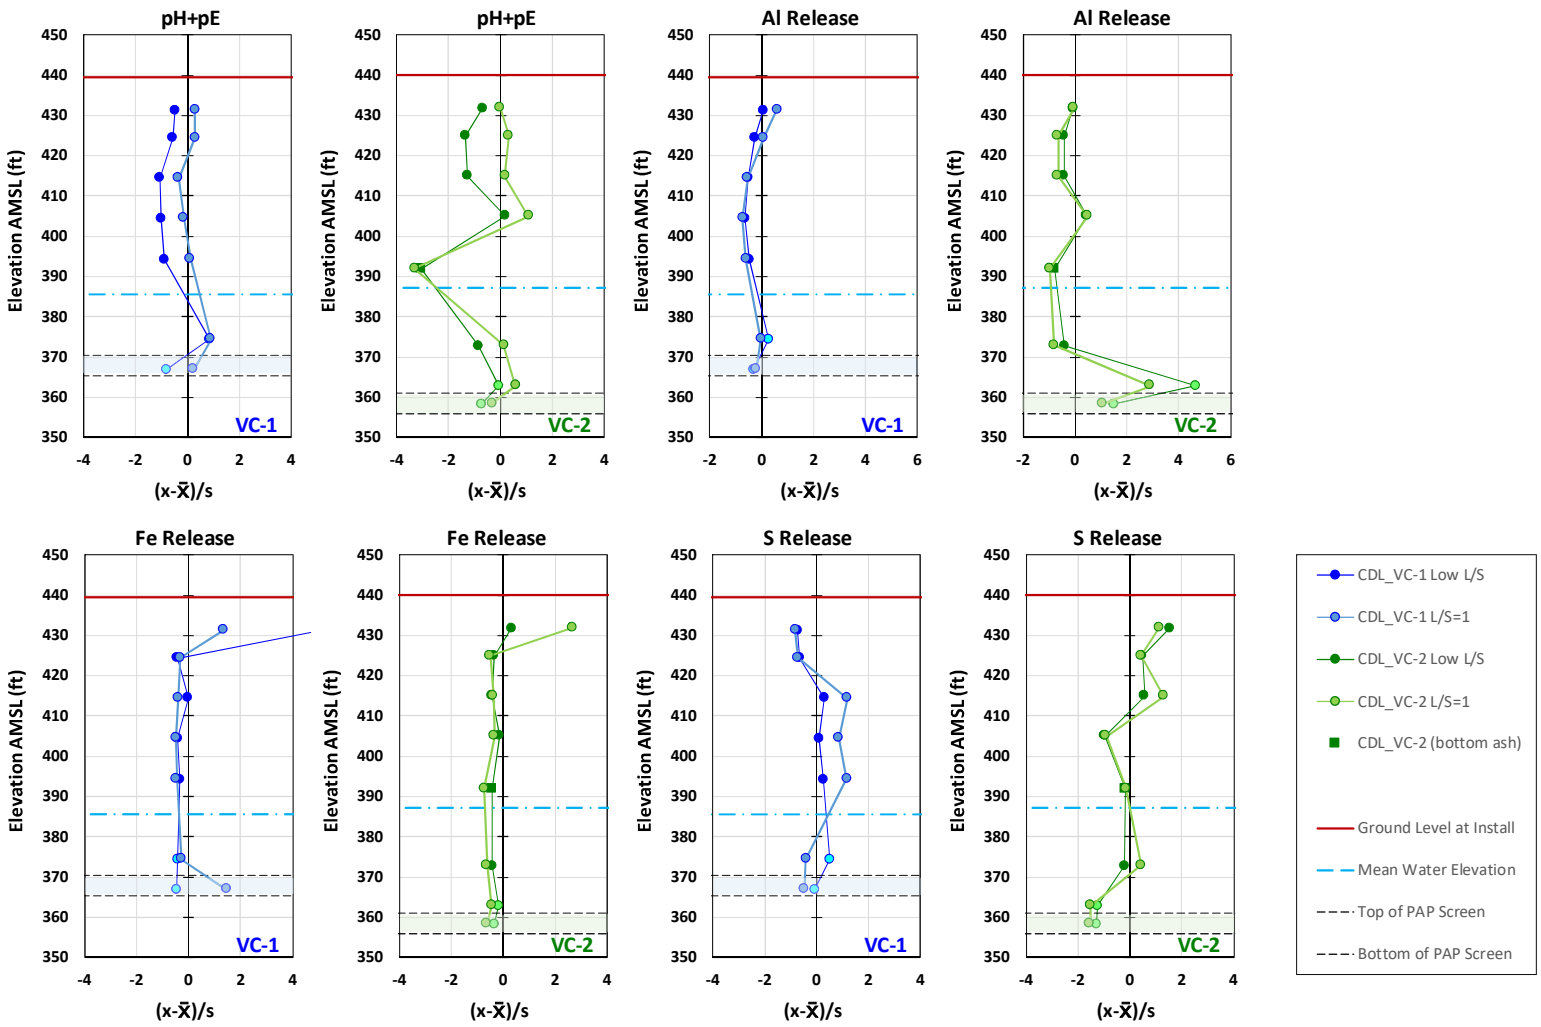

Figure 5-5
Comparison of standardized mass release profiles for Low L/S Field Extractions and L/S ≈ 1 Field Extractions of major constituents from VC-1 and VC-2: pH+pE, aluminum, iron, and sulfur; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL

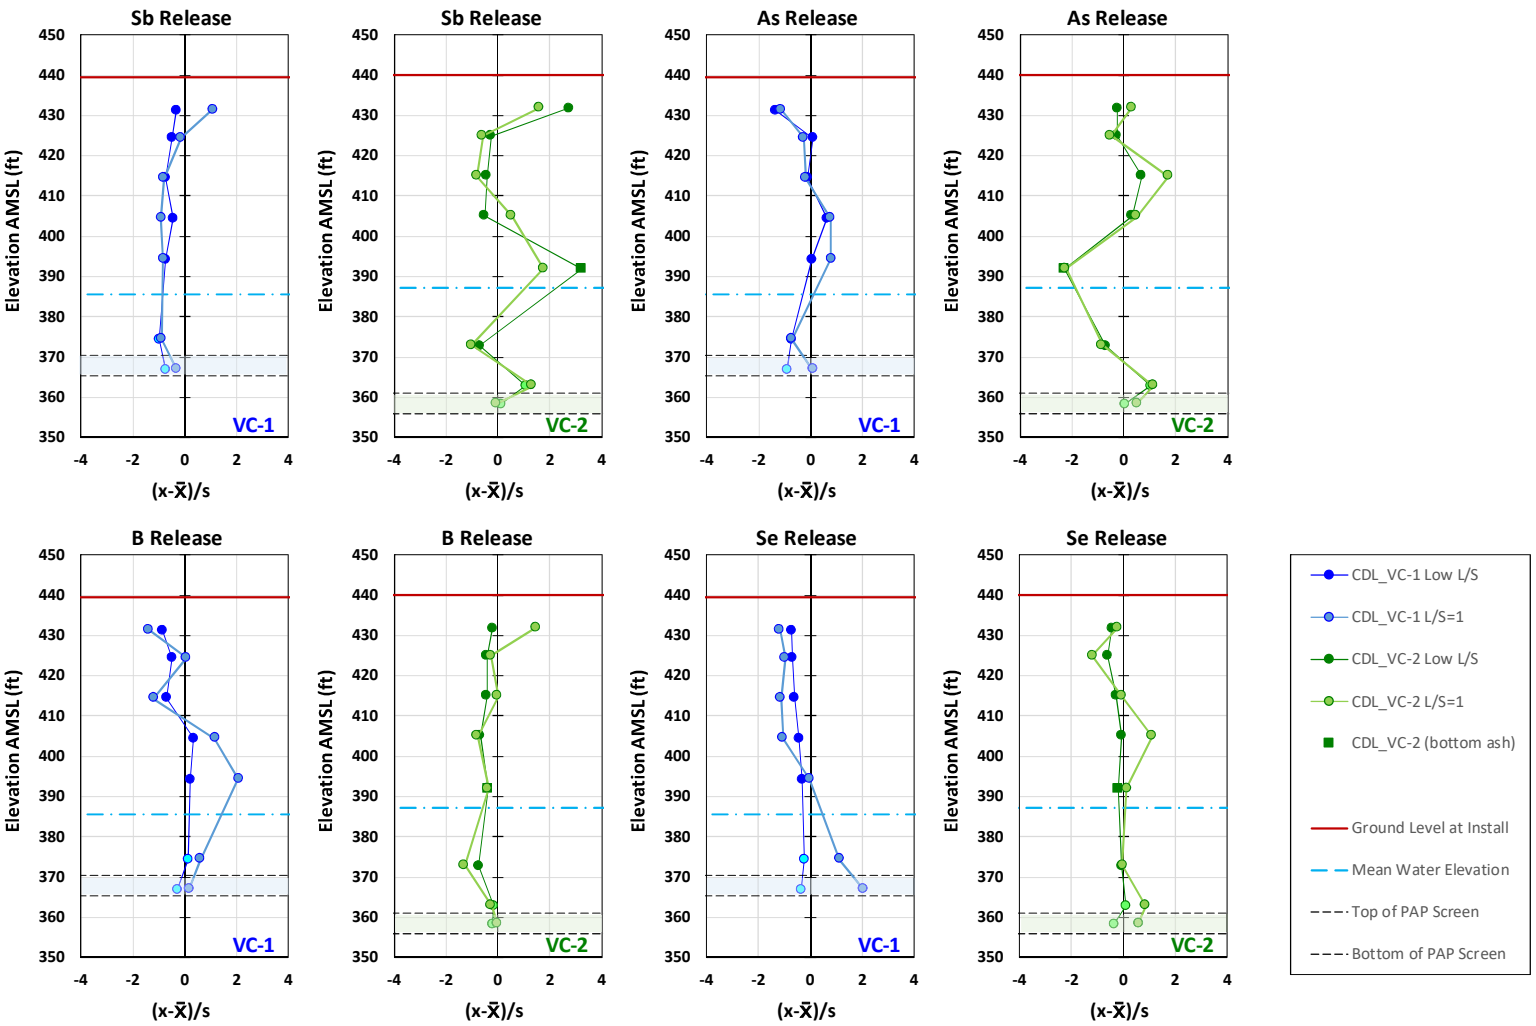

Figure 5-6
Comparison of standardized mass release profiles for Low L/S Field Extractions and L/S ≈ 1 Field Extractions of trace constituents from VC-1 and VC-2: antimony, arsenic, boron, and selenium; interface between dry- and wet-handled ash occurs at approximately 390 ft AMSL.

6
COMPOSITE ASH SAMPLE TEST RESULTS

Subsamples of bulk material collected from split spoon sampling were homogenized within each bulk storage packet. For borehole composites, the material in the storage packets around the PAP screening intervals was composited by equal dry mass from each packet as shown in Table 3-1. These composites of wet-handled ash were labeled for their respective borehole locations (i.e., VC-1 through VC-4). An additional site-wide composite of unsaturated material, labeled as "Dry," was created by equal mass from split spoon samples from dry-handled material in all boreholes collected above the water table. The five composites were subject to detailed investigation of total content, available content, and leaching characteristics as a function of pH and L/S.

Total Content

The total content analysis results for the five composite materials are shown in Table 6-1.[3] In preparation for EPA Method 3052, ash samples were dried under nitrogen and ground to pass a No. 100 (150 μm) sieve. Therefore, the total content results are reported on a dry-mass basis (mg/kg-dry), whereas typical EPA Method 3052 results would be based on "as received" solid sample (mg/kg), which can include the inherent moisture in the solid sample.

The coal ash composites are comprised mainly of Al, Ca, Fe, K, Na, and Si (not measured). Of the 26 constituents analyzed, Sb, Co, Mg, Mn, Hg, Ag, and Tl were reported for at least one of the five composites to have low total content relative to the commercial laboratory's reporting limit. Mercury was detected above reporting limit only in the "Dry" composite and, therefore, was not considered in the analysis of test leachates or the comparison to groundwater concentrations. The remaining low-concentration constituents were retained because preliminary testing indicated that leaching concentrations were low, but quantifiable in LEAF leaching tests.

For most elements analyzed (16 of 26), the dry-handled ash composite had a total content value within the range of values for the wet-handled composites. Only Pb, Hg, and Mo had a total content a factor of 1.5 or more higher than the highest wet-handled composite value within the range, while Cd, Li, Sr, and Zn had total contents slightly higher (within a factor of 1.0 to 1.5) than the highest wet-handled value. Total content values for Mn, K, and Na were slightly lower than the lowest wet-handled total content value.

[3] As noted in the test description in Section 3, boron was not analyzed for total content because metaborate is added to the digestion process for Method 3052.

Table 6-1
Total Contents for Composite Samples (VC-1, VC-2, VC-3, VC-4, and Dry) Based on EPA Method 3052

Analyte	Symbol	MDL (mg/kg)	VC-1 (mg/kg)	VC-2 (mg/kg)	VC-3 (mg/kg)	VC-4 (mg/kg)	Dry (mg/kg)
Aluminum	Al	2.9	21,000	17,000	27,000	18,000	27,000
Antimony	Sb	1.9	6.2	4.5 J	5.0 J	7.7	7.4
Arsenic	As	1.3	51	63	48	94	54
Barium	Ba	0.22	370	480	820	390	360
Beryllium	Be	0.014	11	7.9	5.9	13	9.5
Cadmium	Cd	0.74	4.4	3.5	5.1	3.8	6.0
Calcium	Ca	10	13,000	9,400	24,000	9,300	21,000
Chromium	Cr	0.13	170	140	130	180	160

Lead	Pb	1.0	62	70	67	74	160
Lithium	Li	0.27	68	55	50	66	71
Magnesium	Mg	3.4	340 J	430 J	610	300 J	490 F1
Manganese	Mn	0.10	380 B	390 B	430 B	330 B	280 B
Mercury	Hg	0.058	ND	ND	ND	0.058 J	0.46
Molybdenum	Mo	0.15	27	26	18	37	62
Nickel	Ni	2.1	130	93	89	160	120
Potassium	K	240	12,000	16,000	14,000	12,000	11,000
Selenium	Se	1.6	14	10	9.3	17	16
Silver	Ag	0.10	1.2 J	1.0 J	0.93 J	1.3 J	1.1 J
Sodium	Na	240	5,400	5,200	4,900	5,100	3,800
Strontium	Sr	0.054	68	57	67	95	130 F1
Thallium	Tl	9.3	13 J	14 J	9.7 J	14 J	9.4 J
Vanadium	V	0.056	670	450	480	660	620
Zinc	Zn	4.6	410	430	410	420	460

Notes:
B the compound was found in the blank and sample.
F1 the matrix spike recovery is outside of acceptance limits
J the result is less than the reporting limit but greater than or equal to the MDL; estimated concentration.
ND the compound was not detected at a concentration above the MDL.

Leaching Test Results

For this project, leaching test results included LEAF test results (EPA 1313, 1313_L/S=1, EPA 1314) and traditional leaching tests (TCLP, SPLP, ASTM). All leaching data are presented in Appendix C for each composite sample as a function of pH and L/S. The graphs used in the following discussion of leaching test results were derived from the appendix figures either by combining data series (e.g., comparisons between composites) or by limiting axis domains. In

some cases, discussion graphs are presented as graphs of mass release (mg/kg-dry), which were derived from eluate concentrations (mg/L) multiplied by the associated L/S value (L/kg-dry). Mass release graphs are not presented in the appendix.

pH-Dependent Leaching Tests (EPA 1313, 1313_L/S=1)

Titration Curves

Titration curves from pH-dependent tests conducted on composite samples are presented in Figure 6-1. The titration curve indicates the amount of acid or base (shown as acid additions less than zero) required to provide a specific eluate pH, sometimes referred to as the acid/base neutralization capacity of the material. This data may be useful when leachates or materials from other processes or natural environments are introduced to a storage facility (e.g., pyritic tailings co-disposed with fly ash).

In LEAF nomenclature, the pH response when no acid or base is added to the extraction at an L/S of 10 mL/g-dry is referred to as the "natural pH" of the material. Because the natural pH is defined at an L/S of 10 mL/g, the term "own pH" will be used to differentiate the pH response at other L/S values (e.g., 1313_L/S=1) from the natural pH. The natural pH (EPA 1313) and own pH (1313_L/S=1) are tabulated for the five composite materials in Table 6-2 and represented in Figure 6-1 as large color-coded circles about a data point. The values for natural pH for the five composites are generally the same (average value of 10.41±0.18). The composite of the unsaturated ash (Dry) is the least alkaline (pH_{nat}=10.21), but not much more so than the composite of saturated ash at VC-2 (pH_{nat}=10.29). The most alkaline composite is the saturated ash composite at VB-3 (pH_{nat}=10.67). In comparison to natural pH, the own pH values are essentially the same as their associated natural pH values (within approximately 0.2 standard units).

Table 6-2
Natural pH (EPA 1313) and own pH (1313_L/S=1) of composite samples

	Method	L/S (mL/g-dry)	VC-1 pH (SU)	VC-2 pH (SU)	VC-3 pH (SU)	VC-4 pH (SU)	Dry pH (SU)
Natural pH	EPA 1313	10	10.44	10.29	10.67	10.43	10.21
Own pH	1313_L/S=1	1	10.66	10.64	10.71	10.29	10.01

Titration curves from EPA 1313 test results from five composite samples (VC-1, VC-2, VC-3, VC-4, and Dry)

Constituent Concentrations

The concentration of a constituent in each eluate of a pH-dependent leaching test (i.e., EPA 1313 and 1313_L/S=1) is indicative of the speciation of the constituent and the LSP in equilibrium with the L/S, pH, EC, and ORP of the contacting fluid. Eluate concentrations are typically plotted as a function of eluate pH to indicate how LSP changes over a broad range of pH values. These data also can be used to parameterize controlling mineral sets in geochemical speciation models, for example, LeachXS™/ORCHESTRA (Meeussen, 2015), to create a source term for

fate and transport modeling. The pH-dependent leaching behavior of a constituent is useful when disposed materials may be contacted with water containing significant amounts of acid or base (e.g., pyrite-impacted groundwater or alkali process wastewaters).

However, for many field assessments, evaluation of LSP may be limited to an applicable pH domain. The applicable pH domain is typically centered about the natural pH of the material but should consider the potential for leachate pH values to shift with aging or external influences (EPA, 2019). For example, alkaline materials that may be exposed to the environment can carbonate, which neutralizes the pH toward the equilibrium pH of calcium carbonate (pH ~ 8.2). Therefore, an applicable pH domain that is inclusive of critical pH values and is based on target eluate pH values from EPA 1313 would be $8 \leq pH \leq 12$. Example test results from EPA 1313 are shown in Figure 6-2 with the applicable pH domain shaded. These examples show that LSP behavior can vary significantly between constituents (e.g., boron vs. lead) but that the behavior for a constituent is very consistent between composite samples. The concentrations within the applicable pH domain are often, but not always, considerably lower than the maximum concentration over the entire EPA 1313 test pH range.

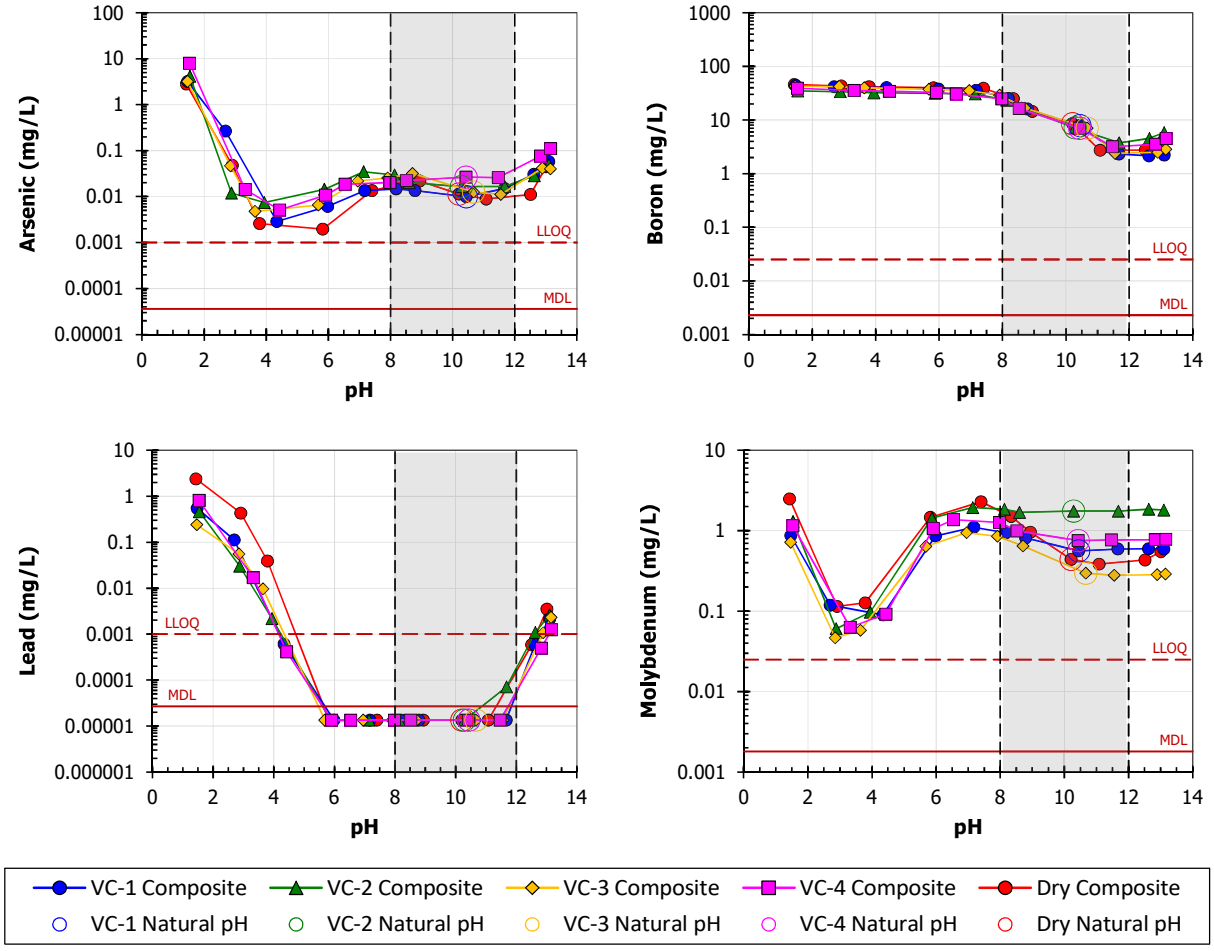

Figure 6-2
Example LSP behaviors from composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) showing applicable pH range ($8 \leq pH \leq 12$) for alkaline materials

Available Content Determination Using EPA 1313

The broad pH range of data provided by EPA 1313 data allows for evaluation of content of leachable constituent, known as the available content (EPA, 2019). The standard EPA methodology (EPA, 2019) for determination of available content is to identify the maximum leaching concentration (mg/L) from EPA 1313 test results at pH value of 2, 9, and 13 and calculate the mass release (mg/kg-dry) at the maximum LSP concentration:

$$AC = C_{1313(\max pH\ 2,9,13)} \cdot (L/S)_{1313}$$

where AC is the available content (mg/kg-dry);
$C_{1313(\max pH\ 2,9,13)}$ is the maximum concentration from EPA 1313 data at pH 2, 9, or 13 (mg/kg-dry); and,
$(L/S)_{1313}$ is the liquid-to-solid ratio for the EPA 1313 extractions of 10 mL/g-dry (10 L/kg-dry).

Values for the available content of constituents for the five composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) are reported in Table 6-3. The ratio of the available content to the total content (Table 6-4) indicates that for most constituents only a fraction (< 20%) is leachable over a broad pH range. In some cases, the available fraction is less than 1% of the total content. In Table 6-4, the high ratios (> 1) for Ca and Mg suggest either that digestion by EPA 3052 was not complete or that there is inherent error associated with multiplying a relatively small digestate concentration by a large effective L/S of 500 or more.

Table 6-3
Available Content for Composite Samples VC-1, VC-2, VC-3, VC-4, and Dry Based on the Maximum Concentration from EPA Method 1313

Analyte	Symbol	VC-1 (mg/kg-dry)	VC-2 (mg/kg-dry)	VC-3 (mg/kg-dry)	VC-4 (mg/kg-dry)	Dry (mg/kg-dry)

Vanadium	V	0.28	0.31	0.28	0.29	0.24
Zinc	Zn	0.024	0.019	0.031	0.022	0.041

Notes: B the compound was found in the blank and sample of the total content analysis extract.
F1 the matrix spike recovery for the total content analysis extract is outside of acceptance limits.
J the total content result is less than the LLOQ but greater than or equal to the MDL; estimated value.

Alternatively, the available content may be presented graphically as the maximum mass release from EPA 1313 data (Figure 6-3). These figures show that the maximum release for many constituents is often determined at pH $\leq$ 2, but that mass release may be similar at other pH values (see Mo). These figures also show that the absolute value determined for the available content may be dependent on the pH value used to determine the maximum concentration from EPA 1313. For example, the maximum mass release values for arsenic and boron are determined at a pH $\leq$ 2; however, the boron data plateaus in the acidic range, while the arsenic data is still on a steep increasing slope as pH decreases. Therefore, a minor change in the EPA 1313 eluate pH

will not significantly impact the available content determination for boron, while the same minor change may significantly alter the determined available content for arsenic.

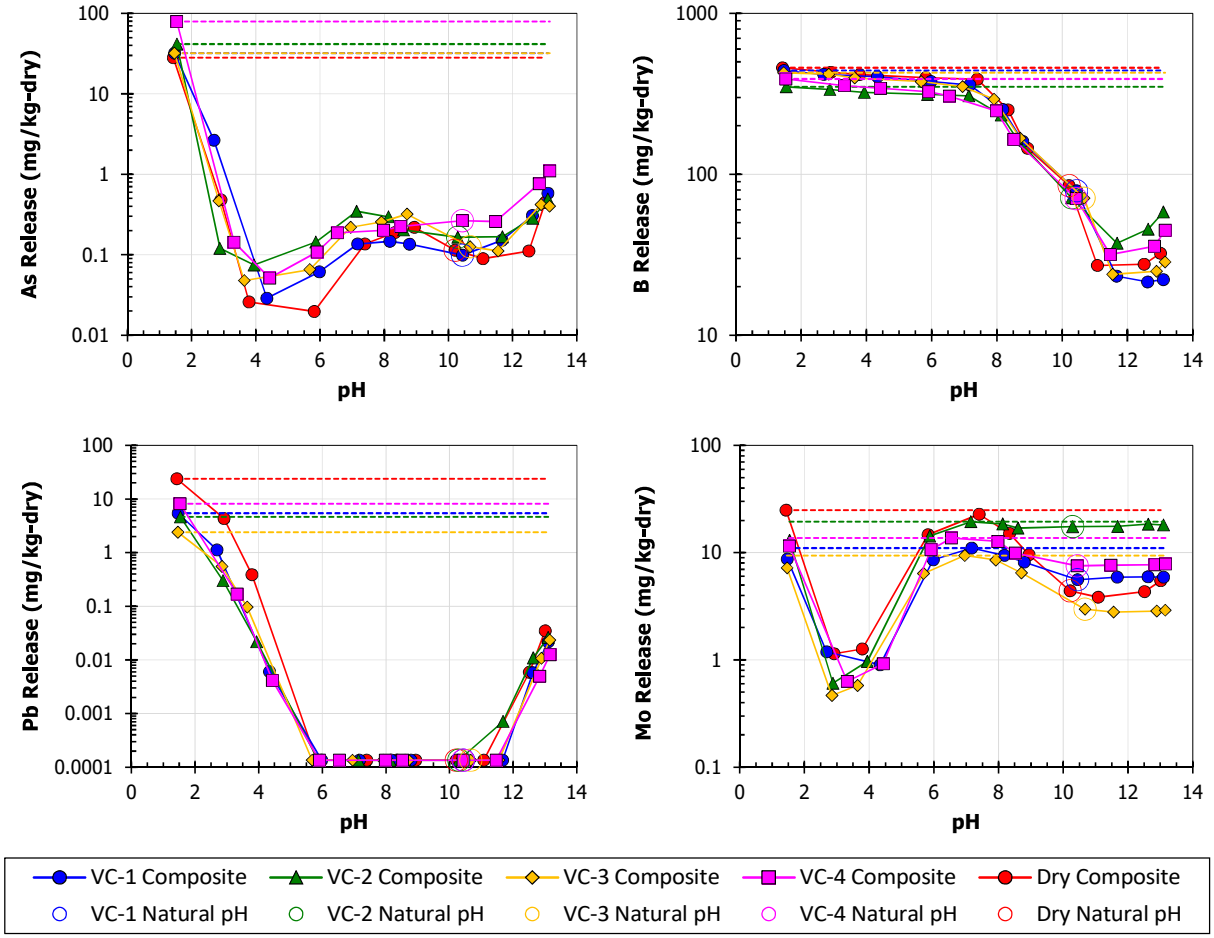

Figure 6-3
Example mass release from composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) showing available content (dashed horizontal lines)

L/S-Dependent Leaching Test Results (EPA 1314)

The results of EPA 1314 indicate how the LSP of constituents changes as the amount of water passing through a bed of material increases (i.e., the cumulative L/S, or ΣL/S). In general, soluble minerals are dissolved and removed from the column at low ΣL/S values; therefore, different minerals and processes (e.g., dissolution vs. desorption) may control the release of constituents at various points along the percolation column elution curve. As leaching progresses, the ionic strength of the porewater decreases, leading to changes in controlling minerals and, in some cases, the controlling LSP mechanisms (e.g., a constituent with an LSP limited by the available content at high concentration may show signs of solubility-controlled LSP at low concentration). In cases where the ΣL/S can be related to the rate of field infiltration, column test data can provide an estimate of leaching concentration as a function of time (Kosson et al., 2014; Garrabrants et al., 2020a, 2020b; EPA, 2019).

pH in Column Eluates

The measured pH values of eluates from the column test (EPA 1314) for the five composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) are presented in Figure 6-4. These graphs also indicate the natural pH (EPA 1313) and the own pH (EPA 1313_L/S=1) as dashed lines, and the range of pH values measured in the PAPs.

For the saturated composites (VC-1, VC-2, VC-3, and VC-4), the evolution of pH in the percolation column shows an initially increasing trend followed by a plateau at an approximate pH of 10, with the starting pH and the plateau varying slightly between composites. However, the evolution of pH for the Dry composite taken from samples above the water table shows a different trend, with an initially high pH that decreases by about 0.5 pH units to plateau at a pH of approximately 9.0. The increase in pH at low L/S for the saturated composites (VC-1 through VC-4) may be due to surficial oxidation or carbonation resulting from contact of moist, alkaline ash with air during sample handling.

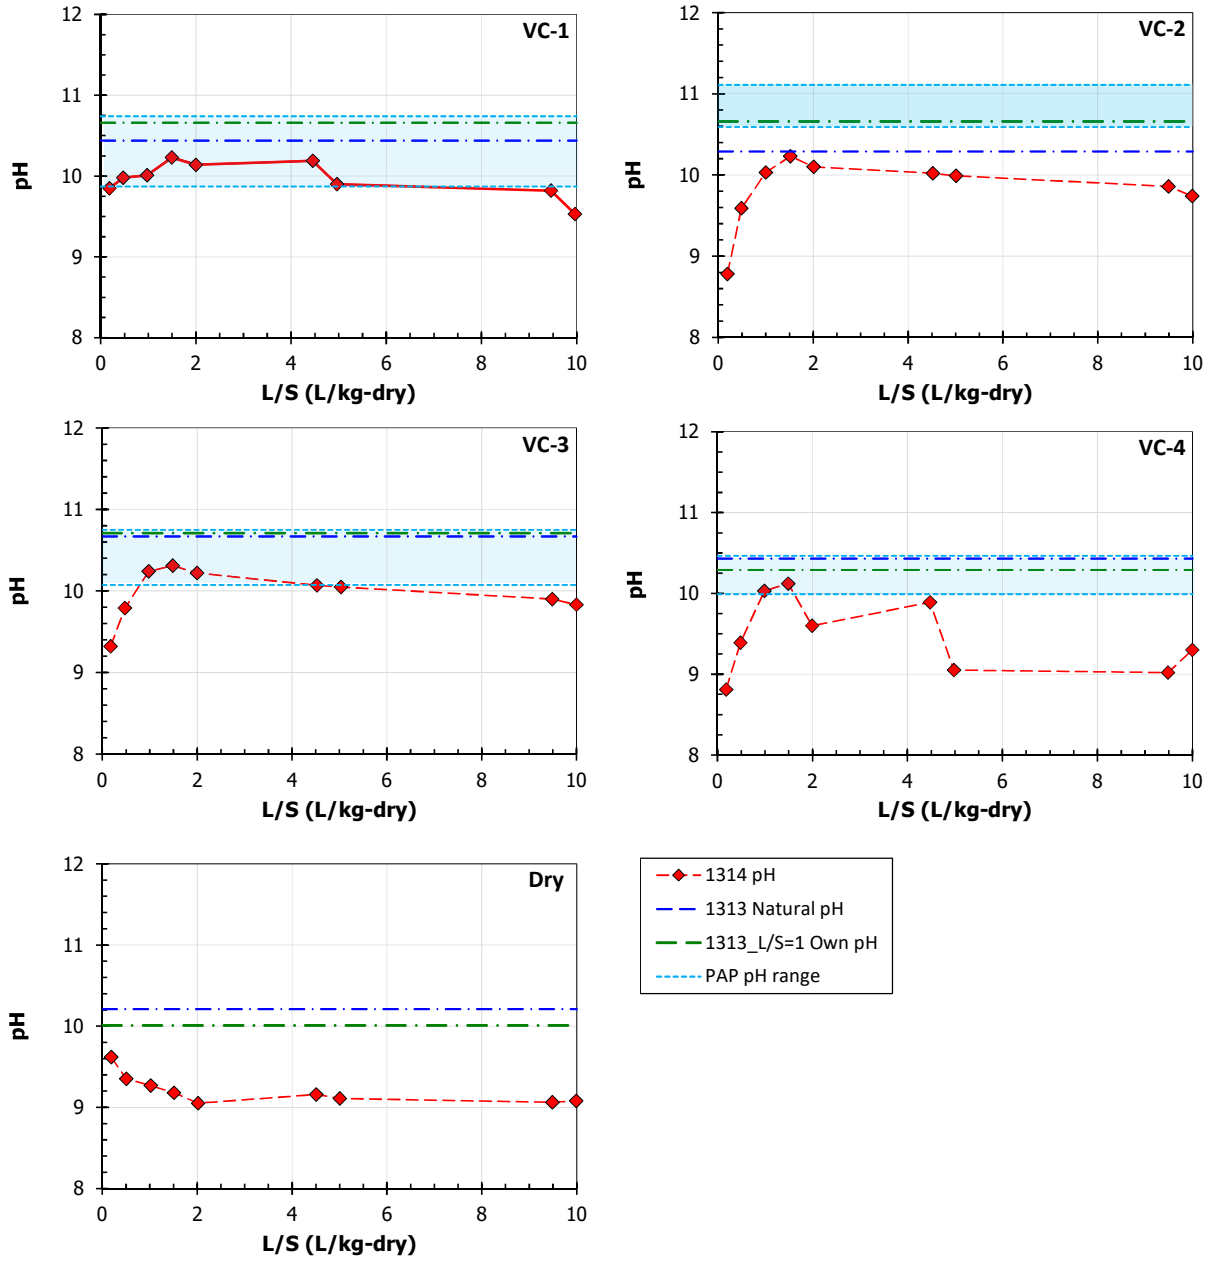

Figure 6-4
Evolution of pH in column eluates (EPA 1314) from five composite samples (VC-1, VC-2, VC-3, VC-4, and Dry) compared to natural pH (EPA 1313), own pH (EPA 1313_L/S1), and range of porewater pH measurements

Table 6-5 compares the eluate pH values from the lowest L/S fraction of EPA 1314 to the range of pH values at higher L/S values, to the natural pH and own pH measured in batch leaching tests (EPA 1313 and 1313_L/S-1), and to the range of pH in porewater samples from the PAPs. In general, column test eluates at low L/S are approximately 1.5 pH units lower than measured in batch leaching tests. The difference may be explained predominantly by ionic strength changes with increasing L/S and interactions with dissolved constituents in equilibrium at the L/S values.

Table 6-5
Comparison of Eluate pH from Low L/S Column Fraction (EPA 1314) to the Natural pH (EPA 1313) and Own pH (1313_L/S=1) of Composite Samples

	Method	L/S (mL/g-dry)	VC-1 pH (SU)	VC-2 pH (SU)	VC-3 pH (SU)	VC-4 pH (SU)	Dry pH (SU)
1st Fraction	EPA 1314	0.2	9.85	8.78	9.32	8.81	9.62
Range	EPA 1314	2-10	9.5-10.1	9.7-10.1	9.8-10.2	9.0-9.9	9.0-9.2
Own pH	1313_L/S=1	1	10.66	10.64	10.71	10.29	10.01
Natural pH	EPA 1313	10	10.44	10.29	10.67	10.43	10.21
Porewater	-	0.35	9.9-10.7	10.6-11.1	10.1-10.8	10.0-10.5	-

Note: Porewater L/S estimated from porosity and density of intact cores collected at the elevation of the PAP.

Constituent Results

The concentration of a constituent's percolation column eluates (EPA 1314) indicates how the LSP changes as water passes through the material. Eluate concentrations and mass release are typically plotted as a function of the cumulative L/S (i.e., the cumulative amount of eluent passing through the column relative to the mass of material in the column).

Examples of typical L/S-dependent behavior from EPA 1314 conducted on the VC-1 composite are shown in Figure 6-5, presented as eluate concentration (mg/L) on the left and cumulative mass release (mg/kg-dry) on the right. In mass release graphs, the gray dashed line indicates the mass release proportional to the cumulative L/S expected if concentration is controlled by constant solubility. The following behaviors are shown in Figure 6-5:

- The eluate concentrations for Sb (top) are essentially constant as a function of L/S and, thus, the mass release is proportional to the cumulative L/S and the mass release curve follows the solubility indicator line. This L/S-dependent behavior is consistent with ***solubility-controlled LSP***.
- EPA Method 1314 data indicate that the constituent concentration of Co (middle) decreases rapidly up to an L/S of 2 L/kg-dry, indicating an ***available content-limited LSP***. Eluate concentrations that are a strong function of L/S may decrease to less than quantitation limits within the test cumulative L/S range, indicating depletion of the available content.
- The L/S-dependent leaching of Se (bottom) is a good example of rapid release of a soluble fraction of the available content without depletion. This differs from the example behavior of Co because, after an initial "wash off" of a highly soluble fraction, leaching concentrations remain detectable and relatively constant, suggesting the constituent exists in ***both content-limited (highly soluble mineral phase) and solubility-controlled (low-solubility mineral phase) LSP*** fractions.

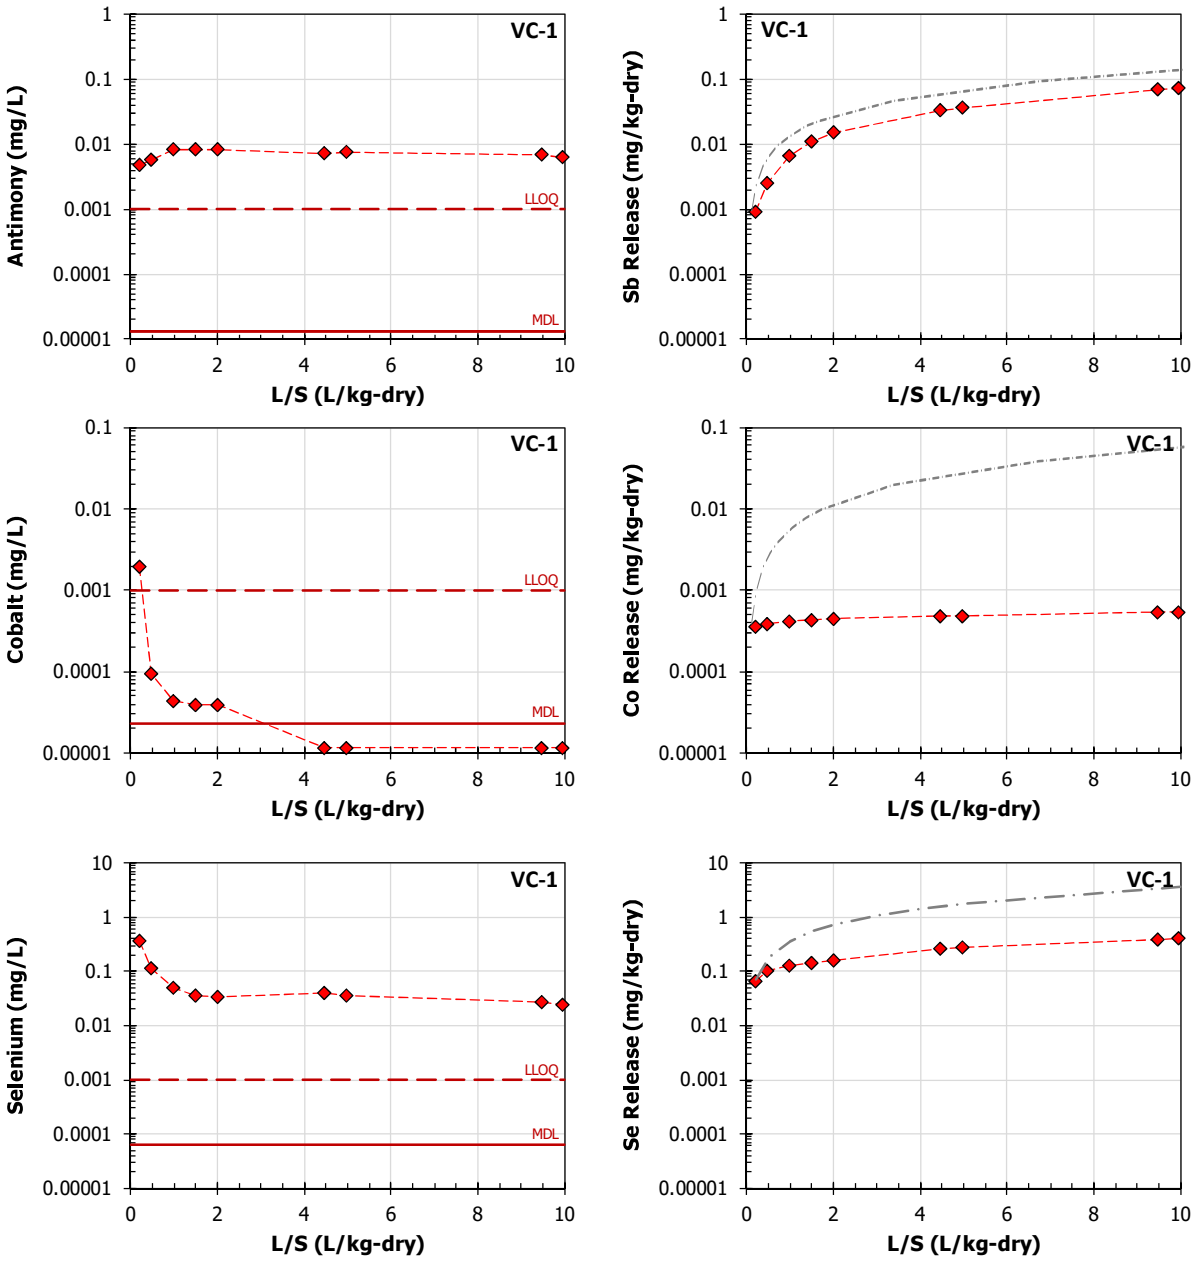

Figure 6-5
Example 1314 test results from VC-1 showing a solubility-controlled constituent (antimony) and depletion of the available content (cobalt) and wash-off of a soluble constituent fraction without depletion (selenium). The gray dot-dashed line indicates prototypical solubility-controlled release fitted to the first EPA 1314 data point.

Determining LSP Behavior

Solubility-Controlled LSP vs. Available Content-Limited LSP

Comparing the impacts of changing pH (e.g., within an EPA 1313 test) with the impact of changing L/S (e.g., within an EPA 1314 test) can be a helpful methodology for distinguishing

the LSP behavior of constituents. Often, the distinction of "solubility-controlled LSP" or "adsorption-controlled" behavior from those with "available content-limited LSP" is a useful classification for grouping large lists of constituents.

The following LSP leaching behaviors were observed from comparison of pH-dependent (EPA 1313) leaching data to L/S-dependent (EPA 1314) leaching data. The focus of the following classifications is limited to the applicable pH domain about the natural pH. Outside of those pH bounds, constituents that were classified as available content-limited may show solubility-controlled LSP or vice versa.

- Solubility-Controlled LSP – When the eluate concentrations are limited by mineral solubility, sorption to mineral phases, and precipitation/dissolution, eluate concentrations are considered ***solubility-controlled.*** Eluate concentrations are a strong function of pH and a weak function of L/S. The LSP for Sb (Figure 6-6) provide a good example of solubility-controlled LSP, as eluate concentrations change by orders-of-magnitude with pH (EPA 1313) but do not change with L/S over the range up to L/S=10 mL/g-dry (EPA 1314). However, the distinction between adsorption and solubility as a controlling mechanism within this classification may be unclear, as both mechanisms are strongly influenced by pH and the patterns for these mechanisms may look similar. Geochemical speciation modeling (not included in this scope) can be useful to discern specific pH-dependent mechanisms.
- Available Content-Limited LSP – When eluate concentrations are limited by the amount of leachable mass in the solid, the characteristic LSP behavior is considered ***available content-limited***. Eluate concentrations are a weak function of pH and a strong function of L/S. Over the applicable pH range ($8 \leq pH \leq 12$), the LSP behavior of Mo (Figure 6-6) presents a good example of available content-limited LSP, as the pH-dependent concentrations (EPA 1313) are relatively stable compared to the significant change in LSP (EPA 1314).
- Wash-Off with Depletion – When a percentage of a constituent is present in porewater or in an easily dissolvable form, there can be a significant initial flush of constituent from a column (i.e., orders-of-magnitude decrease through a $\Sigma L/S$ of 2 L/kg-dry). This behavior is typical for a ***wash-off release mechanism***. The pH-dependent leaching data alone may not indicate this behavior, and the L/S-dependent data become crucial. The endpoint of wash-off can result in depletion of the constituent from the material, evidenced by L/S-dependent concentrations below quantitation limits as presented for Mg in Figure 6-6.

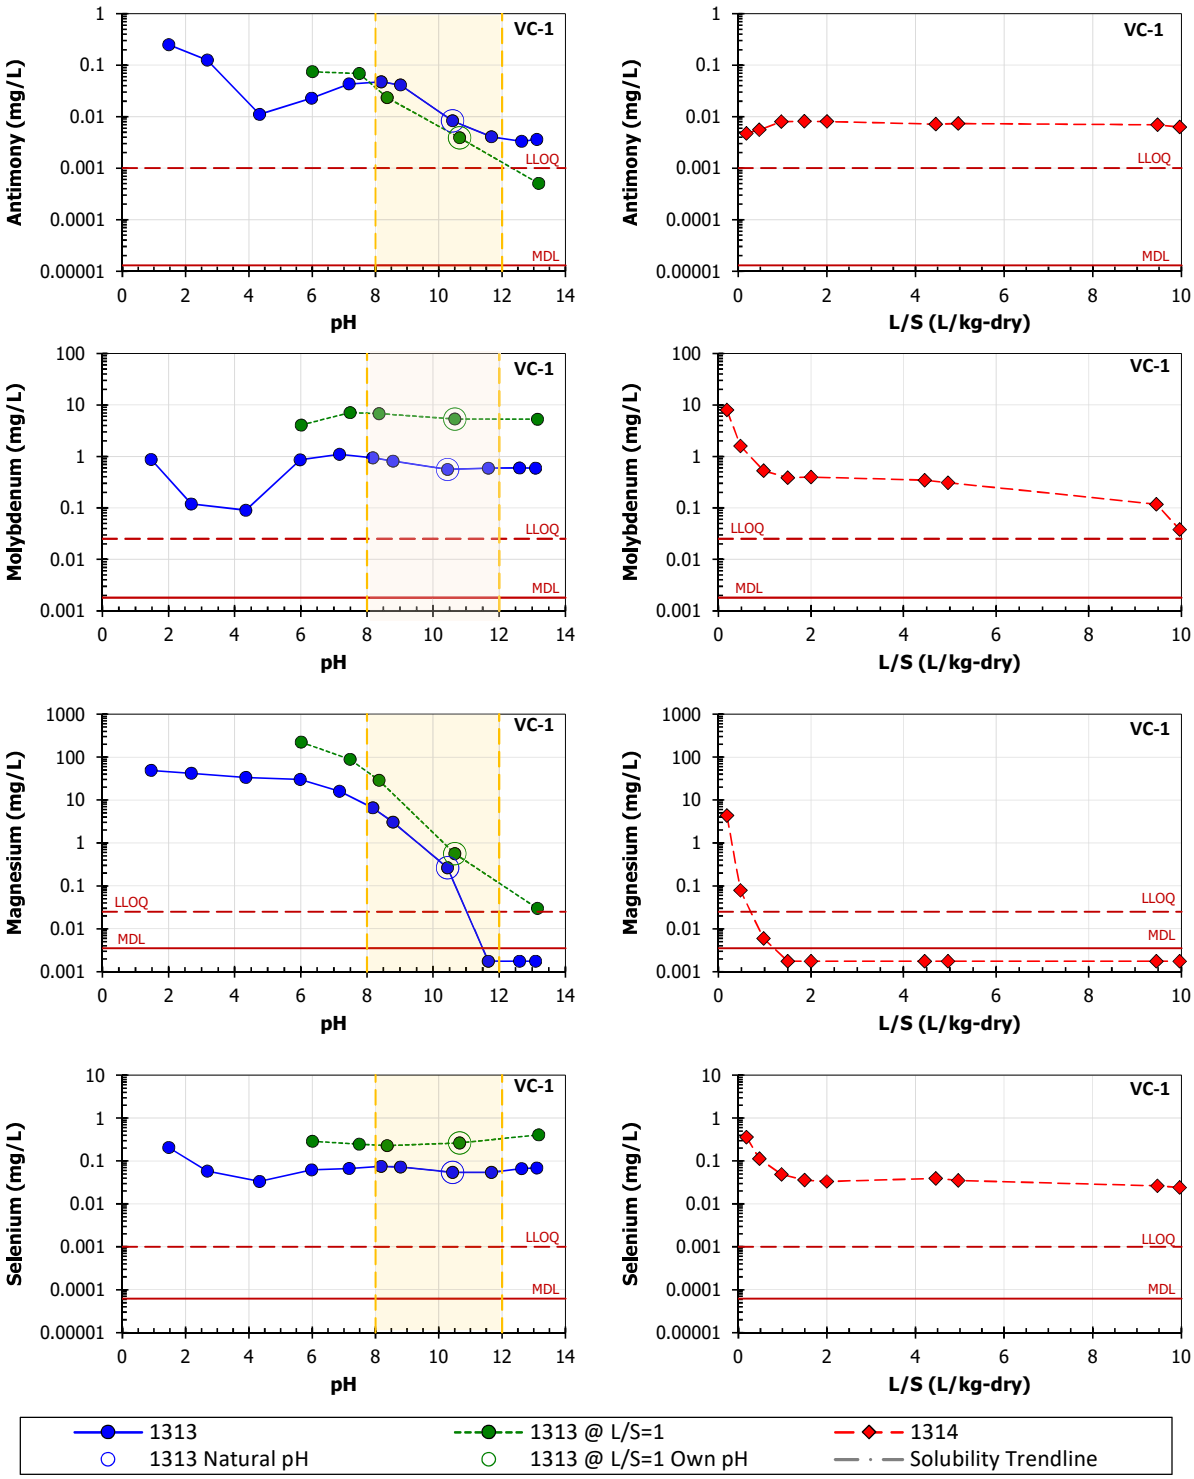

Figure 6-6
Examples of EPA 1313 and EPA 1314 data showing solubility-controlled LSP (antimony); available content-limited LSP (molybdenum); wash-off of soluble fraction leading to depletion (magnesium); and wash-off followed by solubility-controlled LSP (selenium)

- Wash-Off Followed by Solubility Control – In some cases, a secondary fraction of a constituent in the solid material may control eluate concentrations after the initial wash-off. This mechanism results in a relatively constant, detectable eluate concentration following wash-off. In Figure 6-6, Se LSP is a good example of this behavior.
- Non-Detected – For some constituents, eluate concentrations over the applicable pH domain ($8 \leq pH \leq 12$) are below the MDL of the analytical method. Therefore, LSP behavior cannot be determined.

The constituents that are included in each observed behavior are summarized in Table 6-6.

Table 6-6
LSP Behavior over Applicable pH Domain Based on Comparison of EPA 1313 and EPA 1314

LSP Behavior	Constituents
Available Content-Limited	Cl^-, Mo, K, Na
Wash-Off to Depletion	Mg, Mn, NO_3^-
Wash-Off Fraction/Solubility-Controlled	Ba, B, Cd, Cr, Cu, DOC, Li, Ni, Se, Si, Sr, SO_4^{-2}, V
Solubility-Controlled	Al, Sb, As, Ca, DIC, Tl
Non-Detect (values < MDL)	Be, Br^-, Co, F^-, Fe, Pb, PO_4^{-3}, Ag, Zn

The high number of constituents with wash-off followed by a low concentration of solubility-controlled LSP suggest a systematic controlling mechanism in the landfill. Figure 6-7 compares the L/S-dependent data between all composite samples. The data in this figure show that the eluate concentrations for the dry composite are often initially higher than the eluate concentrations of the saturated borehole composites (VC-1 through VC-4). In some cases (e.g., SO_4 in Figure 6-7), the LSP behavior in unsaturated ash is solubility-controlled whereas the LSP behavior in the saturated ash indicates a mobile constituent. These observations suggest that constituents leached from dry-handled ash penetrate into the saturated ash, providing the dissolved or easily solubilized fraction of a constituent in the observed wash-off behavior. Once the overburden constituents are released, the LSP behavior is controlled by the dissolution of more recalcitrant constituents in the saturated ash.

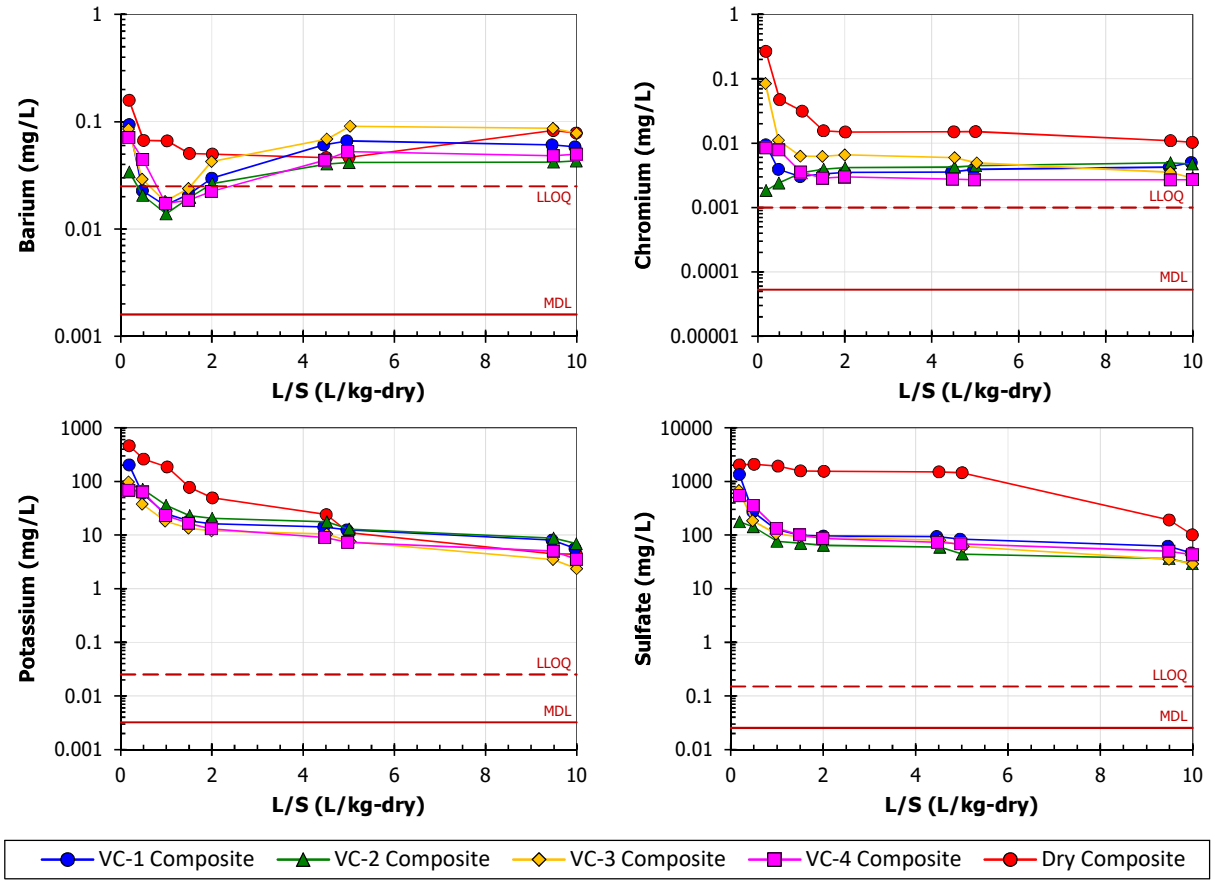

Figure 6-7
Comparison of L/S-dependent (EPA 1314) data showing influence of dry-handled ash (Dry composite) on eluate concentrations of wet-handled ash (VC-1, VC-2, VC-3, and VC-4)

Traditional Extraction Test Results

The L/S and measured pH from the extractions using the traditional leaching tests (TCLP, SPLP, and ASTM) are presented in Table 6-7.

Table 6-7
Liquid-to-Solid Ratio and Measured Extraction pH for Traditional Leaching Tests

Material	TCLP		SPLP		ASTM	
	L/S (mL/g-dry)	pH	L/S (mL/g-dry)	pH	L/S (mL/g-dry)	pH
VC-1	26.8	5.74	26.8	10.47	27.8	10.48
VC-2	28.8	5.39	28.8	10.40	30.0	10.51
VC-3	28.4	6.27	28.4	10.38	29.7	10.60
VC-4	26.9	5.47	26.9	10.32	28.1	10.51
Dry	24.8	5.78	24.8	10.04	24.8	10.20

The amount of extraction fluid for ASTM is determined as the mass of the "as received" test material in grams divided by the test-specific L/S of 20 mL/g. The resultant L/S on a dry basis is greater than 20 because of the water inherent in the pores of the "as received" material. The procedures for TCLP and SPLP require a pressure filtration preconditioning of the test sample to remove excess liquid, which is analyzed separately. The extraction fluid is based on the mass of the pressure-filtered solid material in grams divided by the same L/S of 20 mL/g. Therefore, the calculated L/S for TCLP and SPLP is lower than the L/S for the ASTM test that includes extra water. The measured pH for ASTM, which uses DIW as an extraction fluid, is consistent with the natural pH (1313) and own pH (1313_L/S=1) of the composites at VC-1, VC-2, VC-3, VC-4, and Dry reported in Table 6-2. For SPLP, the measured pH is slightly lower than the ASTM pH, consistent with the small amount of acid used in the extraction fluid. The stability of the measured pH for TCLP extracts across different composites reflects the buffering provided by the organic acetic acid.

The eluate constituent concentrations for TCLP, SPLP, and ASTM tests are presented in Table 6-8, Table 6-9, and Table 6-10, respectively. Since pH is an important factor for solubility-controlled LSP, these tables also include the final eluate pH. Recording of eluate pH allows for comparison of the results of these traditional tests to the pH- and L/S-dependent LEAF test results. In general, SPLP and ASTM concentrations were comparable to each other but were lower than TCLP concentrations, sometimes by orders-of-magnitude. In many cases, the increases in TCLP concentrations were caused by the lower pH of TCLP eluates. Exceptions for this site (which may not be generalizable) include As, Mo, and SO_4^{-2}, where similar concentrations were measure in all three procedures, and PO_4^{-2}, Se, and V, where SPLP and ASTM eluates had higher concentration than TCLP. All of these observations are consistent with the pH-dependent LSP curves discussed above.

Table 6-8
TCLP (EPA Method 1311) Eluate Concentrations

Comparison of Traditional and LEAF Test Results

When the pH and L/S of leaching tests are recorded, the test results from different leaching tests can be compared based on eluate pH or L/S. An example comparison is shown in Figure 6-8 for Mo leaching from the VC-2 composite. In Figure 6-8, the eluate concentrations (mg/L) are shown in the left column, and mass release values (mg/kg-dry) are shown in the right column. The upper row presents data as a function of pH, with L/S-dependence shown in the bottom row.

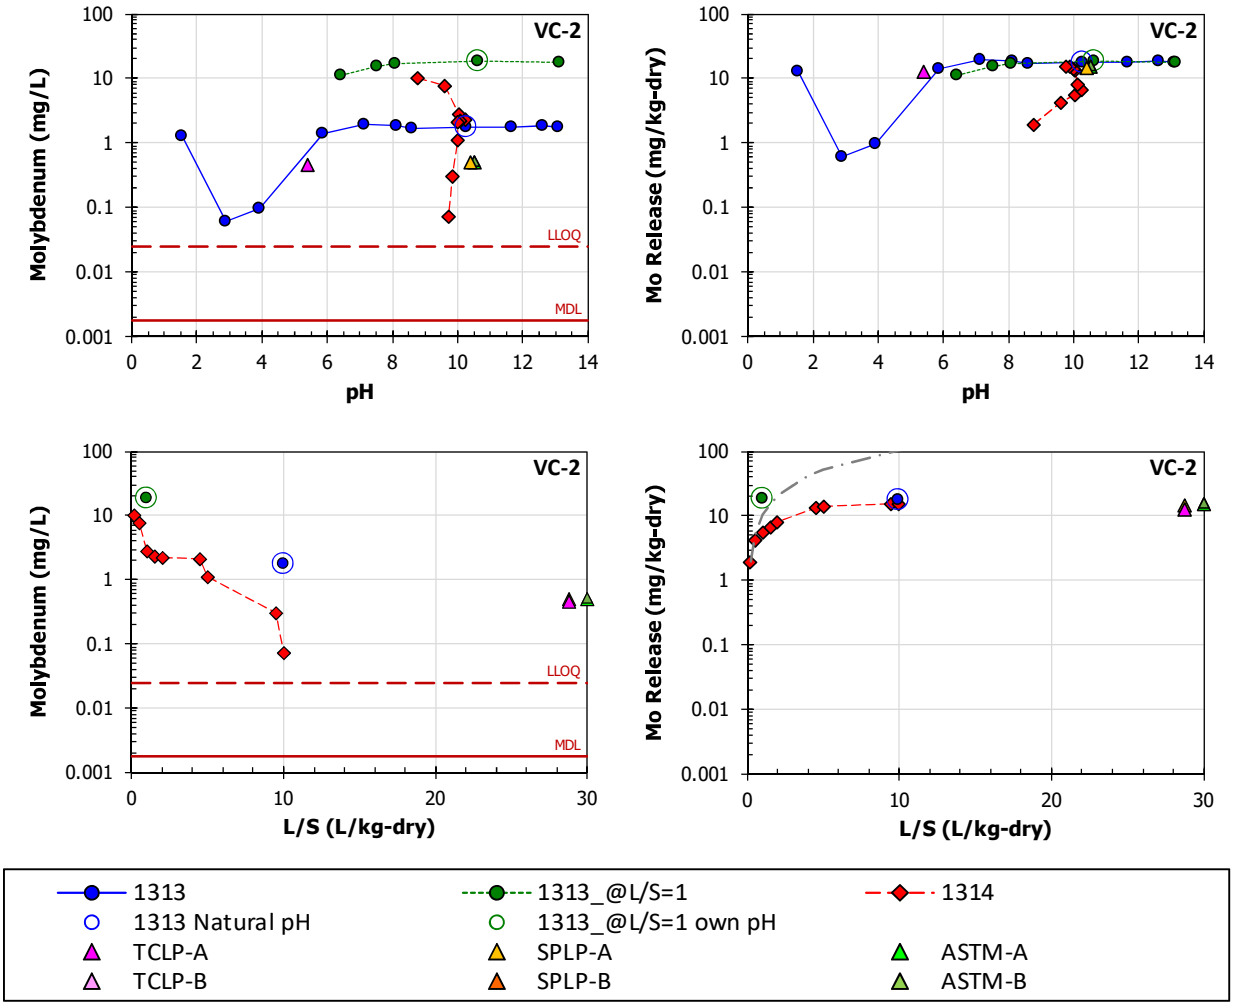

Figure 6-8
Comparison of molybdenum concentration (left) and mass release (right) using traditional (TCLP, SPLP, and ASTM) and LEAF tests (1313, 1313_L/S=1, and 1314); replicates indicated by "-A" and "-B"

For a constituent with available content-limited LSP, for example Mo, the concentrations obtained from the traditional leaching test data are slightly lower than those in EPA Method 1313 and consistent with the higher L/S for the traditional tests. The data for SPLP and ASTM are very close to the leaching response at natural pH measured in EPA Method 1313 due to the little to no acidity added. Conversely, the buffered solution of TCLP leads to a significant lower eluate pH. However, on a mass release basis (Figure 6-8 upper right) all of the results are consistent.

When data for a constituent with available content-limited LSP are compared as a function of L/S, the eluate concentrations of any single extraction at a fixed L/S are unlikely to match the column elution curve. The concentrations in the column test reflect a "progressive" leaching case where material is removed from the column, rather than a batch leaching case represented by single extractions. However, mass release as a function of L/S should be consistent between all tests because the basis of the data is the solid mass. Of course, the L/S of traditional tests are much higher than the L/S of either the LEAF tests or field conditions, so the data are not readily compared or applicable to leaching scenarios with low L/S values.

7
GROUNDWATER, POREWATER, AND SUBSURFACE GAS MONITORING

Measured field parameters for groundwater and porewater sampling as well as graphical presentation of groundwater and porewater concentrations from unfiltered samples are provided in Appendix D-1. These data represented the sampling period from June 2019 through January 2020. Monthly analysis of groundwater wells and PAPs focused on 17 constituents from 40 CFR 257 (As, B, Ba, Be, Ca, Cd, Cl^-, Co, Cr, F^-, Li, Mo, Pb, Sb, Se, SO_4^{-2}, and Tl) and 13 additional constituents (Ag, Br^-, Cu, DIC, DOC, Fe, K, Na, Ni, PO_4^{-3}, Sr, V, and Zn).

Groundwater and Porewater Parameters

Plots of field measurements are shown in Figure 7-1 and Figure 7-2. Within each bar chart, data for the porewater sampled at the four boreholes are presented in solid colors (i.e., blue for VC-1, green for VC-2, gold for VC-3, and purple for VC-4). The downgradient groundwater is presented as stripe-filled bars that are color-coded to their nearest PAP (i.e., the groundwater monitoring well at 209 is associated with VC-2 while the groundwater monitoring well at 931 is more directly opposite VC-4). Due to physical activity at the landfill during sampling (ongoing deposits and grading), not all PAPs were sampled each month.

The data in Figure 7-1 show that the water table elevation, pH, and electrical conductivity remain relatively constant over time at each sample point. The mean water table in the PAPs (386.8 ft AMSL) is approximately 27 feet higher in elevation than the mean water table of the downgradient wells (360.2 ft AMSL). The pH of the porewater in the PAPs is more alkaline ($pH_{ave\text{-}VCs}$=10.5±0.3) than in the downgradient monitoring wells (pH_{ave}=6.7±0.2).

Figure 7-2 presents measured values of water temperature, ORP, and DO, showing seasonal trends for all parameters. The ORP values of the PAP porewater appear to have significant variability, which may be indicative of the nature of the ORP measurement. The mean dissolved oxygen for the two downgradient monitoring wells (DO_{ave}=0.9±0.3 mg/L) is somewhat lower than in the PAPs ($DO_{ave\text{-}VCs}$=1.5±0.3 mg/L). The dissolved oxygen data for all of the porewater and groundwater measurements are notably less than the 9.1 mg/L for saturated surface water at 20 ºC (USGS, 1998) and, therefore, the porewater is considered to be suboxic.

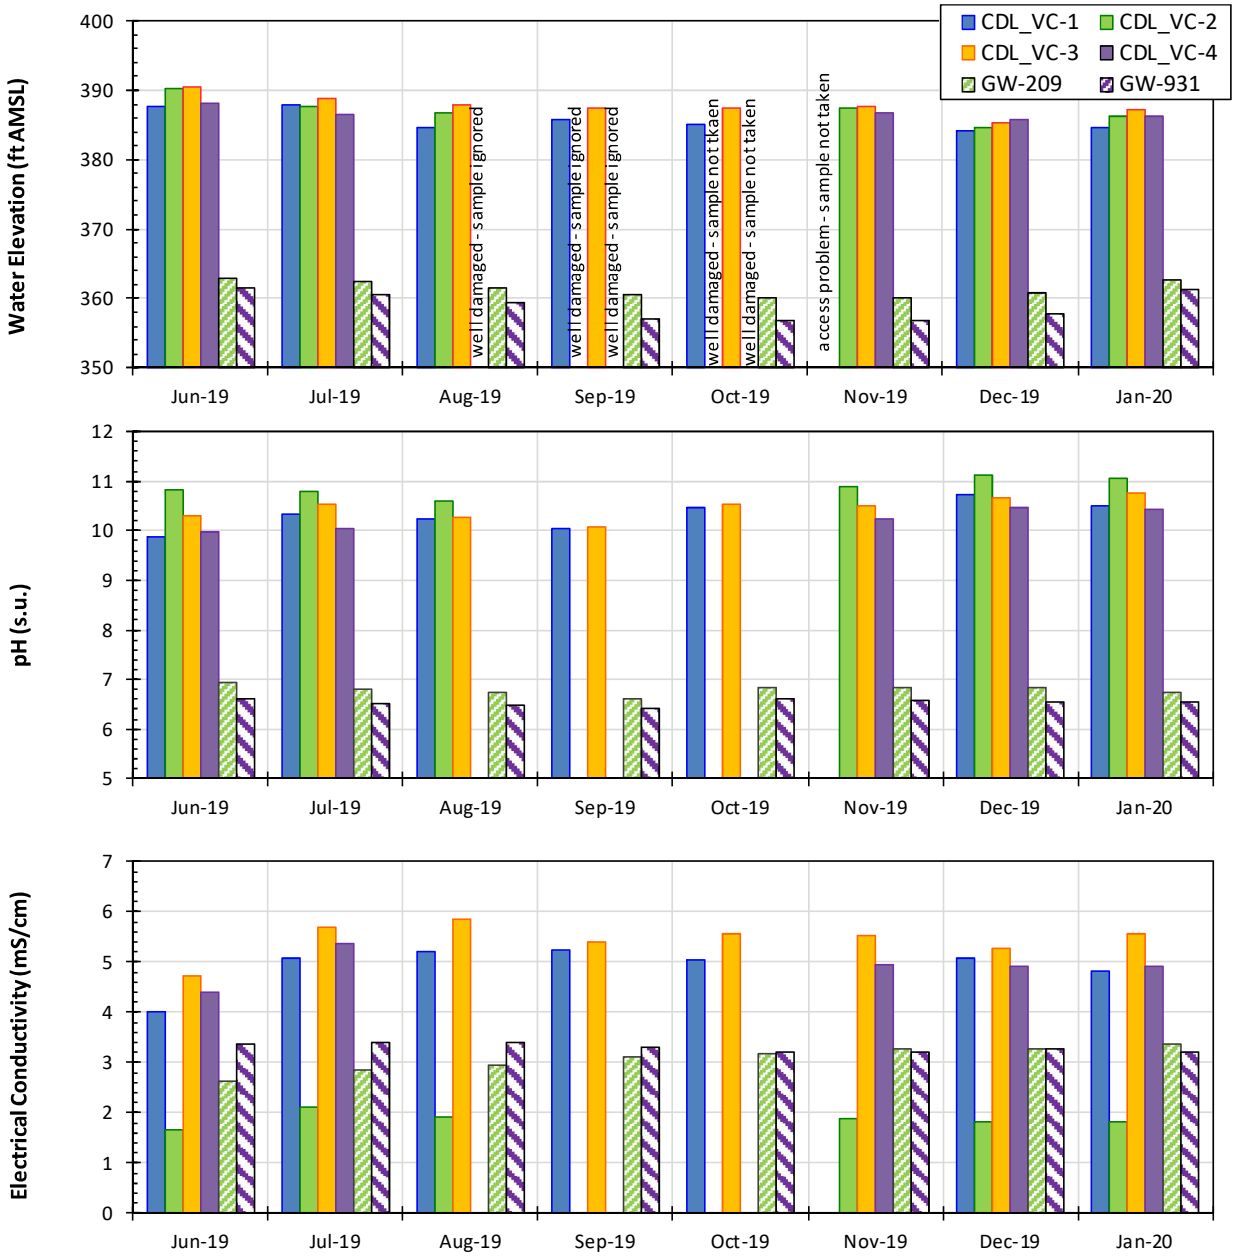

Figure 7-1
Groundwater and porewater field parameters from monthly sampling: water table elevation, pH, and EC

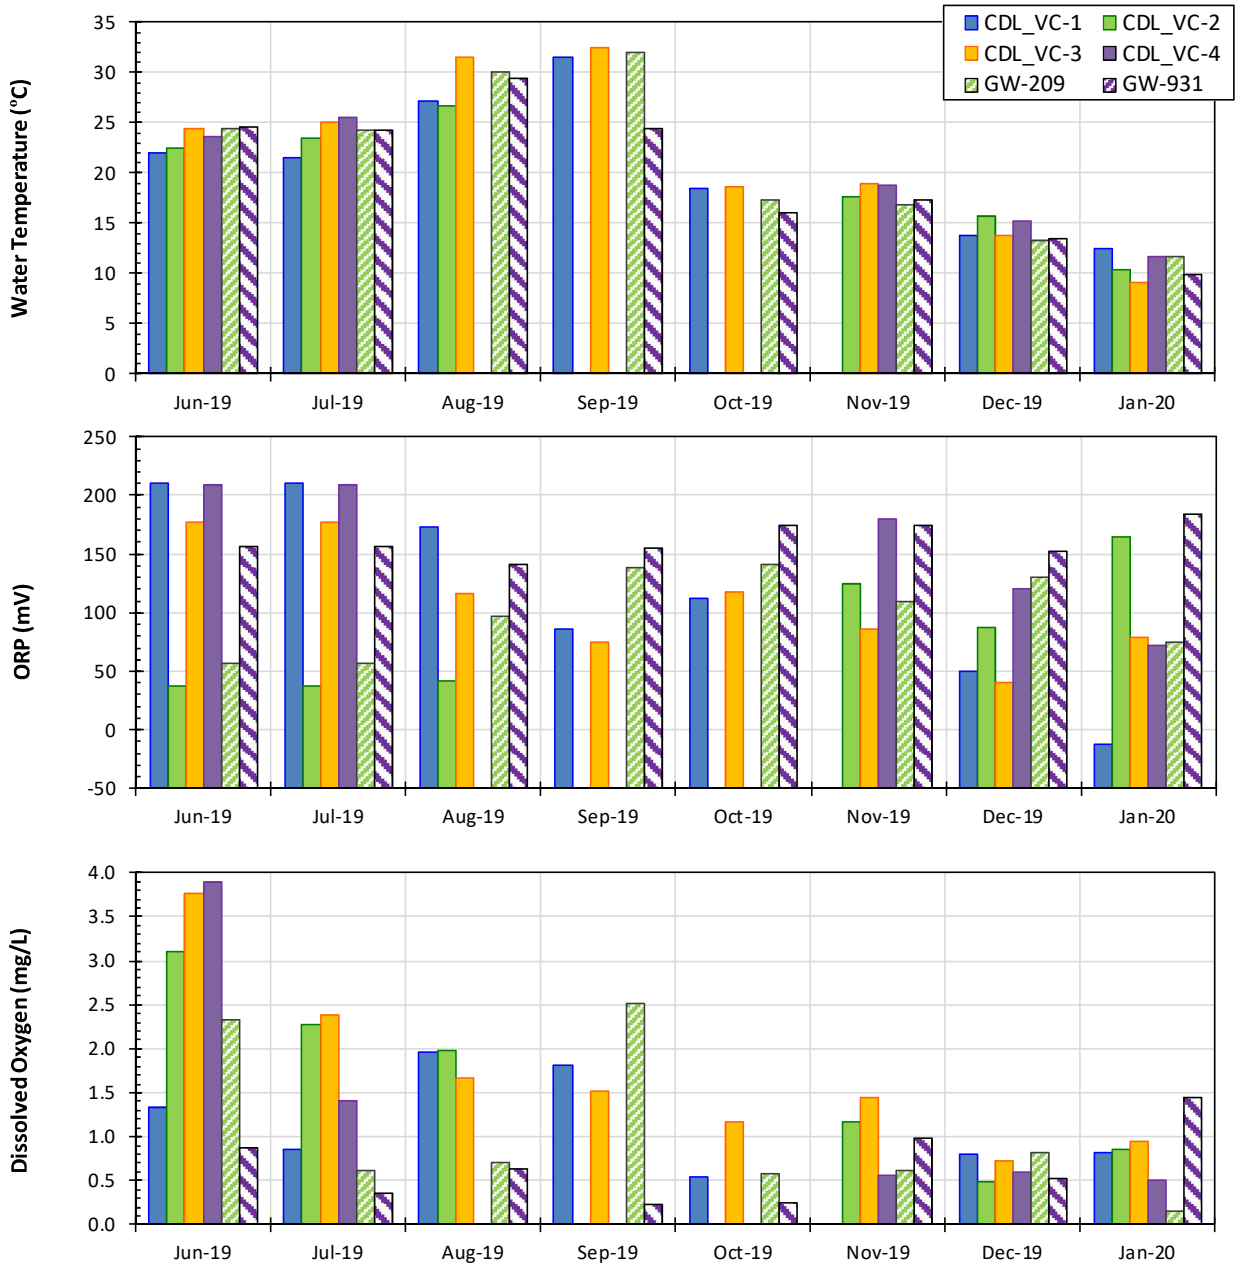

Figure 7-2
Groundwater and porewater field parameters from monthly sampling: water temperature, ORP, and DO

Concentrations in Groundwater and Porewater

Monthly analysis of groundwater wells and PAPs focused on 30 constituents, including 17 from 40 CFR 257 (As, B, Ba, Be, Ca, Cd, Cl^-, Co, Cr, F^-, Li, Mo, Pb, Sb, Se, SO_4^{-2}, and Tl). Thirteen additional constituents that were analyzed were Ag, Br^-, Cu, DIC, DOC, Fe, K, Na, Ni, PO_4^{-3}, Sr, V, and Zn. Examples of the results for selected constituents are presented in Figure 7-3 and Figure 7-4, while the graphical results for all 30 constituents are presented in Appendix D-1.

Given the geography and groundwater flow patterns at this site, there was not an upgradient monitoring well that could be used in a comparison to determine whether or not there were any impacts to groundwater from this CCP unit; therefore this analysis will not attempt to determine whether or not the groundwater quality represents releases from the coal ash. The discussion that follows allows for either possibility as the relationship between porewater and downgradient groundwater is explored.

An analysis of variance (ANOVA) was initially attempted to compare the groundwater and porewater datasets, but in most cases low p-values indicated that groundwater and porewater concentrations were not from the same statistical population. Instead, downgradient concentrations were directly compared to porewater concentrations using means and standard deviations. Table 7-1 summarizes the standard deviation analysis as follows:

- "GW >> PW" and "GW << PW" indicate that the mean groundwater concentration (GW) for a groundwater monitoring well was greater than or less than the mean porewater concentration (PW) at the associated PAP by a difference of three standard deviations or more;
- "GW > PW" and "GW < PW" indicate that the mean groundwater concentration at a groundwater monitoring well was greater than or less than the mean porewater concentration at the associated PAP by a difference of greater than one standard deviation, but less than three standard deviations; and,
- "GW ≈ PW" indicates that the mean groundwater concentration from a groundwater monitoring well was within one standard deviation of the mean porewater concentration of the associated PAP.

In Table 7-1, Ag, Be, Cr, F^-, and Pb are not included because the concentrations of these constituents were below the analytical MDL in both porewater and groundwater. The summary in the table assumes the potential for a connection between specific PAPs and specific groundwater monitoring wells (e.g., VC-2 and Well 209), based solely on geography and a general understanding of groundwater flow direction.

Table 7-1
Relationships between Groundwater and Porewater Based on PAP-Downgradient Groundwater Pairs (Well 209 and PAP at VC-2; Well 931 and PAP at VC-4)

	Monitoring Well 209 (GW) to PAP at VC-2 (PW)	Monitoring Well 931 (GW) to PAP at VC-4 (PW)
GW >> PW	B, Ca, Cl^-, Co, Fe, SO_4^{-2}	Co, Fe
GW > PW	-	Ni, Zn
GW ≈ PW	Ba	Ba, Cl^-,
GW < PW	As, Cu*, V	-
GW << PW	Cd*, Li, Mo, Ni, Sb*, Se, Tl*, Zn*	As, B, Ca, Cd*, Cu, Li, Mo, Sb*, Se, SO_4^{-2}, Tl*, V

Notes * Indicates that groundwater concentrations were all or mostly below the MDL

The following are observations from this summary.

- Co and Fe have higher concentrations in groundwater than in porewater for all comparisons, while Ba and Cl^- concentrations were similar or much higher in groundwater depending on the comparison. Higher groundwater concentrations suggest that porewater from the coal ash is not the primary source of the groundwater concentration and a limited relationship exists between recent porewater concentration and the downgradient groundwater concentrations at this site. Similar concentrations could be indicative of a release, especially if the constituent is environmentally conservative (e.g., B, Cl^-, and SO_4^{-2}); however, it is unlikely that there would be no dilution when leachate would be released to groundwater. The history and variety of residual storage at this site (e.g., underlying large area of sluiced ash, bottom ash collection ponds, gypsum storage stacks) confounds the ability to use boron as an indicator species for release from this landfill.
- Nine constituents (As, Cd, Cu, Li, Mo, Sb, Se, Tl, and V) have higher concentration in porewater than in both downgradient monitoring wells for all comparisons. Higher concentrations in coal ash porewater suggest that porewater has the potential to affect downgradient groundwater quality; however, porewater concentrations for several of these constituents (Cd, Li, Mo, Sb, Tl, and V) are 2 to 3 orders-of-magnitude higher in the coal ash deposit than in the downgradient wells, suggesting limited impact from porewater on downgradient monitoring well concentrations at this site.

Overall, these observations indicate that at this site, high porewater concentrations cannot be assumed to indicate impacts on downgradient groundwater concentrations.

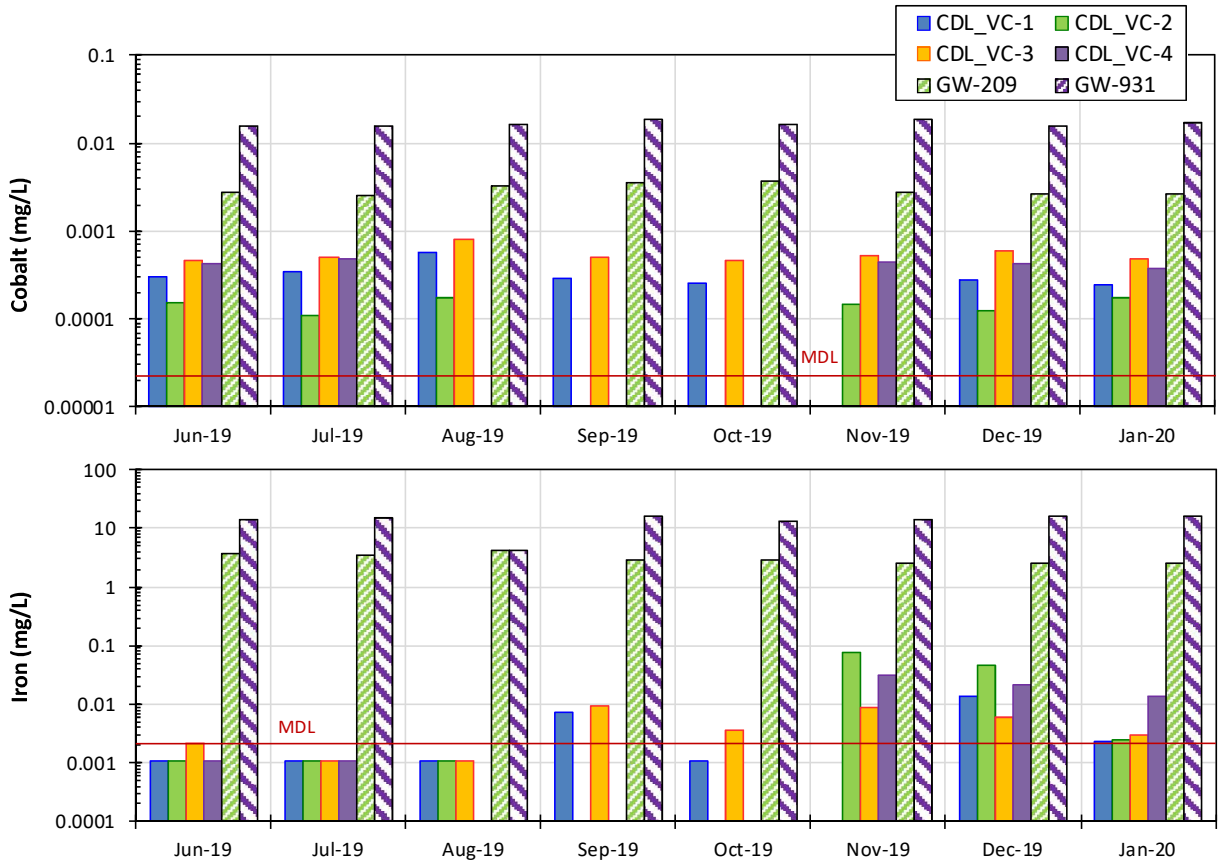

Figure 7-3
Groundwater and porewater monitoring from monthly sampling showing lower concentrations in coal ash porewater (VC-1, VC-2, VC-3, and VC-4) than in downgradient groundwater wells (209 and 931); concentrations plotted on a logarithmic axis

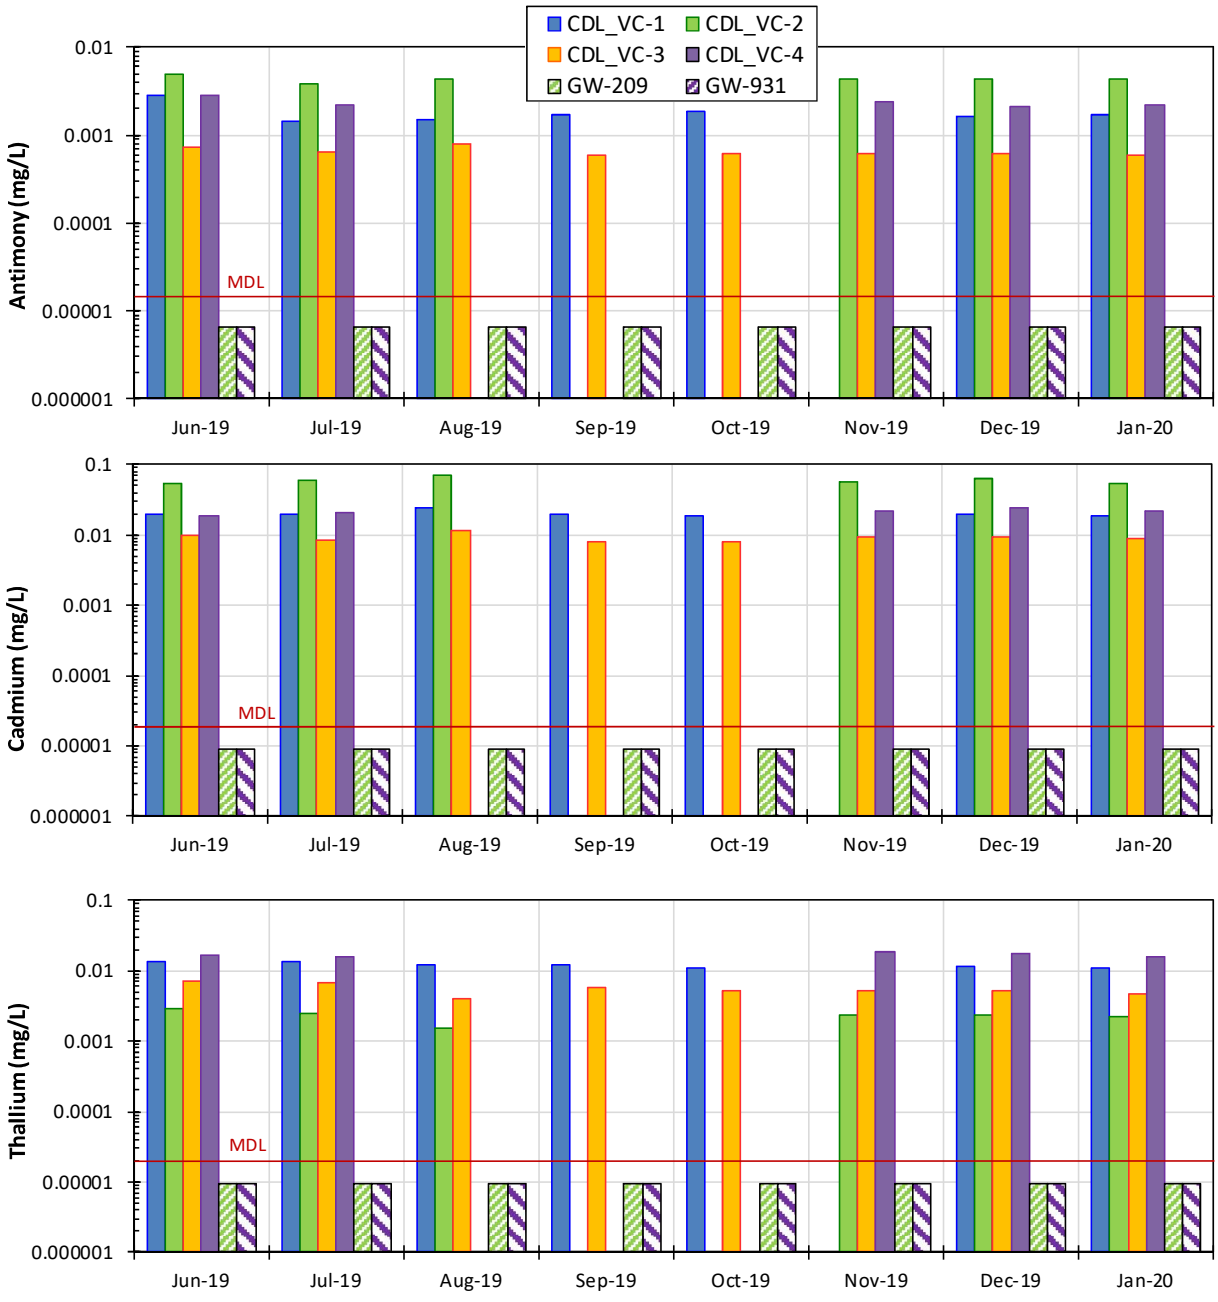

Figure 7-4
Groundwater and porewater monitoring from monthly sampling showing significantly higher concentrations in coal ash porewater (VC-1, VC-2, VB-3, and VC-4) than in groundwater from the downgradient wells (209 and 931); concentrations plotted on a logarithmic axis

Temporal and Spatial Variability in Porewater Parameters

Data reflecting the temporal variability of porewater parameters from monthly monitoring are presented as time-series plots as a function of date. The shapes of the time series distinguish porewater properties that are relatively constant over the sampling period from porewater properties that vary with time. Time-series plots are presented in Appendix D-2. Examples of time series plots for field parameters (Figure 7-5) indicate that variability over the sampling period may be primarily attributed to seasonal changes (e.g., temperature, redox conditions as seen by pH+pE). The trends in porewater constituent concentrations (Figure 7-6) show that many parameters remained relatively constant throughout the monitoring period. The trend lines for VC-2 (green) and VC-4 (pink) were interrupted due to activity on the landfill that caused damage to the PAP. The damage was repaired and the PAPs redeveloped prior to continuation of data collection.

The spatial variability between PAP concentrations was evaluated based on the differences between mean constituent concentrations. Concentrations of a constituent in a PAP were deemed systematically different if the mean concentration in that PAP was more than a factor of five higher or lower than the mean of other PAPs. Based on this analysis, the following observations were made:

- The mean concentrations of Ag, Be, Cr, F^-, and Pb were below the MDL for the analysis and, therefore, no spatial variability could be determined.
- The mean concentrations of Cl^-, Cu, Fe, SO_4^{2-}, Tl, and Zn in VC-2 and Cd and Sb in VC-3 were lower than the mean concentrations in the other PAPs; however, some of this variability may be explained by the damage to wells VC-2 and VC-4.
- The mean concentrations of Cl^- in VC-4, Li in VC-1, and Mo in VC-2 (Figure 7-6) were higher than the mean concentrations in the other PAPs.

Of the 23 constituents evaluated, only Cu and Zn had mean concentrations between PAPs that varied by more than an order-of-magnitude; however, no pattern in spatial variability was observed.

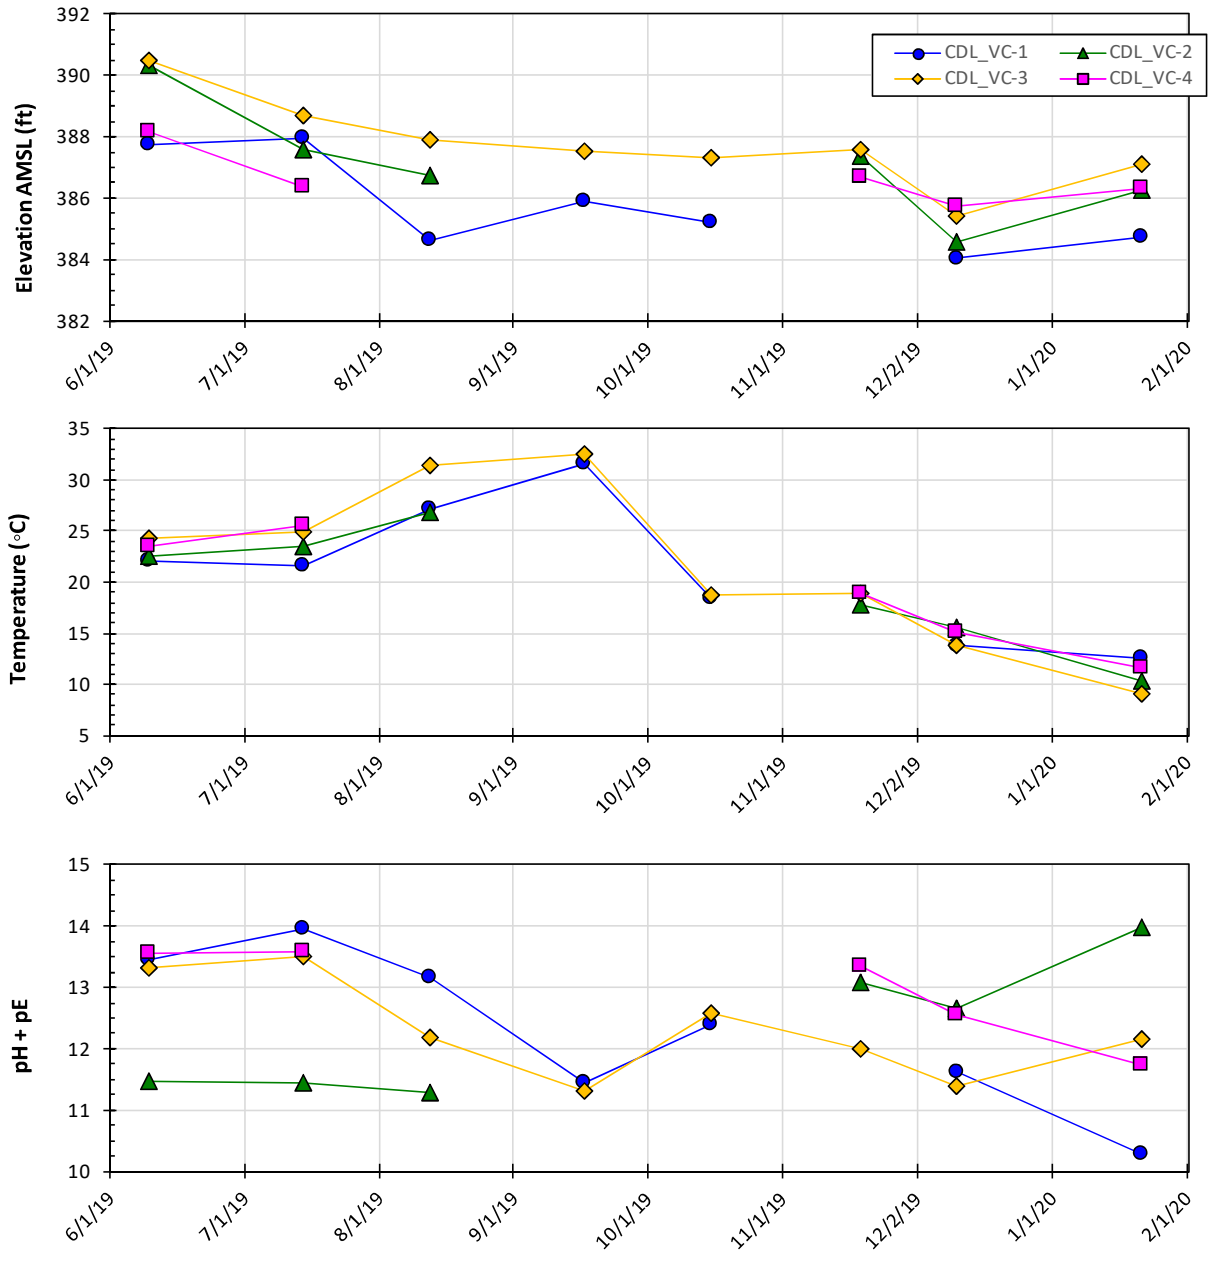

Figure 7-5
Example temporal porewater data showing seasonal or other variability: elevation, temperature, and pH+pE

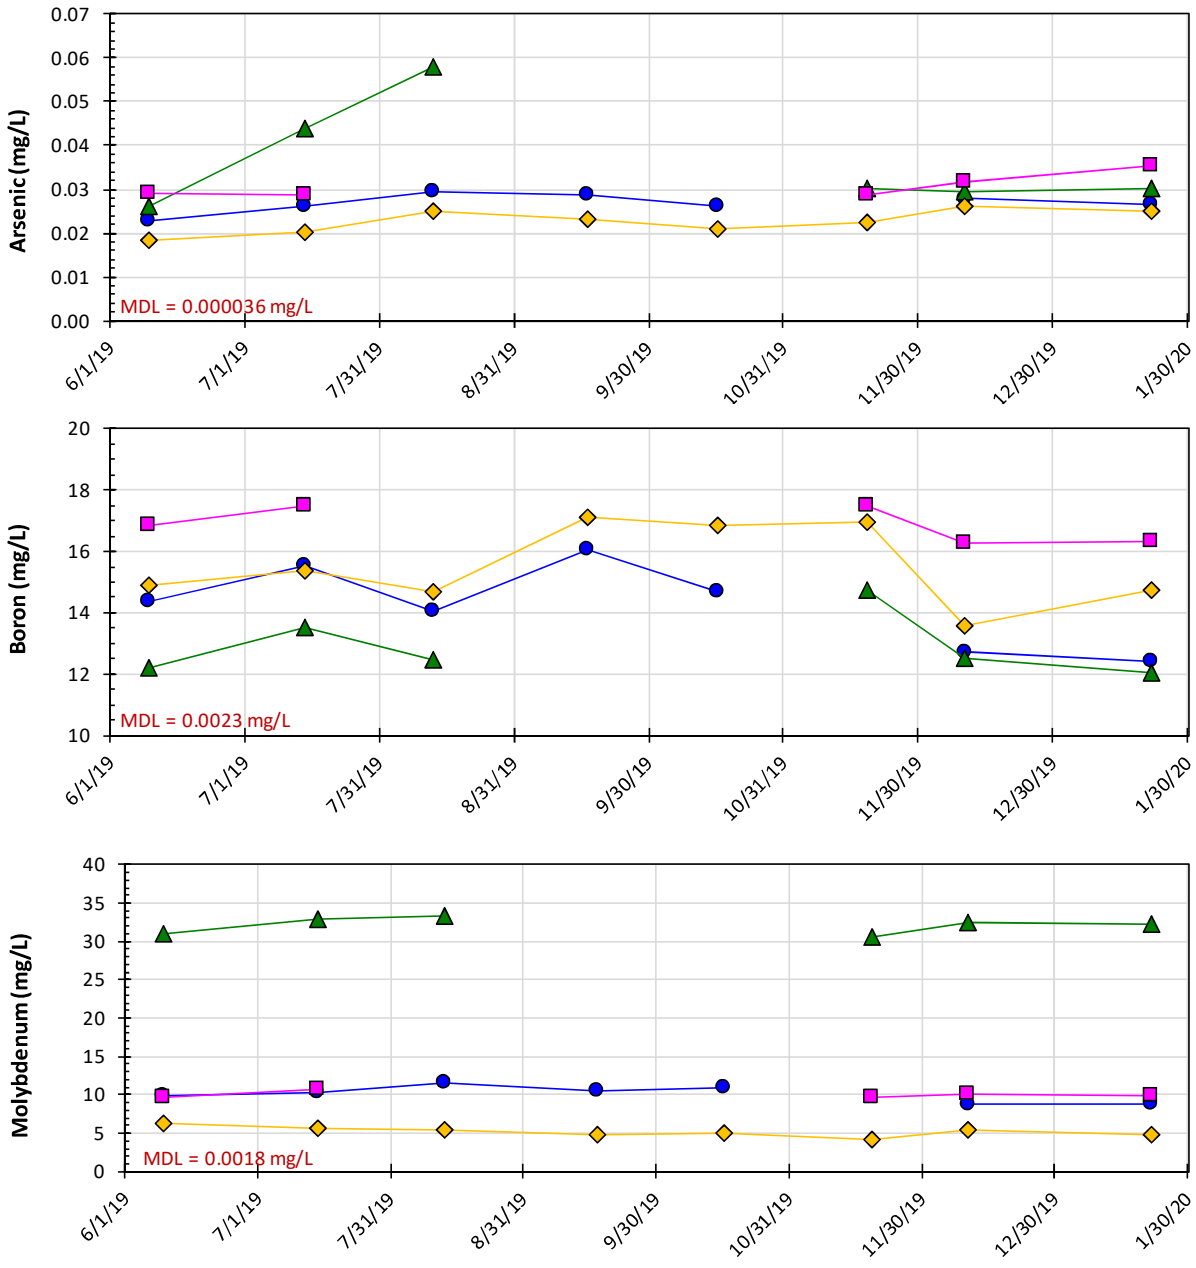

Figure 7-6
Example temporal porewater data showing relatively constant conditions: arsenic, boron, and molybdenum

Subsurface Gas Monitoring

Concentrations of O_2, CO_2, CH_4, NH_4, and H_2S were measured in the four boreholes using gas access points (GAPs). GAPs were installed at VC-1 and VC-3 at three depths (5, 15, and 50 feet BGS), while VC-2 and VC-4 had GAPs installed at 5 and 15 feet BGS. Full tabular data for subsurface monitoring are presented along with graphical comparisons in Appendix D-3.

The results of monthly gas monitoring varied to some degree by borehole:

- VC-1 consistently had higher subsurface O2 concentrations at a depth of 5 feet BGS than at 15 or 50 feet BGS (Figure 7-7). The data at this borehole suggest that oxygen is quickly depleted in the subsurface. At VC-3 and VC-4, there appears to be period of instability as initial O2 concentrations were significantly higher than after the first two months.
- CO2 levels were generally low and variable as a function of depth and time (Figure 7-8).
- CH4 concentration in subsurface gas was detected in VC-1 only at very low concentrations at depth (Figure 7-9). In this scenario, methane detection is likely indicative of localized decay of organic matter rather than a strongly reduced subsurface environment as noted in the closed impoundment discussed in EPRI (2020).
- Subsurface NH4 and H2S concentrations were negligible, detected very sporadically and at very low concentrations (Appendix D-3).

These data are indicative of a heterogeneous redox environment. At depth (> 5 feet BGS), O_2 concentrations, in particular, confirm the suboxic environment indicated by DO measurements in the porewater.

Concentration (ppm) of methane (CH_4) from GAPs at borehole VC-1, VC-2, VC-3, and VC-4 in the subsurface of the dry-handled landfill

Comparison of Leaching Tests to Monthly Porewater Samples

The results of LEAF leaching tests and traditional tests (TCLP, SPLP, and ASTM) were plotted as a function of pH along with the porewater concentrations measured at the corresponding borehole (VC-1, VC-2, VC-3, or VC-4). Examples of these comparisons are shown in Figure 7-10 through Figure 7-12, while a full set of results is presented in Appendix E. In the pH-dependence graphs, monitored porewater data are presented both as data points representing monthly measured porewater concentrations and as dashed lines representing the mean pH and mean concentration of all measured values.

To the right of each pH-dependence graph, bar charts show the ratio of the leaching test concentration to the mean porewater concentration. The seven ratios are shown in increasing order of L/S, including:

- the 1st eluate from EPA 1314 at ΣL/S=0.2 mL/g-dry,
- the 2nd eluate from EPA 1314 at cumulative ΣL/S=0.5 mL/g-dry (displayed as L/S=0.3)[4],
- the 1313_L/S=1 concentration at own pH at L/S=1 mL/g-dry,
- the 1313 concentration at natural pH at L/S=10 mL/g-dry,
- TCLP conducted at an average L/S of 23 mL/g-dry,
- SPLP conducted at an average L/S of 22 mL/g-dry, and
- ASTM at an average L/S of 27 mL/g-dry.

The eluate-to-porewater-concentration ratios indicate how closely leaching test concentrations can predict measured field concentrations. For example, Figure 7-10 shows that B porewater concentrations are well predicted by low L/S batch leaching (1313_L/S=1) and, coincidently, by TCLP; however, the test-specific L/S of TCLP and resultant eluate pH are not representative of that in the coal ash porewater. For boron, all leaching test data estimate porewater concentrations within an order-of-magnitude. These observations are consistent with available content-limited LSP where eluate concentration is a strong function of L/S. Since the L/S of ASTM and SPLP is significantly greater than the L/S in the field, these traditional tests tend to underestimate the porewater concentrations for available content-limited LSP constituents by an order-of-magnitude or more.

[4] The first eluate is taken at L/S=0.2, the second is taken 0.3 pore volumes later, so the L/S is 0.3 and ΣL/S=0.5.

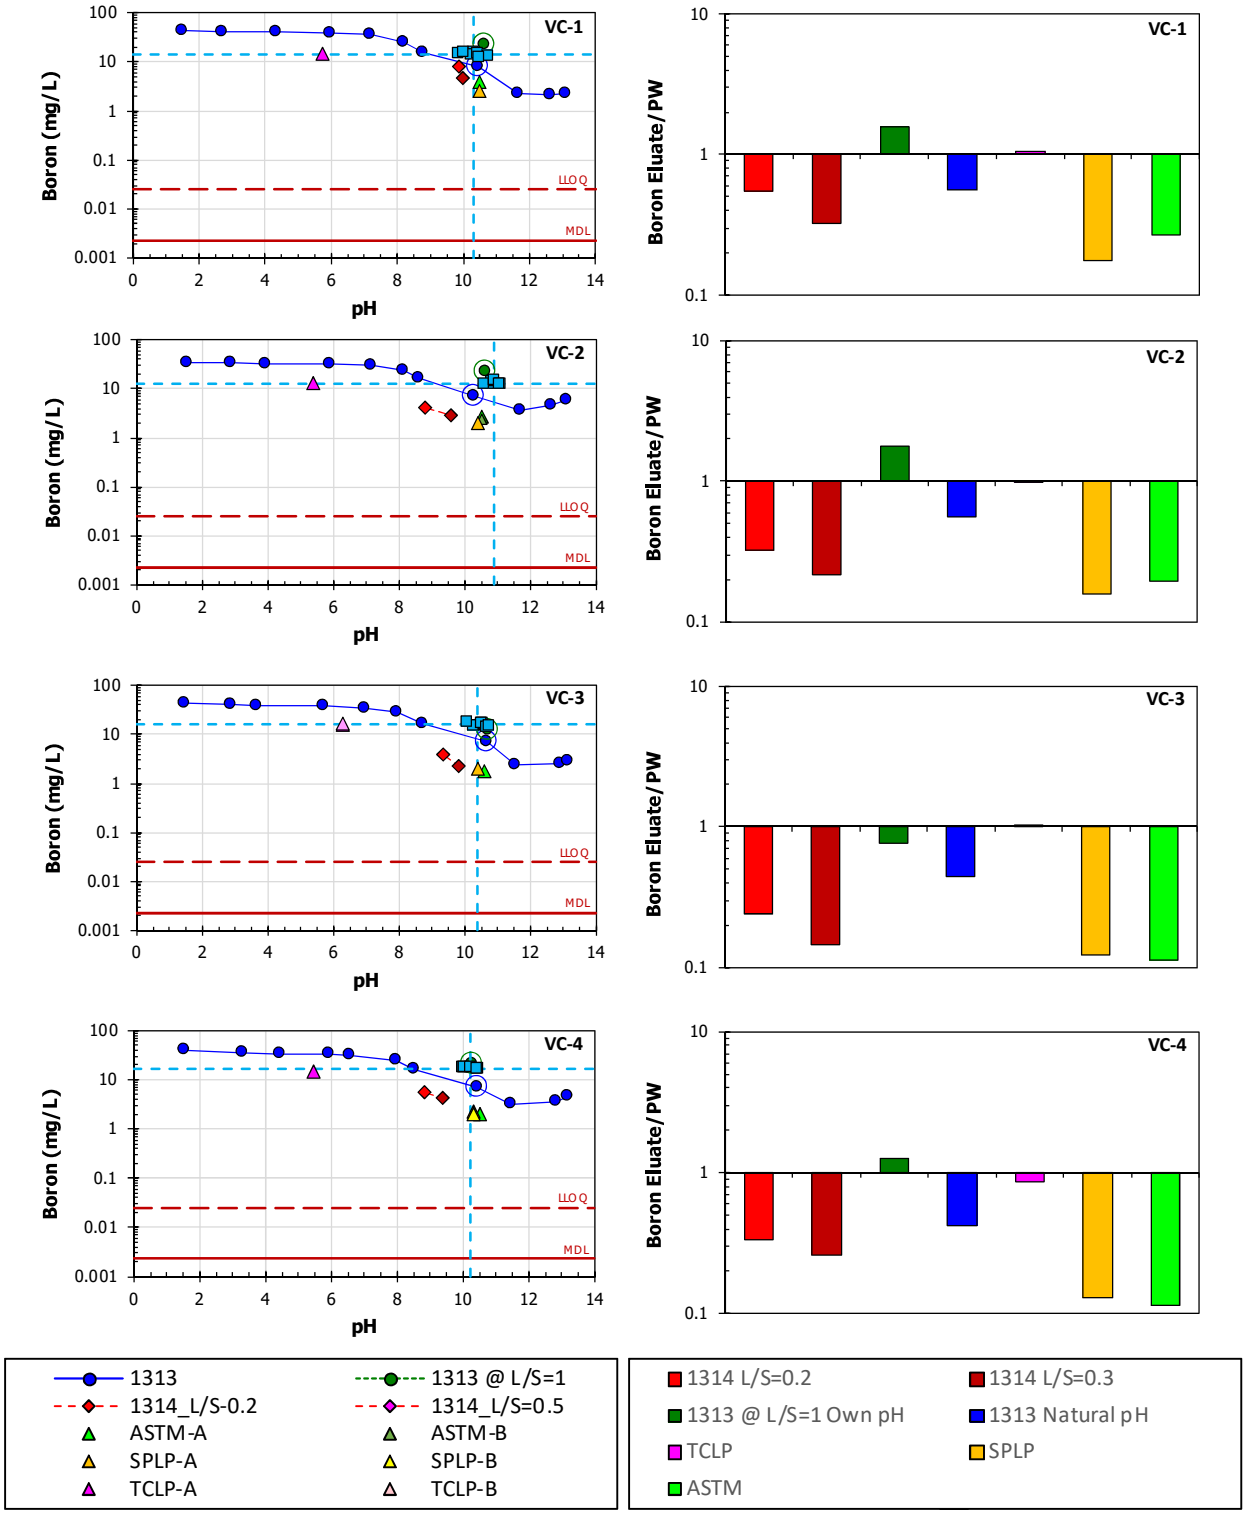

Figure 7-10
Boron concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right)

Of the 30 evaluated constituents, only chromium compared poorly to all of the leaching test concentrations. The porewater concentrations of Cr were less than the analytical MDL of 0.000053 mg/L in all four PAPs, while leaching tests returned concentrations between 0.001 and 0.1 mg/L (Figure 7-11). Subsurface gas measurements indicated a deficit of oxygen (Figure 7-7) without generation of carbon dioxide (Figure 7-8) or significant methane (Figure 7-9), which suggests suboxic conditions. Under these conditions, Cr is reduced to Cr(III), which would be insoluble at the porewater pH conditions. When samples are collected from the field, homogenized in the laboratory, and exposed to laboratory conditions during testing, the material oxidizes enough to convert a portion of Cr(III) to Cr(IV), leading to increased chromium concentrations in leaching test eluates. Conversely, arsenic, also a redox-sensitive constituent, is predicted within an order of magnitude in all leaching test approximations (Figure 7-12). The ability of leaching tests to approximate arsenic concentrations in the porewater is most likely due to the speciation of arsenic and the subsurface conditions. In literature, arsenic retained in fly ash as calcium-arsenate and arsenate hematite was less susceptible to changes due to redox conditions (Deonarine et al., 2016). In addition, the subsurface conditions here, while suboxic, are not sufficiently reducing to be affected by short-term exposures of the solid materials to oxygen in laboratory leaching tests.

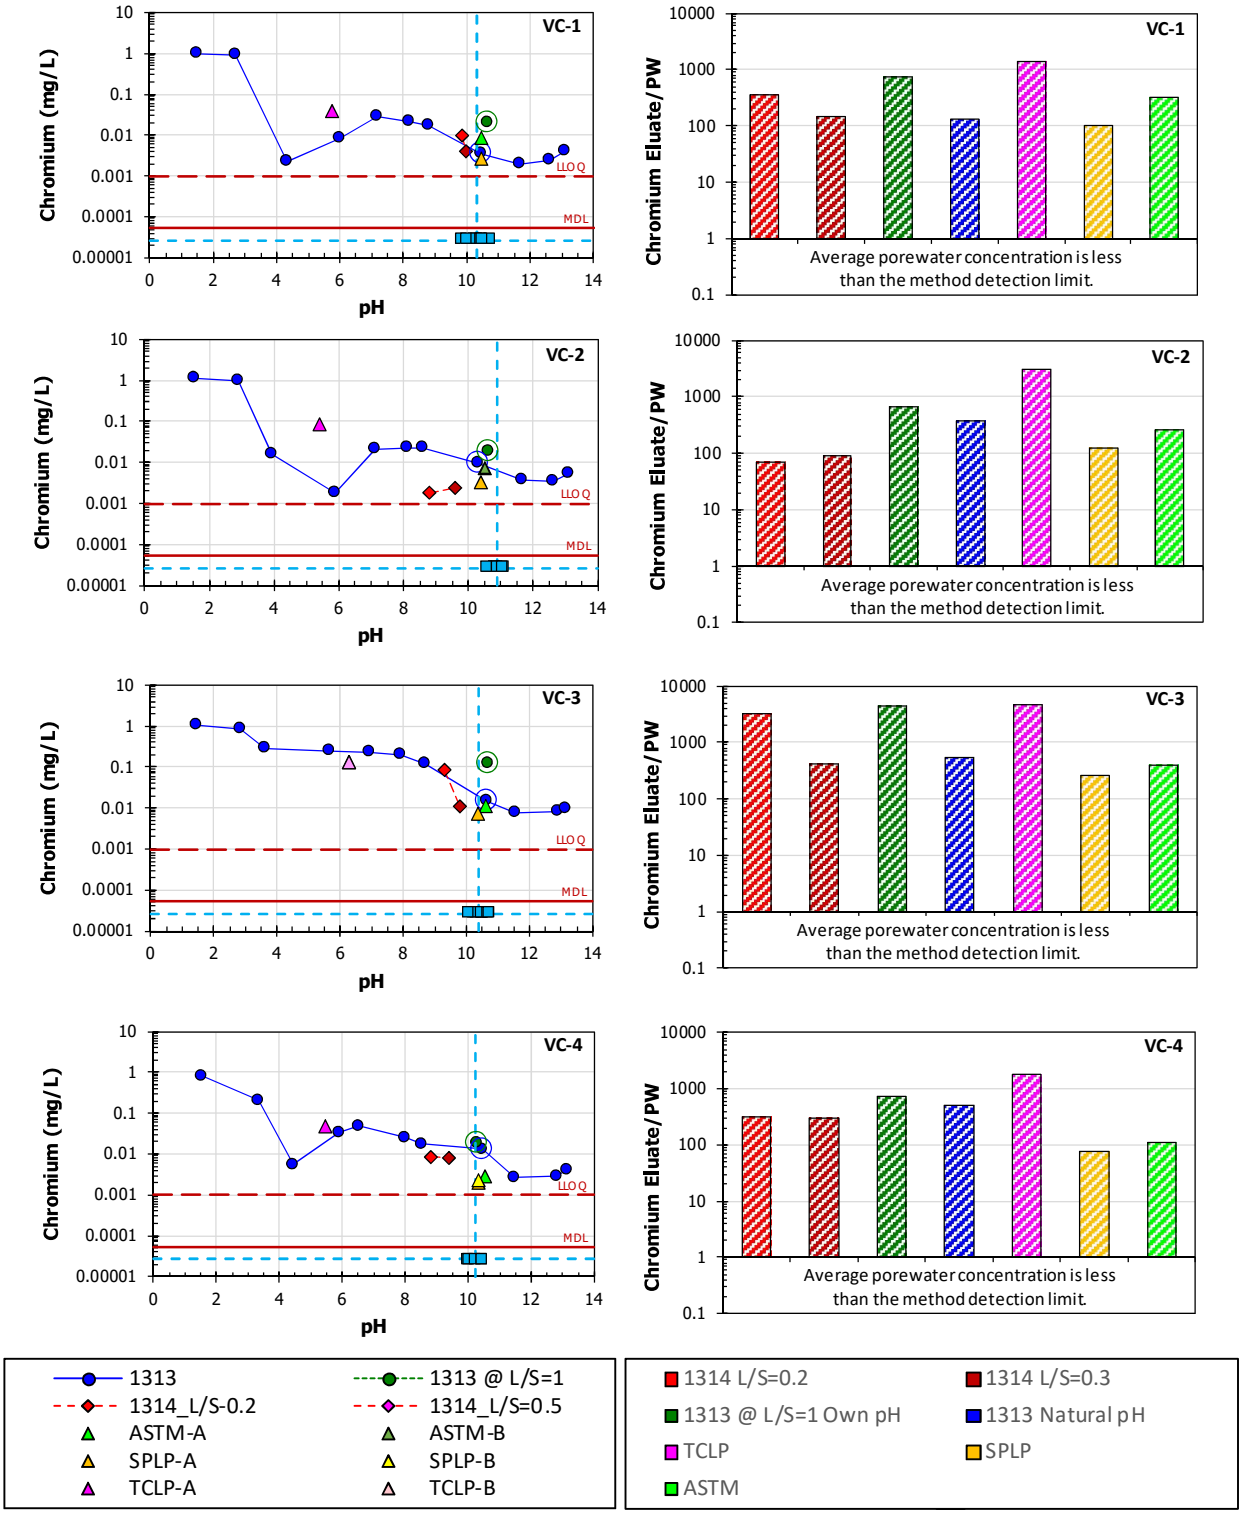

Figure 7-11
Chromium concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right); crosshatched ratio results indicate estimates based on at least one MDL value

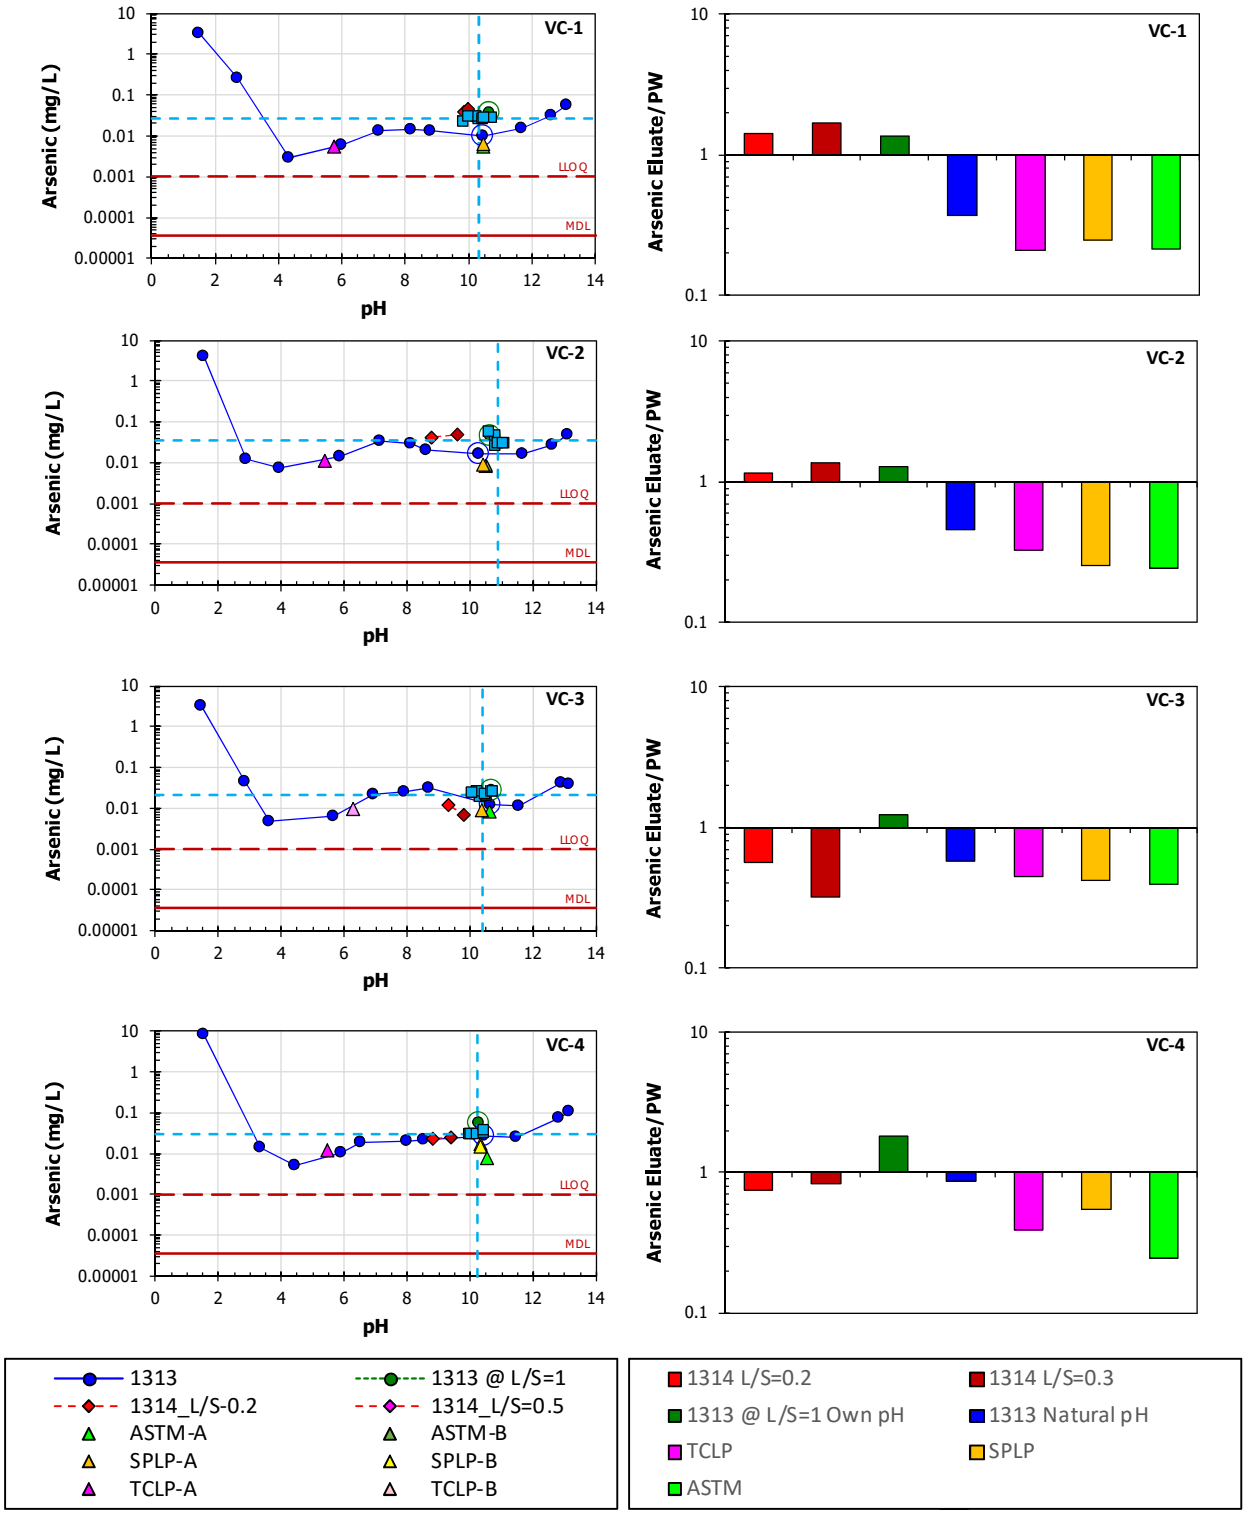

Figure 7-12
Arsenic concentration from leaching tests compared to measured and mean porewater concentrations shown as a function of pH (left) and as a ratio of eluate concentration to porewater concentration (right)

A qualitative summary of the ability of different leaching tests to estimate the measured porewater concentrations at each of the PAPs is shown in Table 7-2 for constituents with solubility-controlled LSP, Table 7-3 for constituents with wash-off followed by solubility control, Table 7-4 for constituents with available content-limited LSP, and Table 7-5 for constituents with non-detected data. In these tables, shading is used to indicate if the leaching test estimate is within 25% of the mean porewater concentration (green), within an order-of-magnitude of the mean porewater concentration (orange), or greater than an order-of-magnitude from the mean porewater concentration (red). These classifications are based on a percentage difference:

$$\%D = \frac{(z - PW)}{PW}$$

where %D is the percentage difference between leaching and porewater concentrations;
z is the leaching tests concentration (mg/L); and
PW is the mean porewater concentration from monthly PAP monitoring (mg/L).

When "GW <MDL" appears in the Notes column, the mean porewater concentration was less than the analytical MDL. Within the field of the table, an asterisk is used to indicate that the leaching test results were less than the MDL.

These tables provide an overview of the ability of leaching tests, conducted on materials collected from a suboxic environment and tests at mildly oxidizing conditions in a laboratory setting, to estimate porewater concentrations. This comparison indicated that the ability of leaching tests, conducted under specific test conditions, to predict porewater concentration varied by constituent and test. While no single leaching test consistently predicted concentrations within 25% of porewater concentrations for all constituents, the following observations were made:

- TCLP tends to over-predict porewater concentrations in alkaline ash (average pH_{nat}~10.4) by more than an order-of-magnitude for many constituents, in part, due to the pH (pH~5) imposed by the acetic acid leaching solution;
- EPA 1313, ASTM, and SPLP were usually within an order-of-magnitude for the solubility-controlled constituents where pH is the critical factor in LSP concentration and the leaching solution (i.e., deionized water for EPA 1313 at natural pH and ASTM, weak acid solution for SPLP) does not significantly alter eluate pH;
- EPA 1313 (L/S=10 L/kg-dry), ASTM (L/S~30 L/kg-dry), and SPLP (L/S~30 L/kg-dry) often under-predicted porewater concentrations by more than an order-of-magnitude for available content-controlled constituents because of the high L/S ratio relative to porewater L/S (0.35 L/kg-dry); and,
- EPA 1313_L/S=1 and low L/S 1314 column fractions usually yielded results within an order-of-magnitude of the porewater concentrations for both solubility-controlled and available content-controlled constituents.

When summarized by constituent, leaching test predictions *typically*:

- Over-predicted porewater concentrations for Sb and Cr;

- Under-predicted porewater concentrations for Ba, B, Cd, Ca, Cl^-, DOC, Li, Mo, Ni, K, Na, Sr, and SO_4^{-2};
- Over-predicted at L/S=0.2 and under-predicted at higher L/S for Co;
- Over-predicted at L/S<1.0 and under-predicted at higher L/S for P;
- Over-predicted at L/S<=1.0 and under-predicted at higher L/S for V; and,
- Did not consistently over- or under-predict porewater concentrations for As, Cu, DIC, Fe, Se, Tl, and Zn.

The above constituent evaluation does not include TCLP tests where leaching concentrations were primarily higher than porewater or those constituents where eluates and porewater concentrations were both usually less than MDL (i.e., Be, Br^-, F^-, Pb, and Ag).

The results of this qualitative summary should not be used without consideration of the redox conditions of the field and should always be shown along with the graphical data (e.g., Figure 7-10 through Figure 7-12) that indicate the pH result for the tests. For example, the table indicates that TCLP would provide a good estimate of porewater concentration for B; however, this is somewhat of a coincidence because the pH of TCLP is more than four pH units less than the natural pH of the ash.

8
SUMMARY OF OBSERVATIONS

The data presented in this report represent the results of geotechnical, hydrologic, and leaching characterization of samples of coal ash collected from an active CCP management unit at Plant 42197. The hydraulic conductivity of intact cores from the coal ash deposit was measured in context of the distribution of particles in the coal ash samples and the overburden pressure associated with disposal at depth within the coal ash deposit. The leaching test results for LEAF tests (i.e., EPA Methods 1313 and 1314) were compared to the results for traditional tests (i.e., ASTM, TCLP, and SPLP). In addition, porewater estimates derived from leaching tests were compared to measured porewater concentrations, and measured porewater concentrations were compared to groundwater concentrations.

Based on the presented data and analysis, the following general observations can be made:

- Despite differences in coal ash placement (dry-handled ash in the upper portion and wet-handled ash in the lower portion), ***there was little observed variability in vertical concentration profiles***. This observation, in combination with initial concentration from percolation column test results, suggest that infiltration moving through the unsaturated dry-handled ash (e.g., from precipitation, liquid dumps, water spray for dust management) results in migration of readily dissolved constituents from the dry-handled material into the underlying wet-handled coal ash. ***Downward movement of soluble constituents results in the pH and porewater composition within the saturated material similar to the low L/S extraction fractions of composited dry material***.
- The ratio of the available content to the total content shows that ***only a small fraction of total content of most trace constituents is leachable*** over a broad pH range.
- ***Suboxic to anoxic conditions are established at relatively shallow depths (> 5 m) below the ground surface of the dry-handled material***. Oxygen penetration from the surface is limited because of abiotic and biotic reactivity of the freshly deposited fly ash in conjunction with pore filling due to water additions to maintain dust control and compaction of additionally added materials (e.g., bottom ash) for structural workability (truck access).
- ***The high pH within the porewater of deposited material prevents development of significant microbial activity at depths greater than 5 m below the ground surface*** (or potentially even at shallower depths). This is in contrast to observations in some impoundments of only wet-handled material (EPRI, 2020), which showed nearly neutral porewater pH and indicators of robust microbial reduction of iron and sulfate along with methanogenesis.
- ***Hydraulic conductivity of the ashes typically was within the range of 10^{-5} to 10^{-6} cm/s***, with the lower hydraulic conductivities corresponding to higher dry unit weight. Fines content and 2-mm clay content had no consistent influence on hydraulic conductivity, in contrast to

previous experience (EPRI, 2020). Hydraulic conductivity diminished as the effective stress increased, but only modestly.

- ***Some parameters in the PAP porewater (e.g., pH, temp, B, Co, Ni, and Zn) exhibited temporal variability*** due to factors such as seasonal changes or impacts of damage and repair of porewater access points. Other constituents remained relatively constant within each porewater access point throughout the 8-month monitoring period. ***Spatial variability was observed for some constituents between PAPs; however, no consistent pattern was observed***. With the exception of Cu and Zn, concentrations between PAPs were within an order of magnitude.
- There were insufficient data from limited collection points to identify relationships between porewater and downgradient groundwater concentrations. For example, no upgradient groundwater well was identified to provide groundwater conditions in the flow path prior to the landfill. ***The limited data collected from downgradient monitoring wells and PAPs suggest that porewater concentration alone is an unreliable indicator that a constituent has had an impact on elevated groundwater concentrations or for prediction of downgradient concentrations at this site***.
- Traditional leaching tests, such as TCLP, SPLP, and ASTM, are poorer indicators of measured porewater concentrations than LEAF tests. ***Low liquid-to-solid ratio (L/S) eluates from EPA Method 1314 are better indicators than the traditional tests and EPA 1313 for concentrations for available content-limited constituents (e.g., B, Cd, Cl^-, Mo, Se, and SO_4^{-2}) because of the strong L/S-dependence.*** The data presented here showed that the traditional tests, with an L/S greater than 20 L/kg-dry, and EPA 1313 at L/S=10 L/kg-dry often under-predicted field porewater concentrations by an order of magnitude or more. These results indicate that additional information (e.g., available content and porewater L/S) is needed to provide a reasonable approximation of porewater concentrations. ***For constituents with solubility-controlled liquid-solid partitioning (e.g., As, Sb, and Tl), EPA 1313 tests at L/S=1 L/kg-dry provide an estimate of porewater concentrations generally within a factor of 2.*** The combination of pH-dependent leaching data (EPA 1313) with percolation column test results (EPA 1314) provides valuable information for geochemical modeling.
- For field environments that are oxidizing to slightly reducing, leaching test data usually approximated field porewater concentrations of solubility-controlled constituents within an order of magnitude. ***Because of the oxic to suboxic subsurface conditions at this site, sampling, laboratory handing, and testing conditions did not appear to significantly influence the redox condition of the field material.*** This is in contrast to impoundments with highly reducing subsurface conditions, where material handling in the presence of oxygen during sampling and laboratory testing can significantly impact test results. The only constituent not well defined by any of the LEAF tests was chromium, the result for which may have been influenced by oxidization of materials during collection from a suboxic environment and testing in an oxic laboratory. The leaching results for chromium indicate that laboratory testing results for redox-sensitive elements (e.g., As, Cr, Sb, Se, V) may not directly reflect the leaching anticipated in porewater when the field environment is highly reducing, in part due to oxidation incurred during sampling, handling, and testing.

B
INDIVIDUAL SPLIT SPOON SAMPLE ANALYSIS

Table of Appendices

B-1 Concentration Profiles from In-Field Low L/S Extractions

B-2 Standardized Concentration Profiles of In-field Low L/S Extractions Using the Global Material Mean and Standard Deviation

B-3 Comparison of Standardized Release Profiles for Low L/S and L/S≈1 Extractions

B-1 Concentration Profiles from In-Field Low L/S Extractions

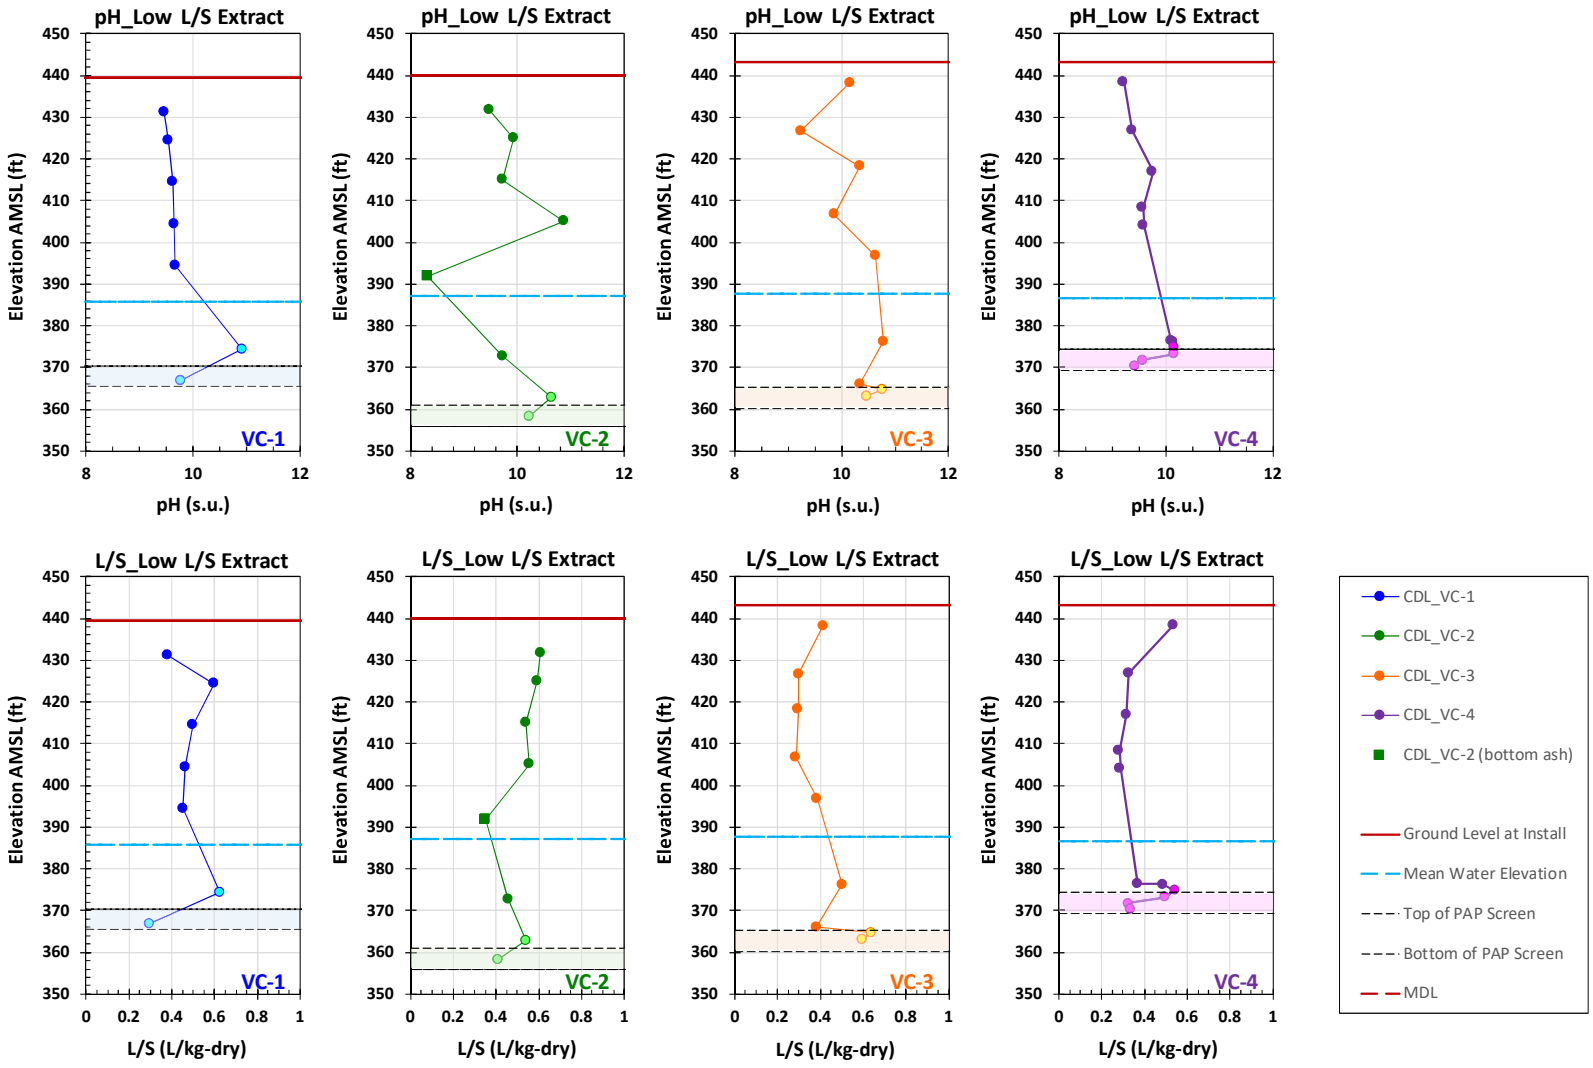

Figure B-1
Concentration profiles from in-field low L/S extractions: pH and liquid-to-solid ratio (L/S)

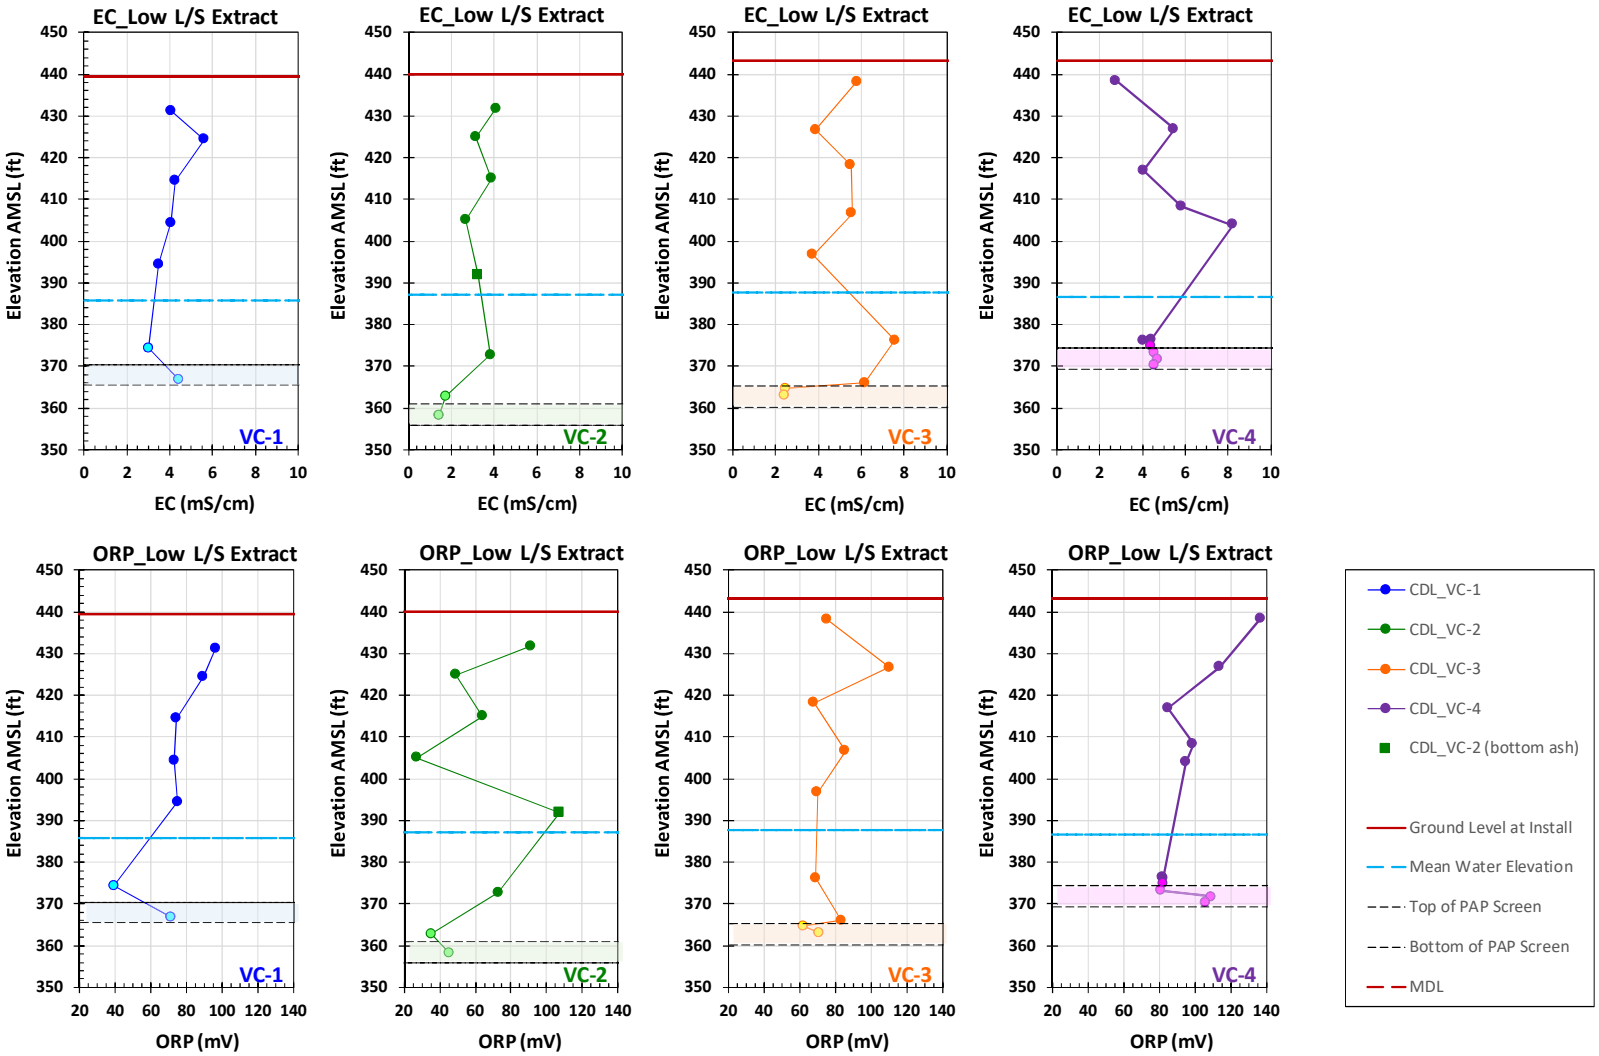

Figure B-2
Concentration profiles from in-field low L/S extractions: electrical conductivity (EC) and oxidation-reduction potential (ORP)

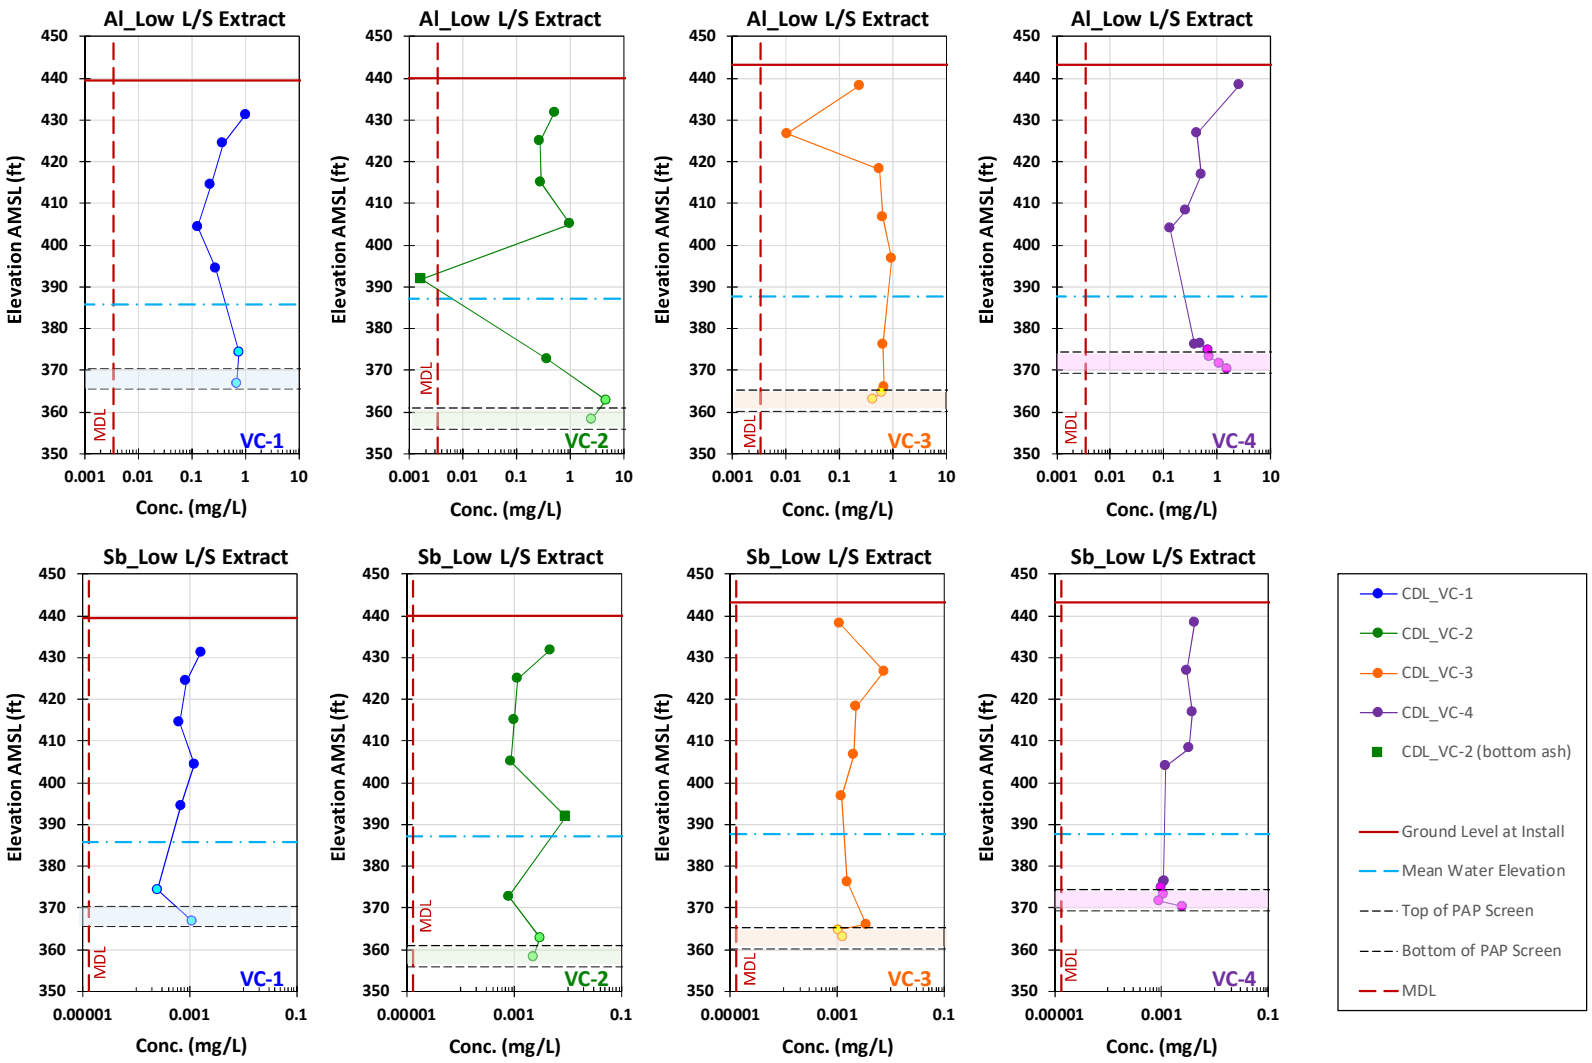

Figure B-3
Concentration profiles from in-field low L/S extractions: aluminum and antimony

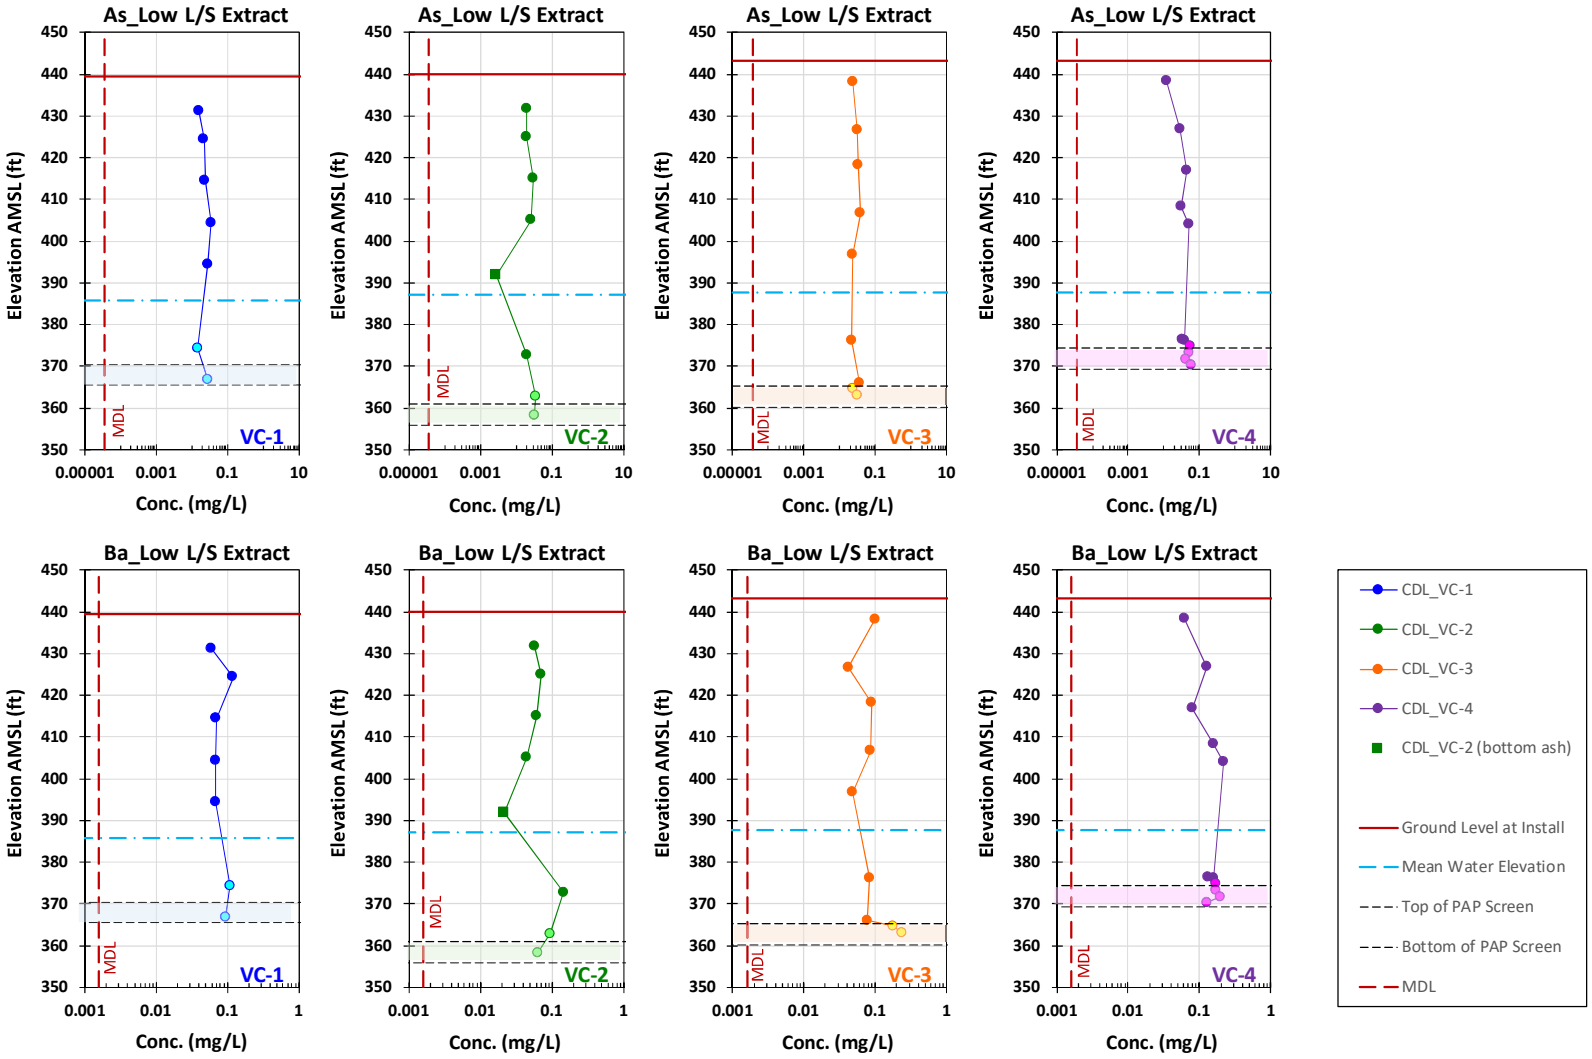

Figure B-4
Concentration profiles from in-field low L/S extractions: arsenic and barium

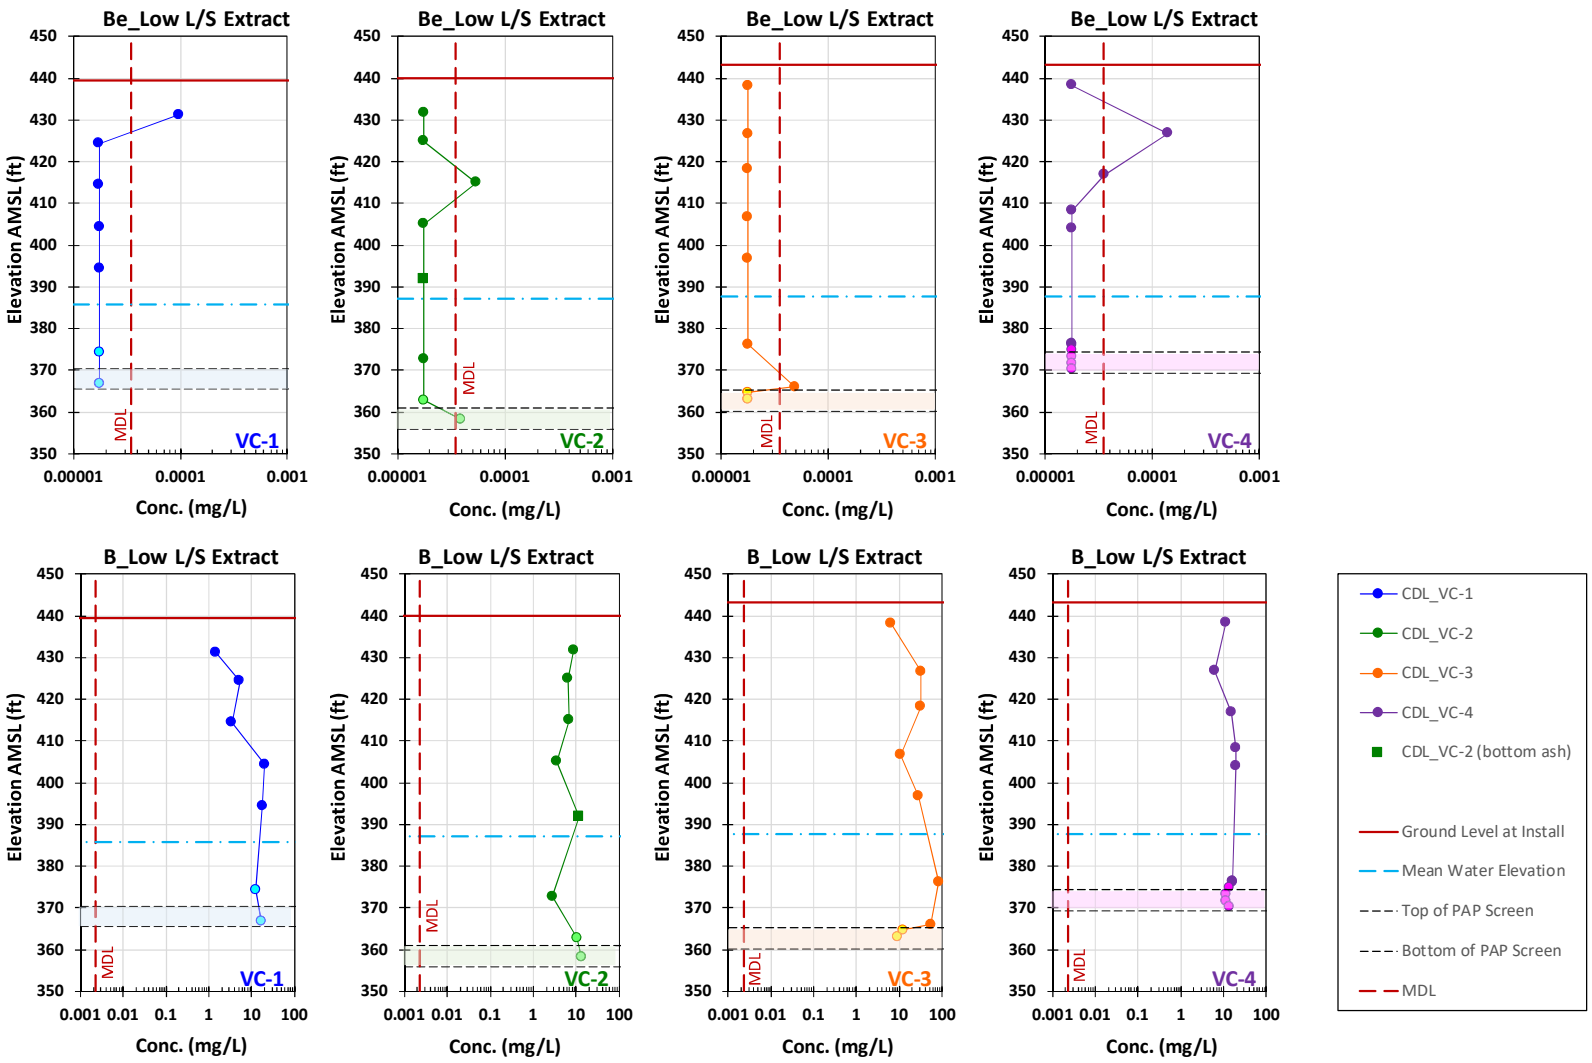

Figure B-5
Concentration profiles from in-field low L/S extractions: beryllium and boron

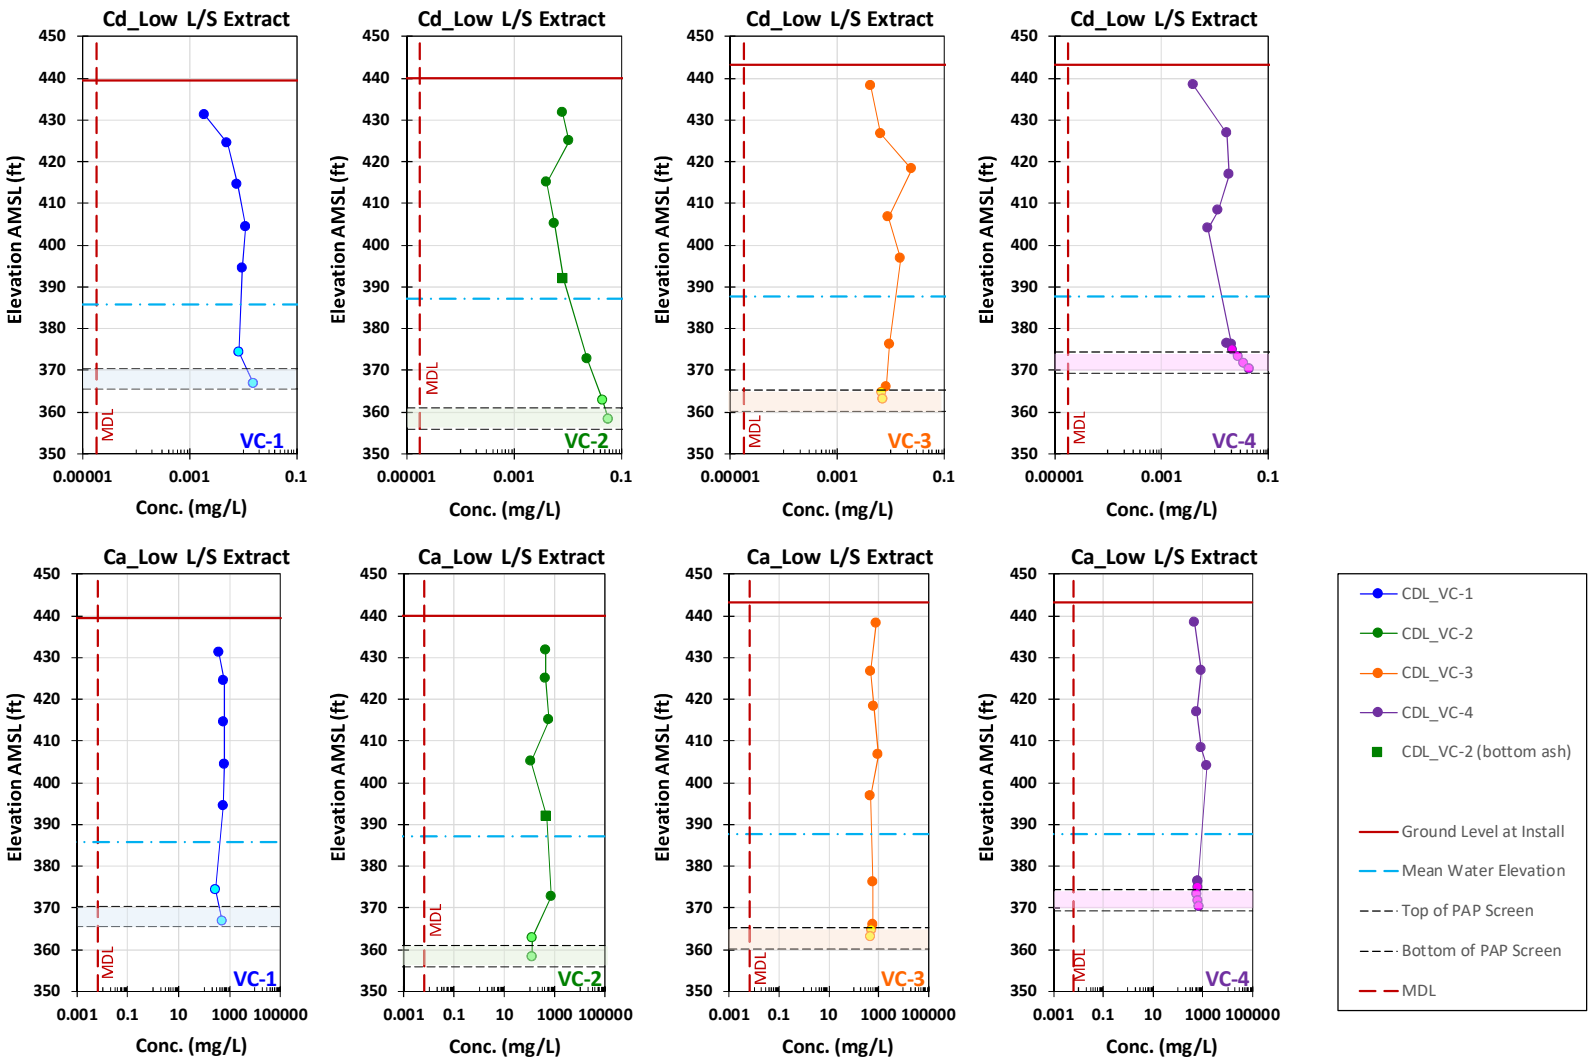

Figure B-6
Concentration profiles from in-field low L/S extractions: cadmium and calcium

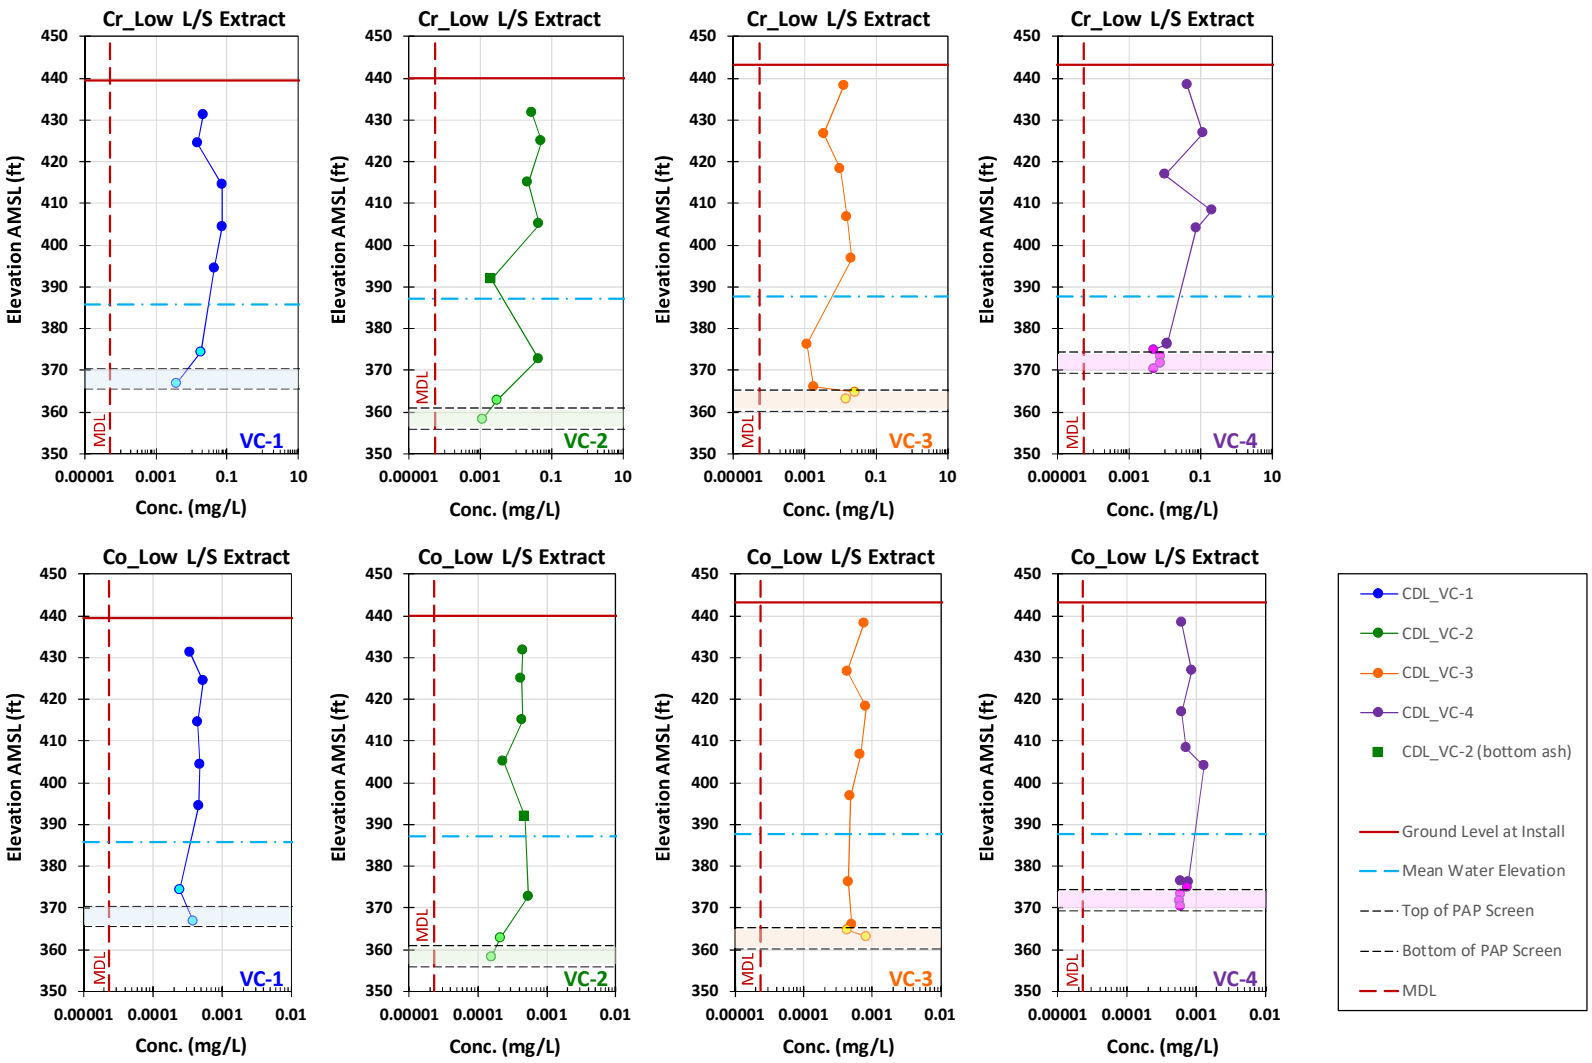

Figure B-7
Concentration profiles from in-field low L/S extractions: chromium and cobalt

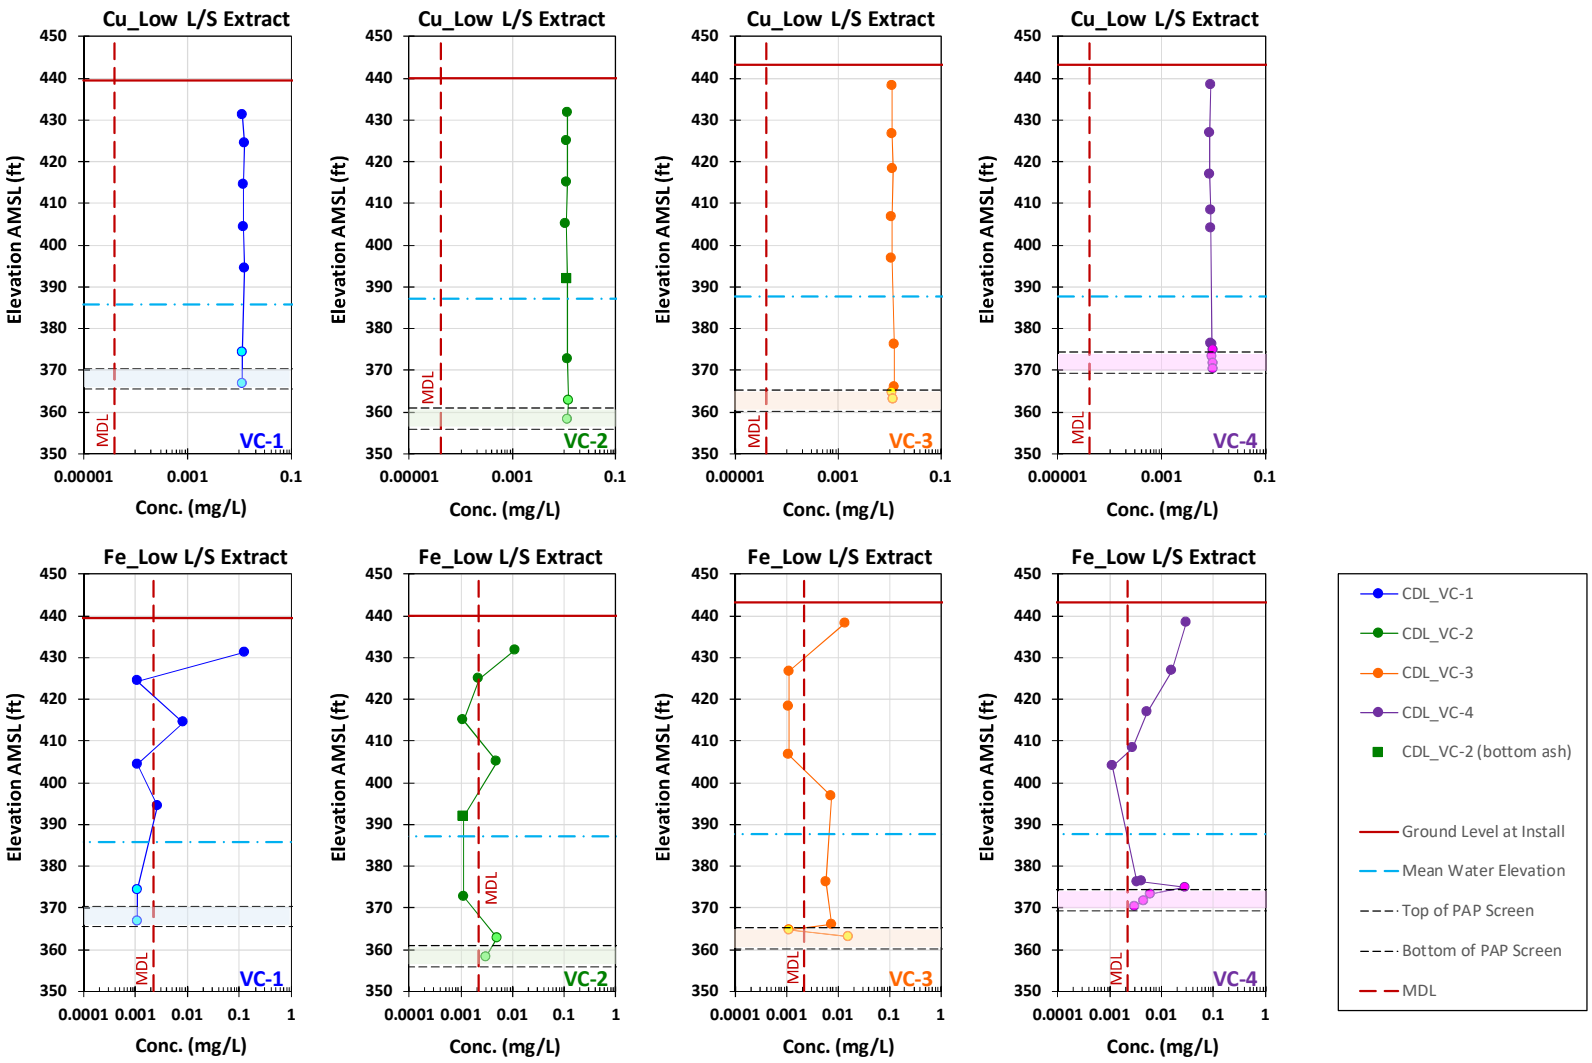

Figure B-8
Concentration profiles from in-field low L/S extractions: copper and iron

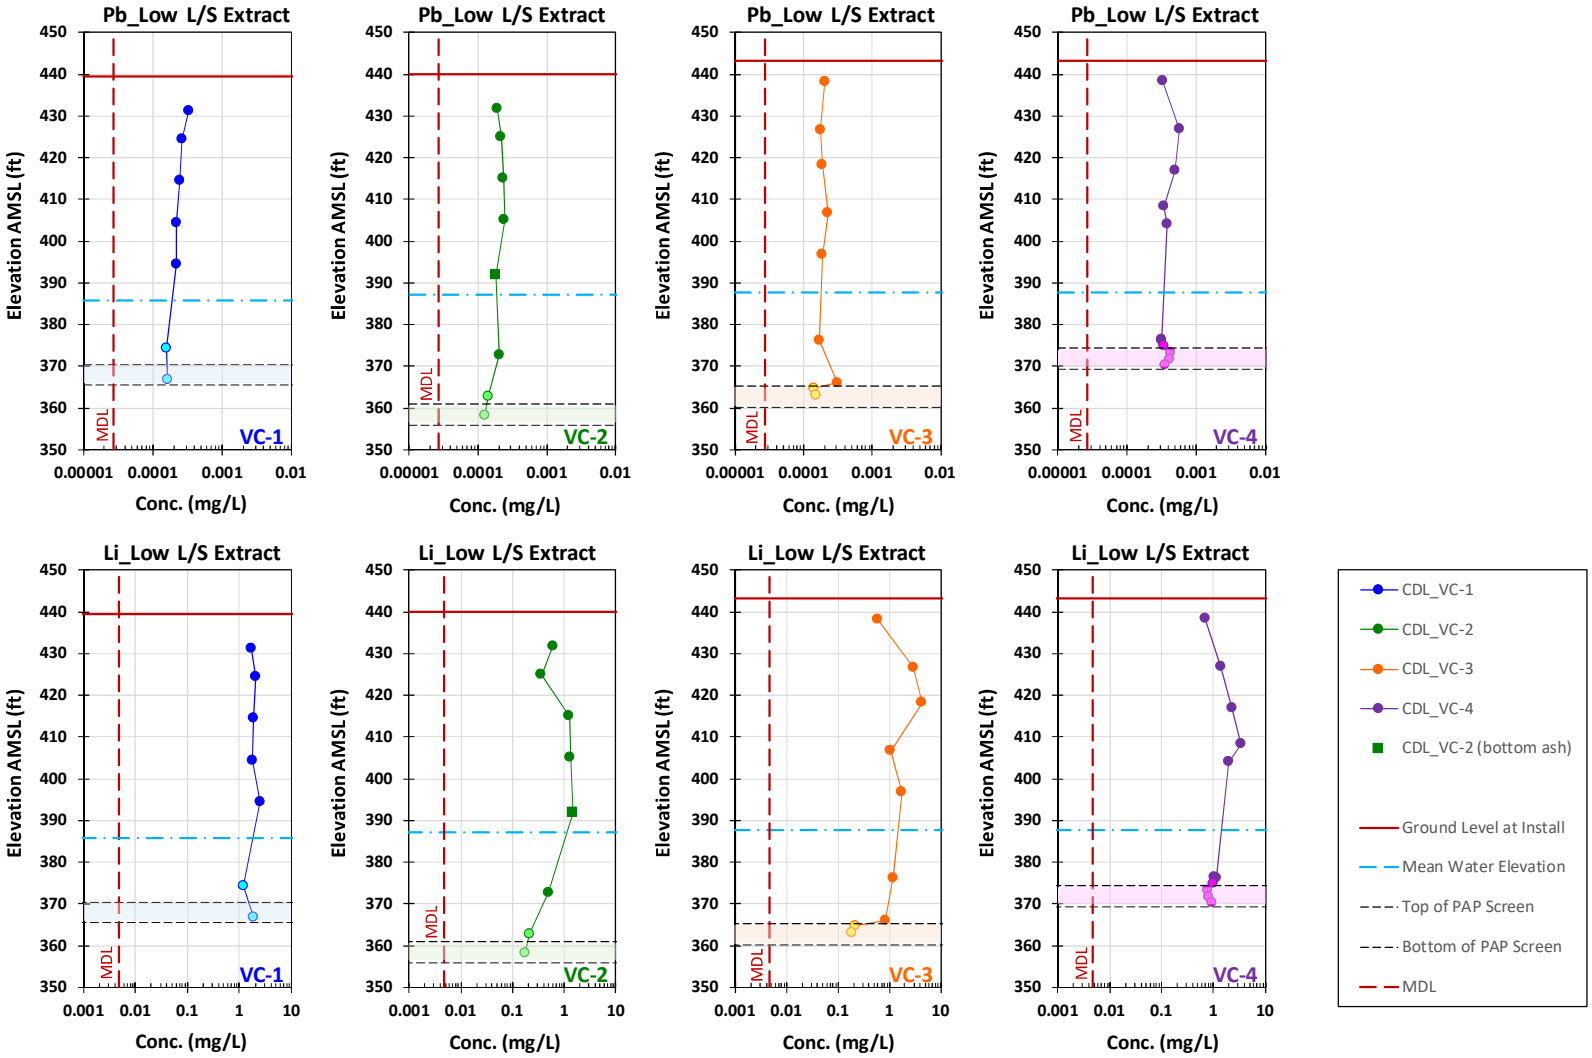

Figure B-9
Concentration profiles from in-field low L/S extractions: lead and lithium

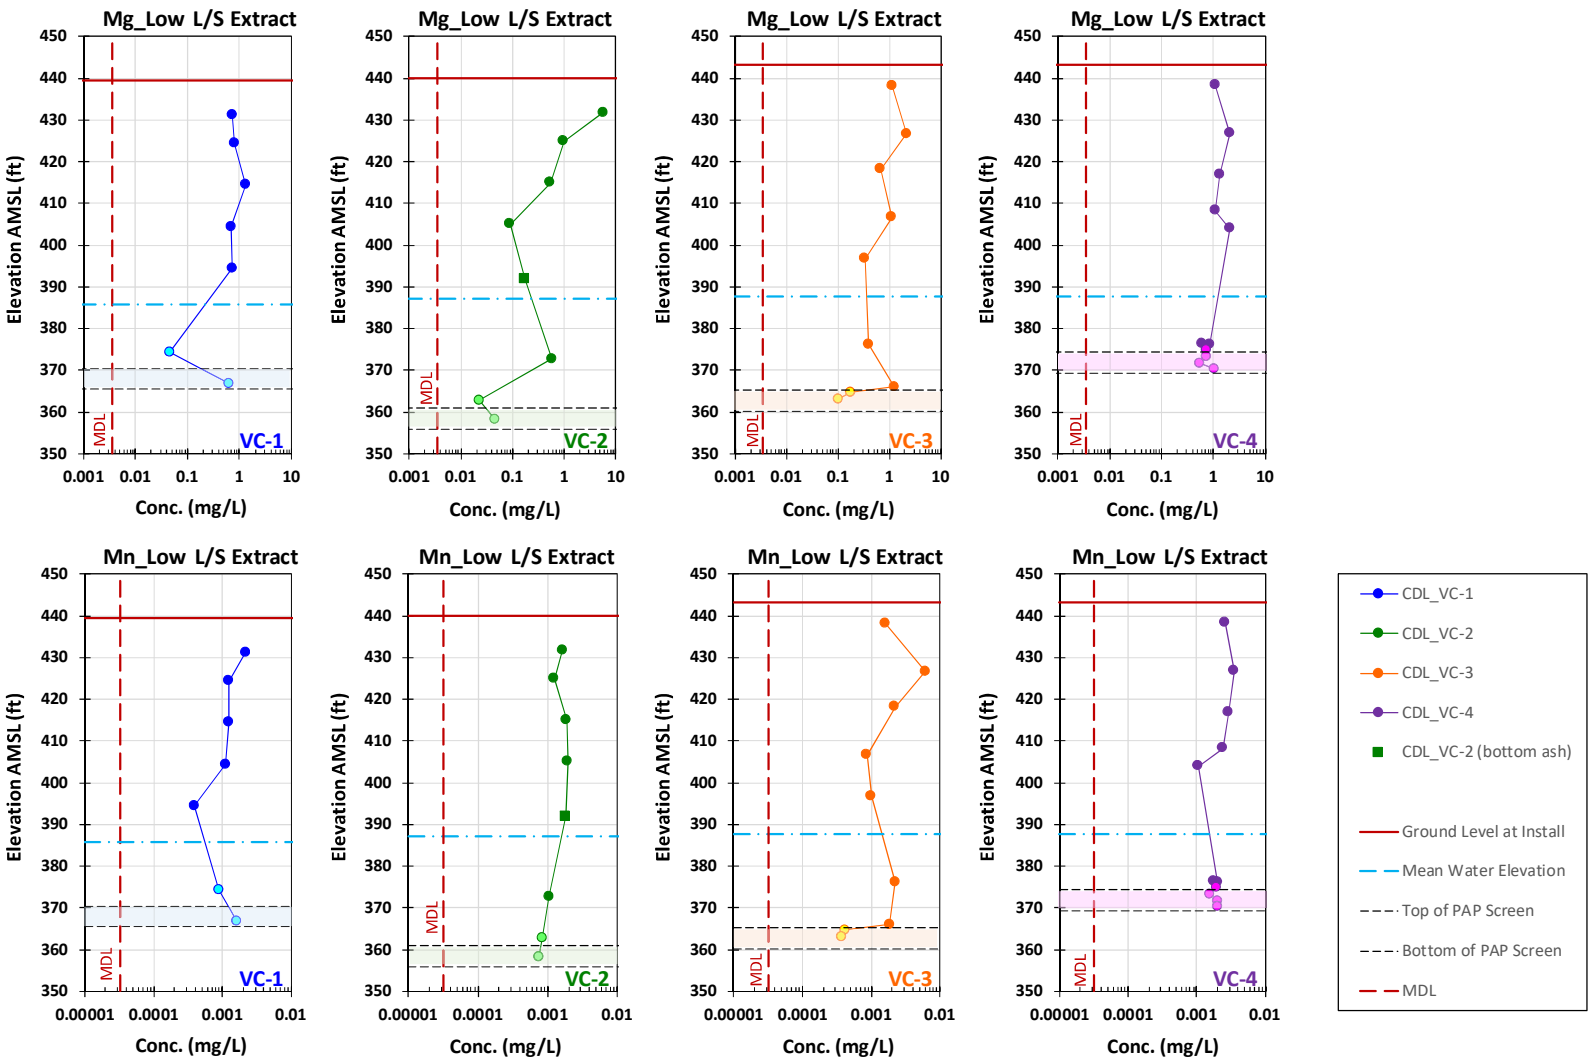

Figure B-10
Concentration profiles from in-field low L/S extractions: magnesium and manganese

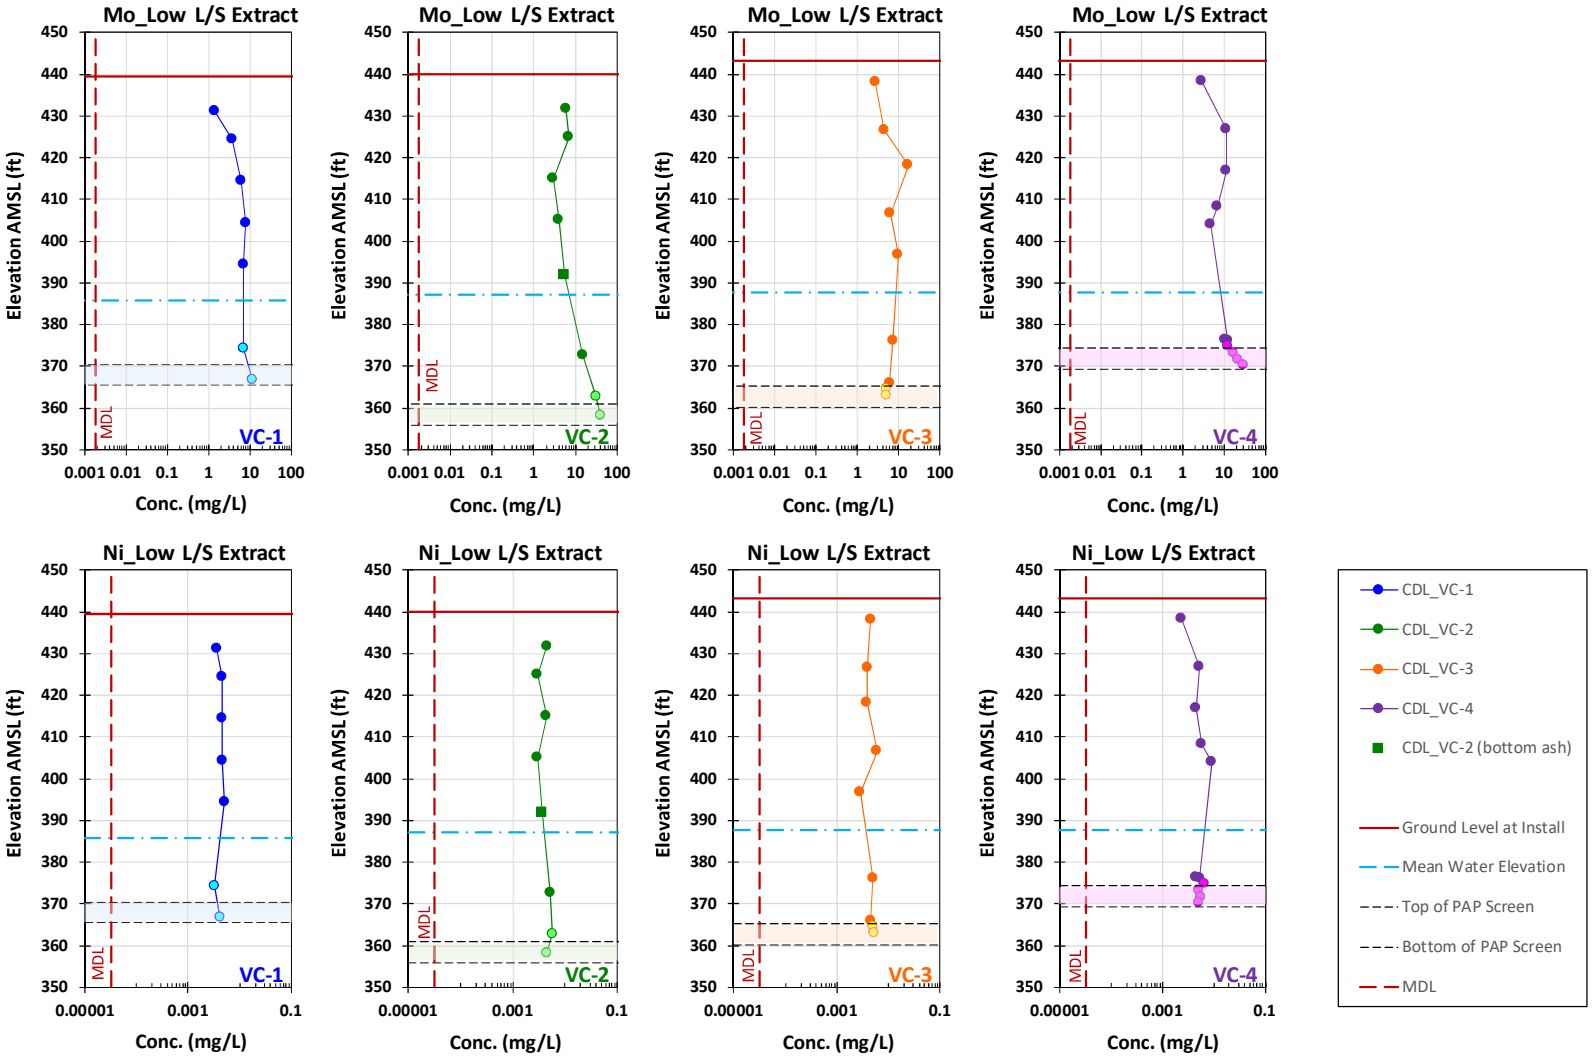

Figure B-11
Concentration profiles from in-field low L/S extractions: molybdenum and nickel

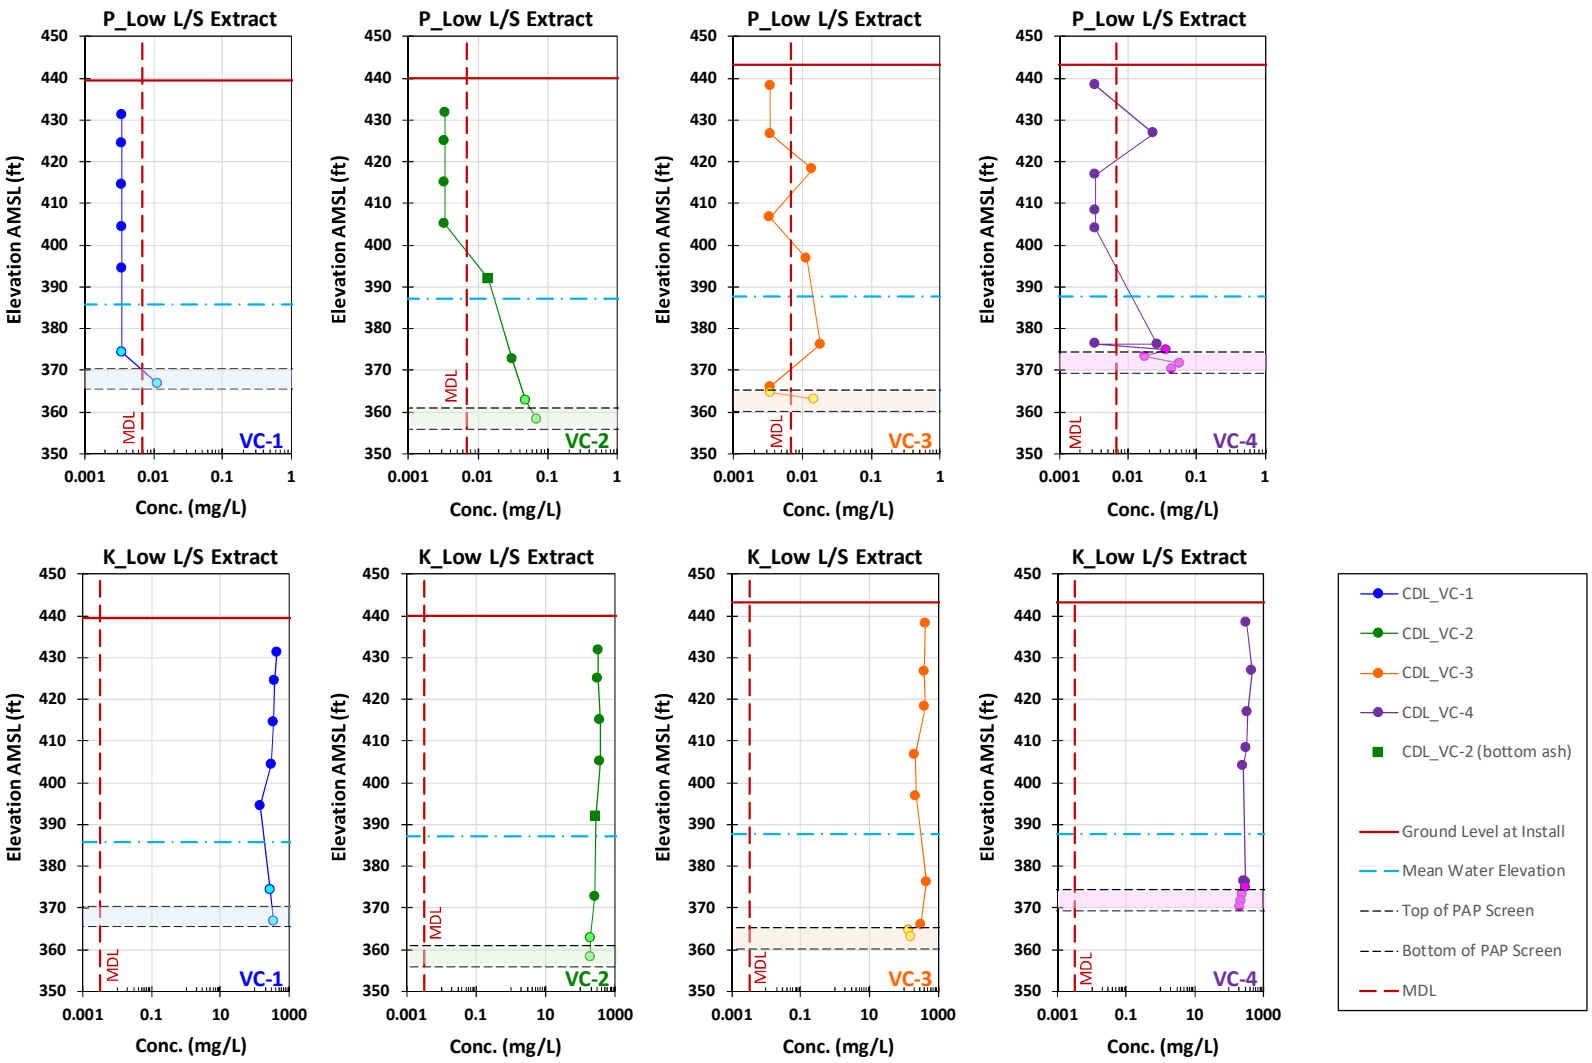

Figure B-12
Concentration profiles from in-field low L/S extractions: phosphorus and potassium

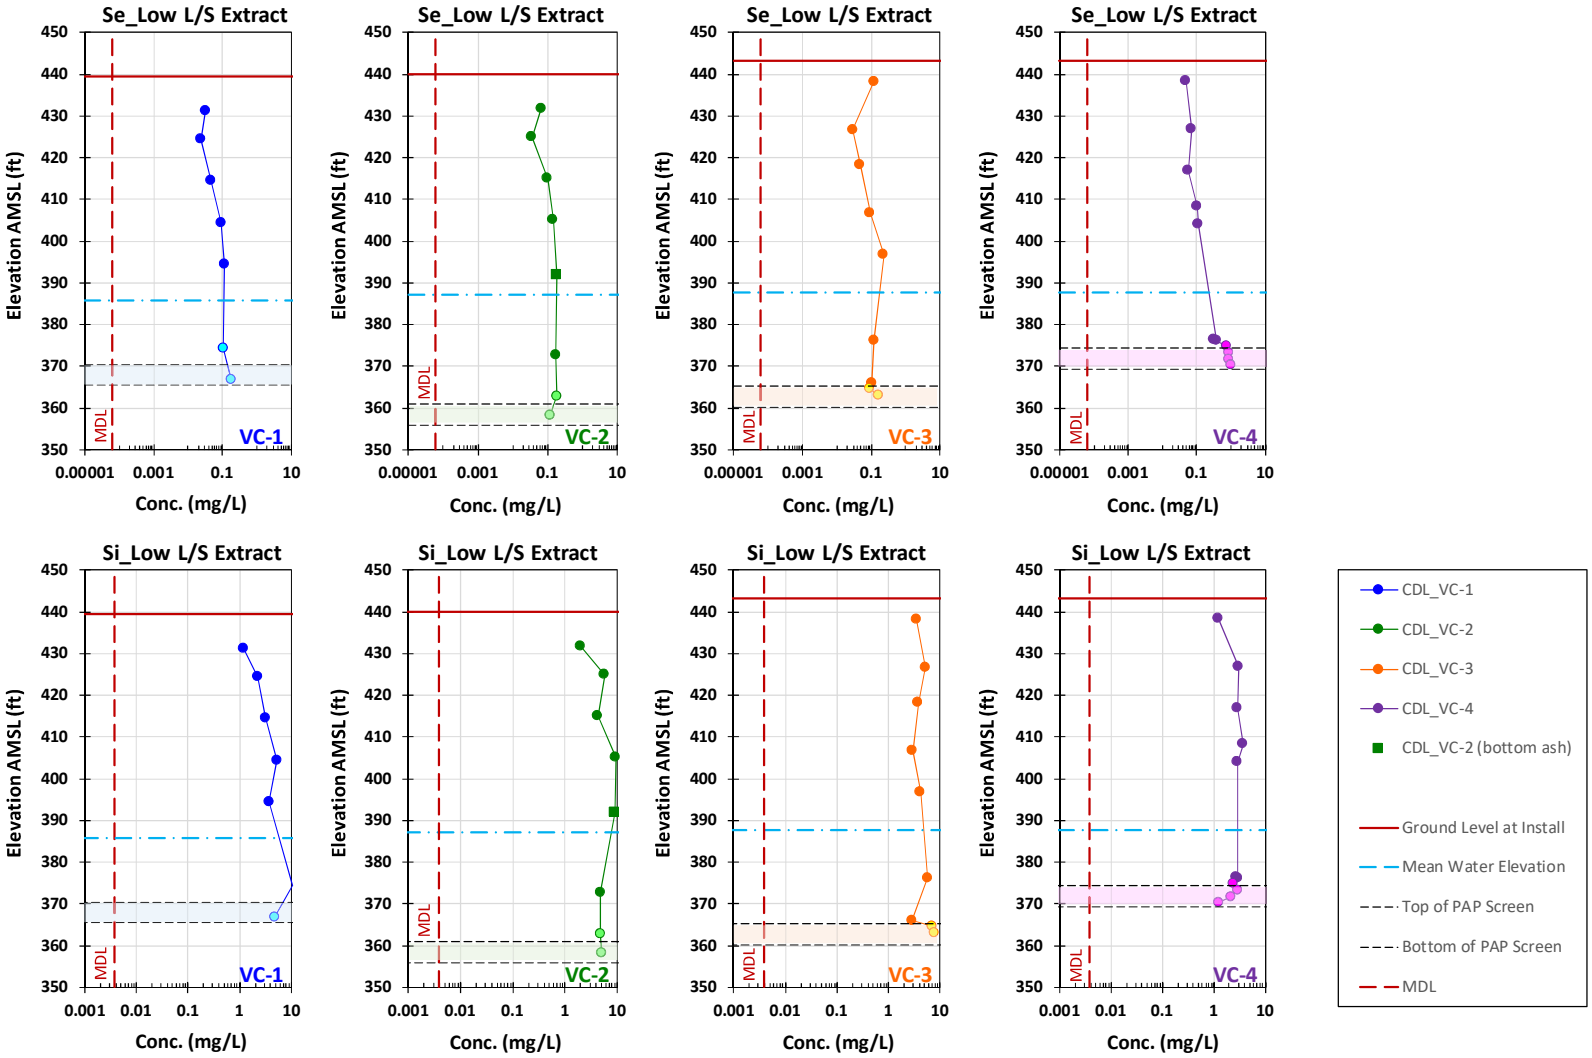

Figure B-13
Concentration profiles from in-field low L/S extractions: selenium and silicon

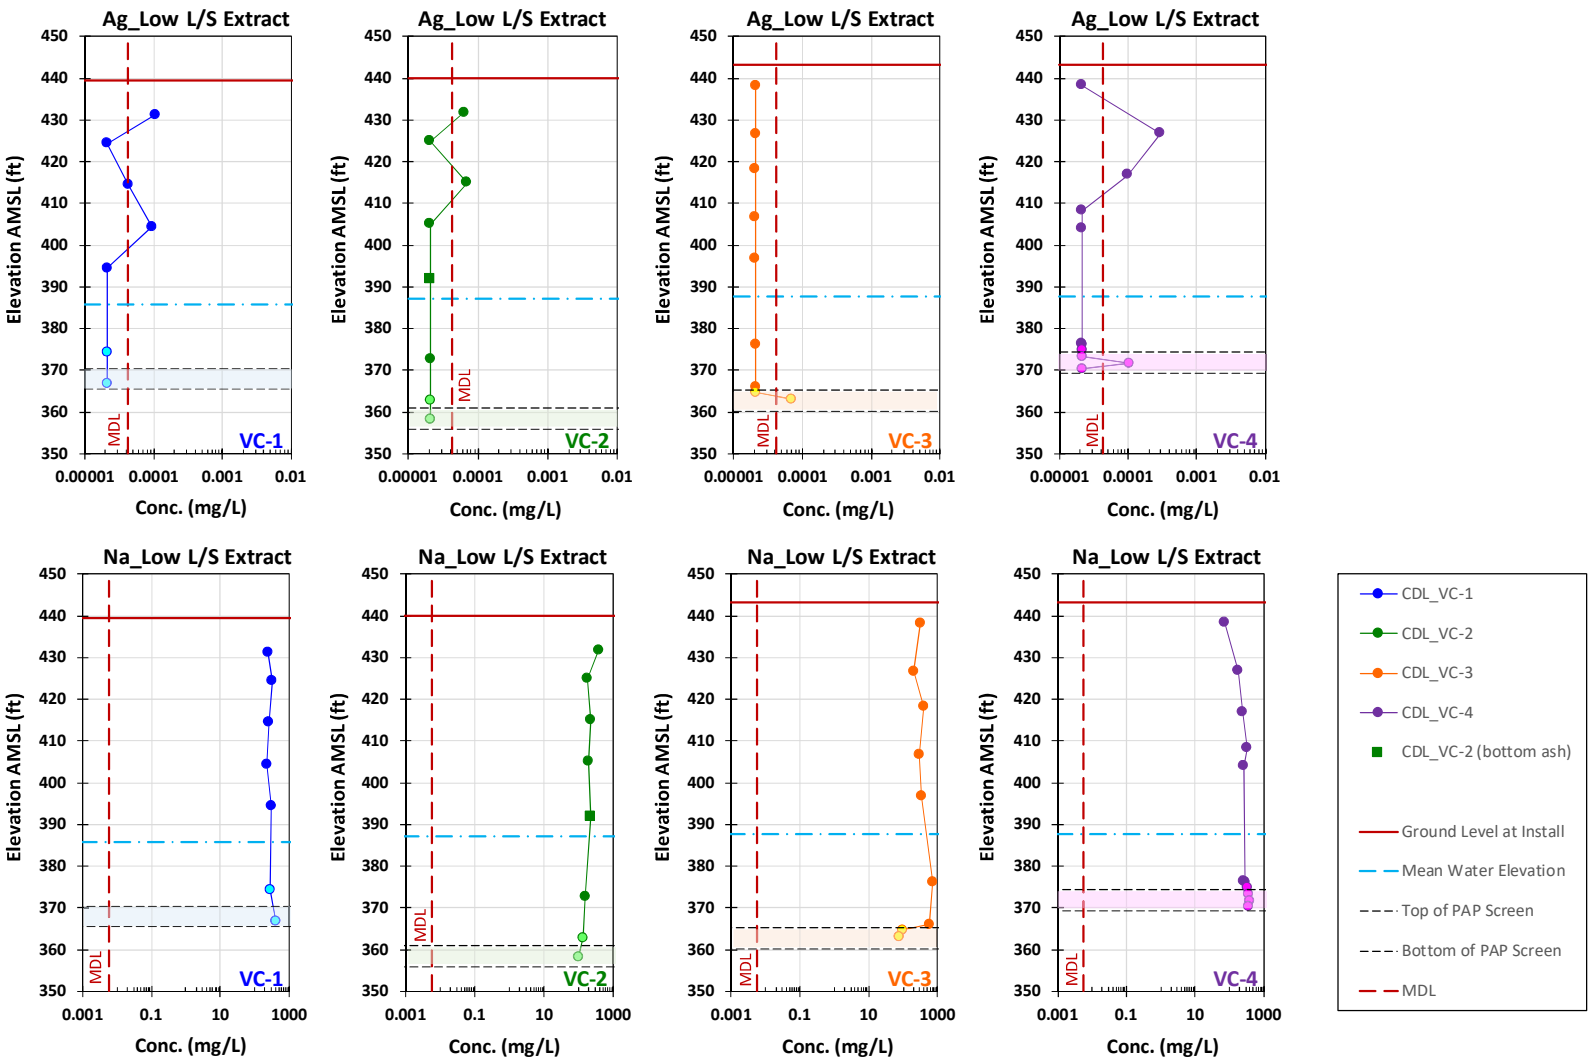

Figure B-14
Concentration profiles from in-field low L/S extractions: silver and sodium

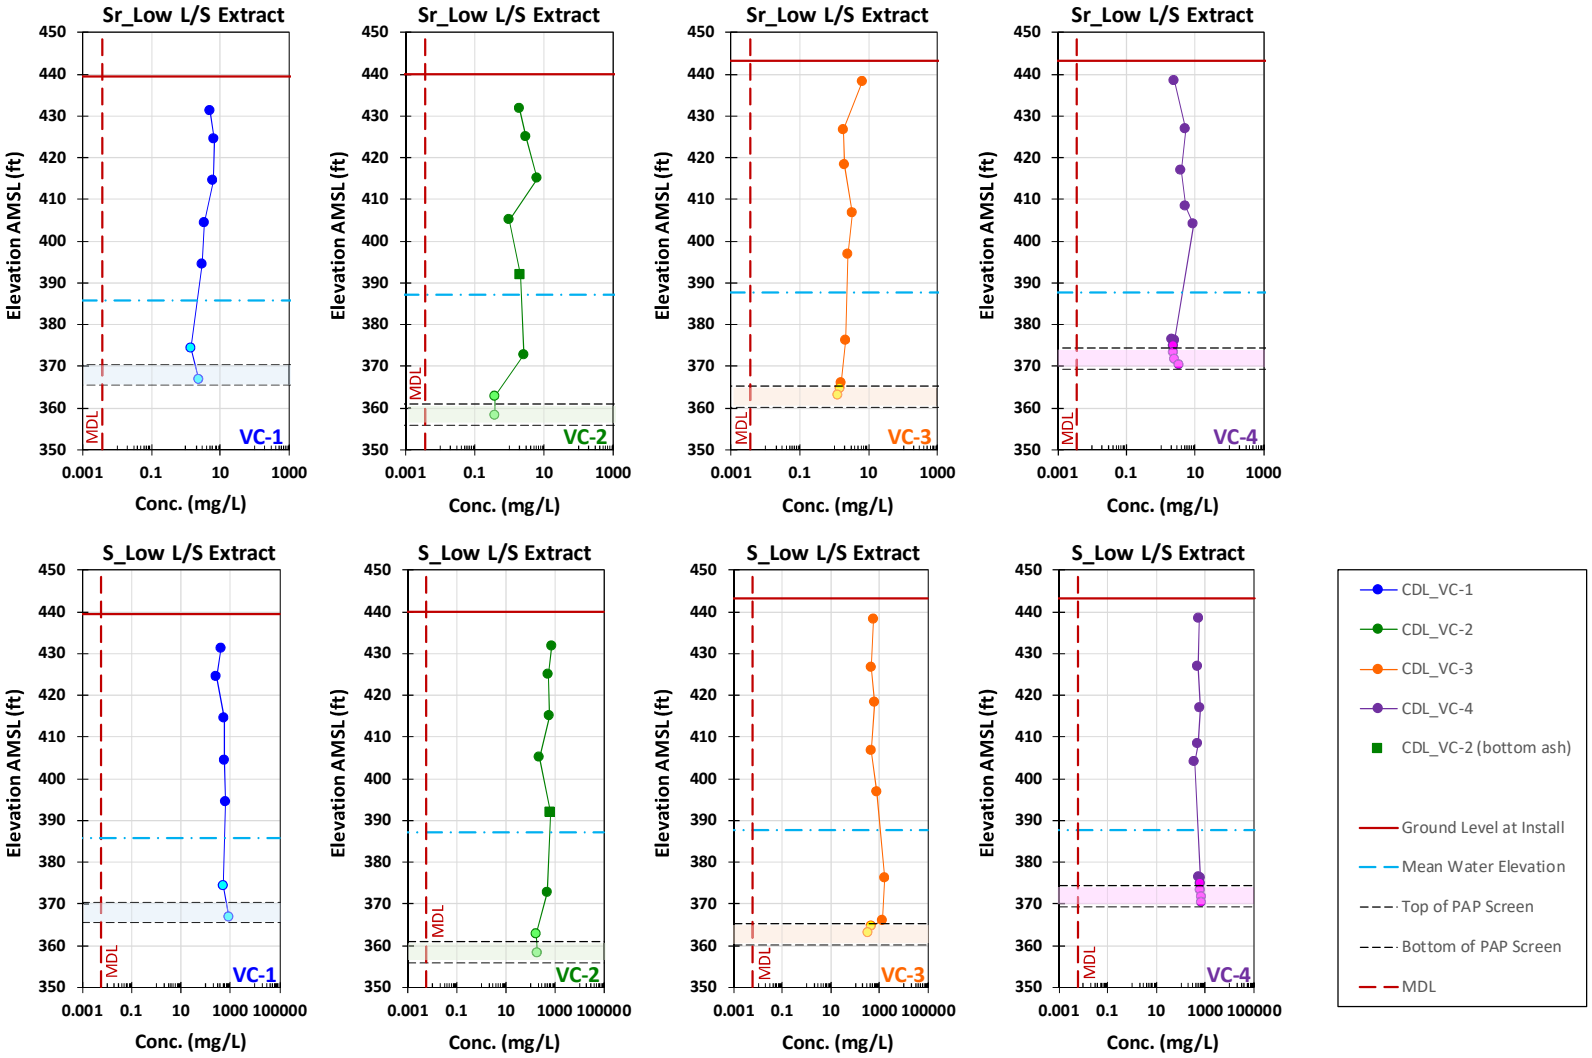

Figure B-15
Concentration profiles from in-field low L/S extractions: strontium and sulfur

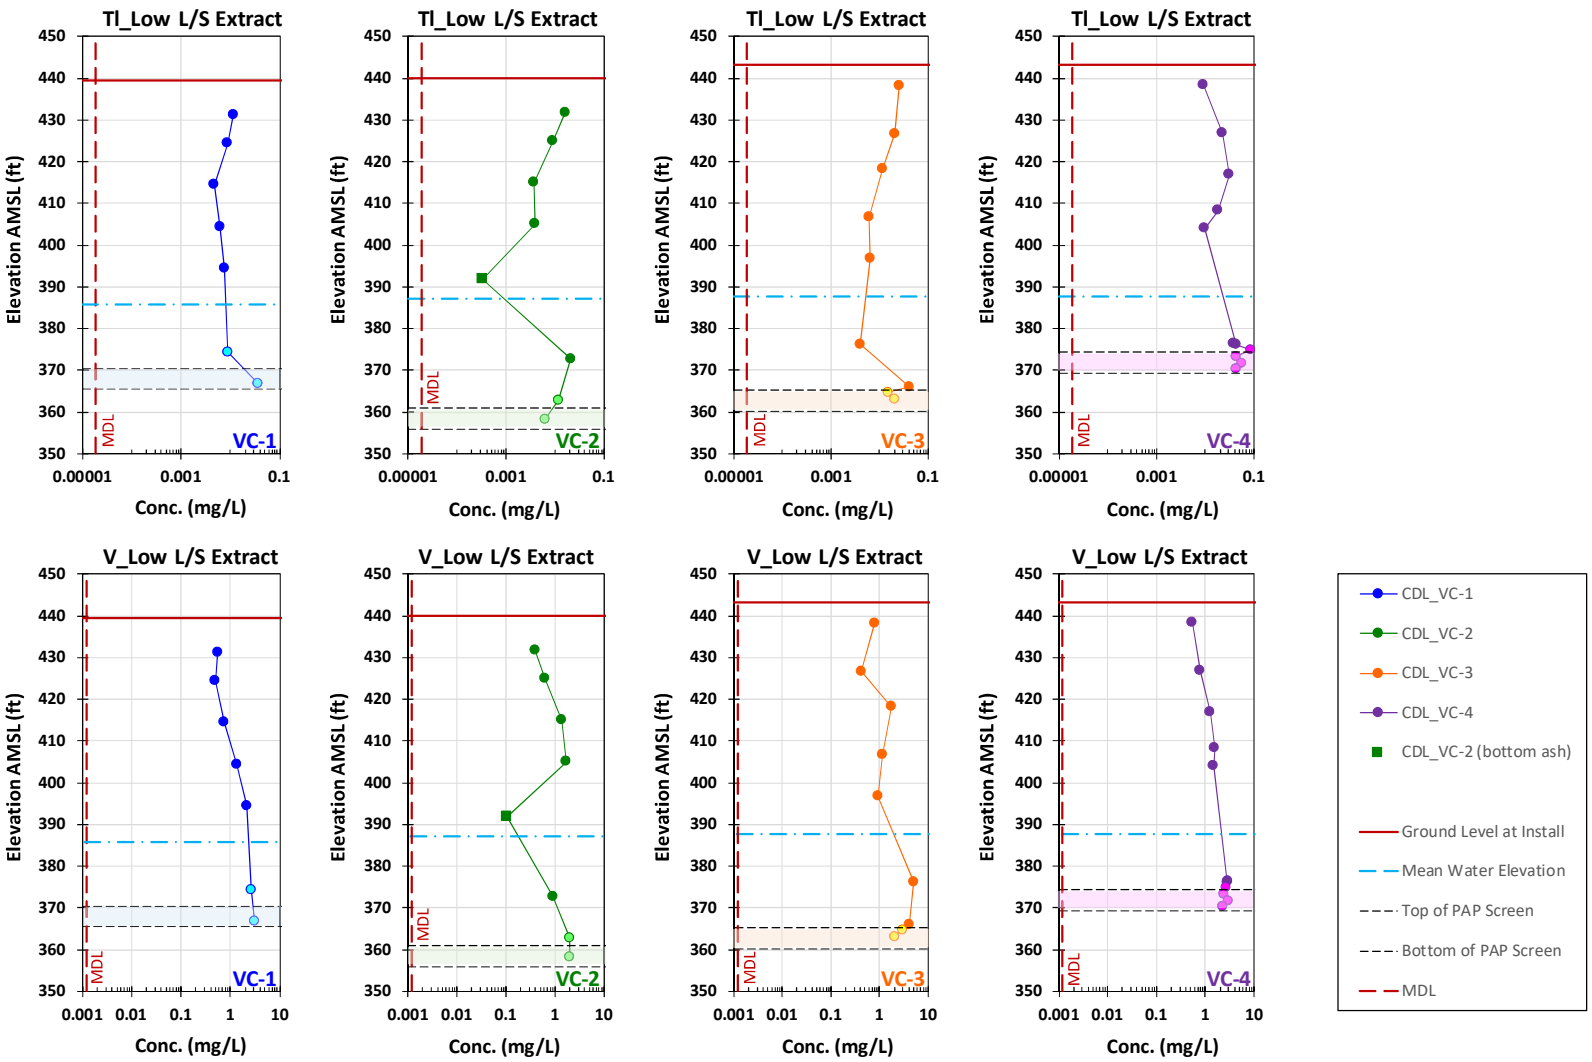

Figure B-16
Concentration profiles from in-field low L/S extractions: thallium and vanadium

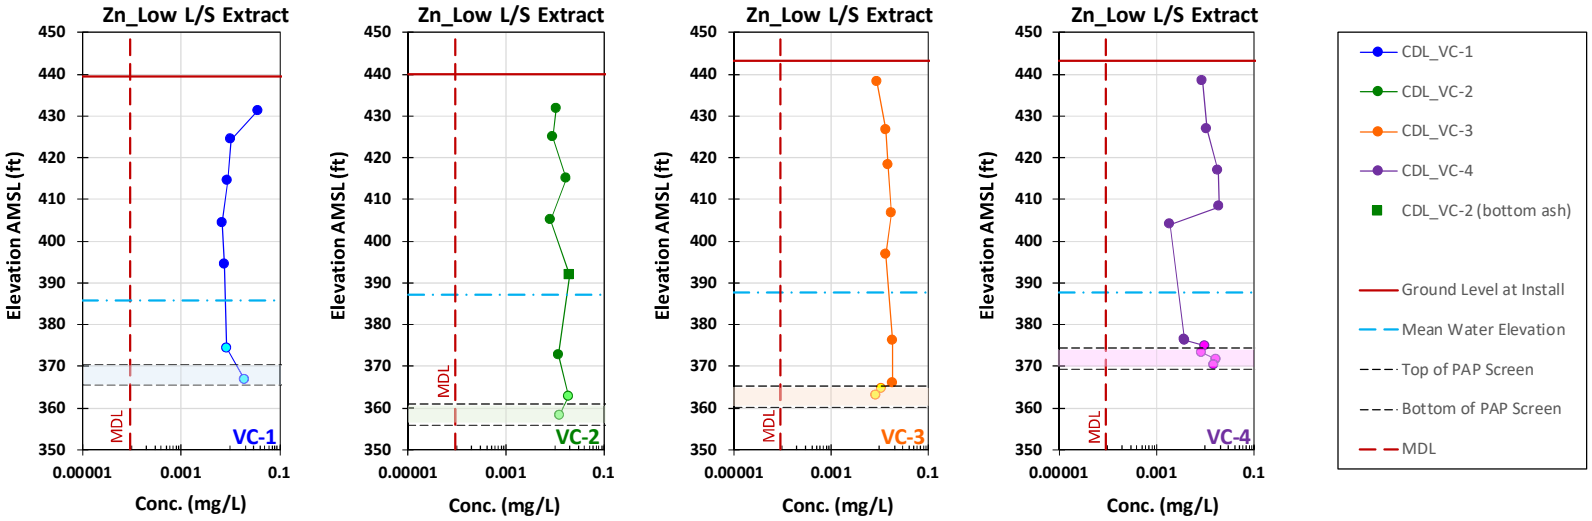

Figure B-17
Concentration profiles from in-field low L/S extractions: zinc

B-2 Standardized Concentration Profiles of In-field Low L/S Extractions Using the Global Material Mean and Standard Deviation

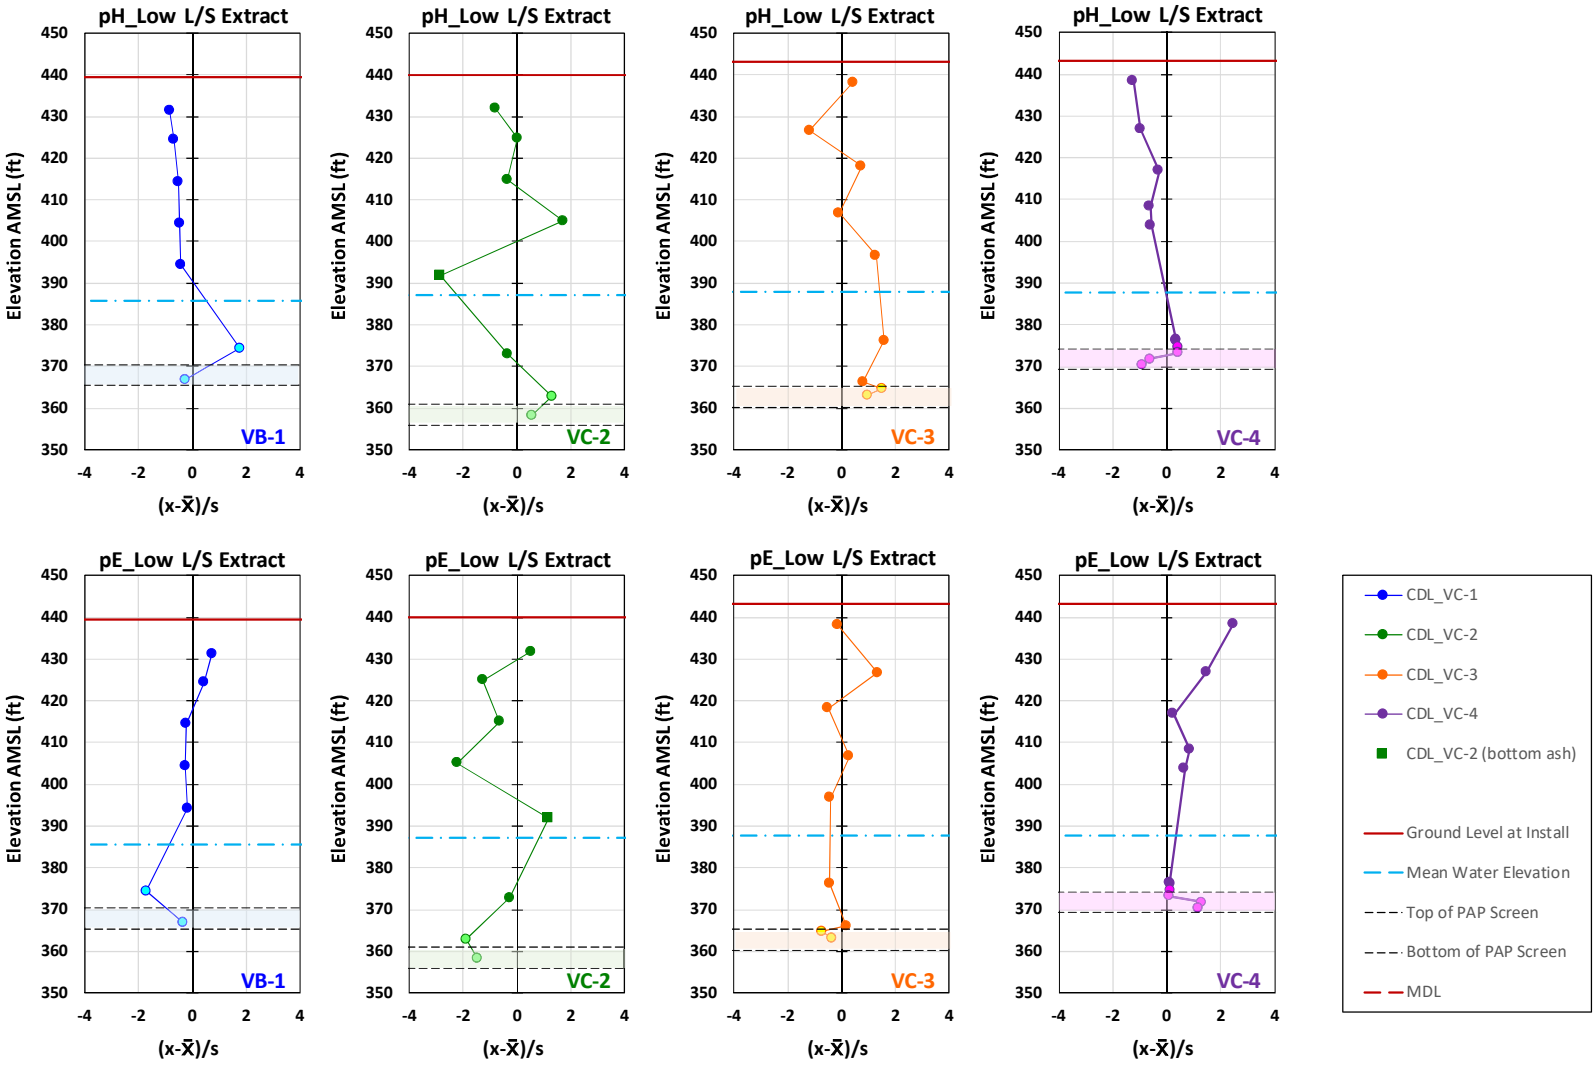

Figure B-18
Profiles from in-field low L/S extractions standardized using the global material mean and standard deviation: pH and pE

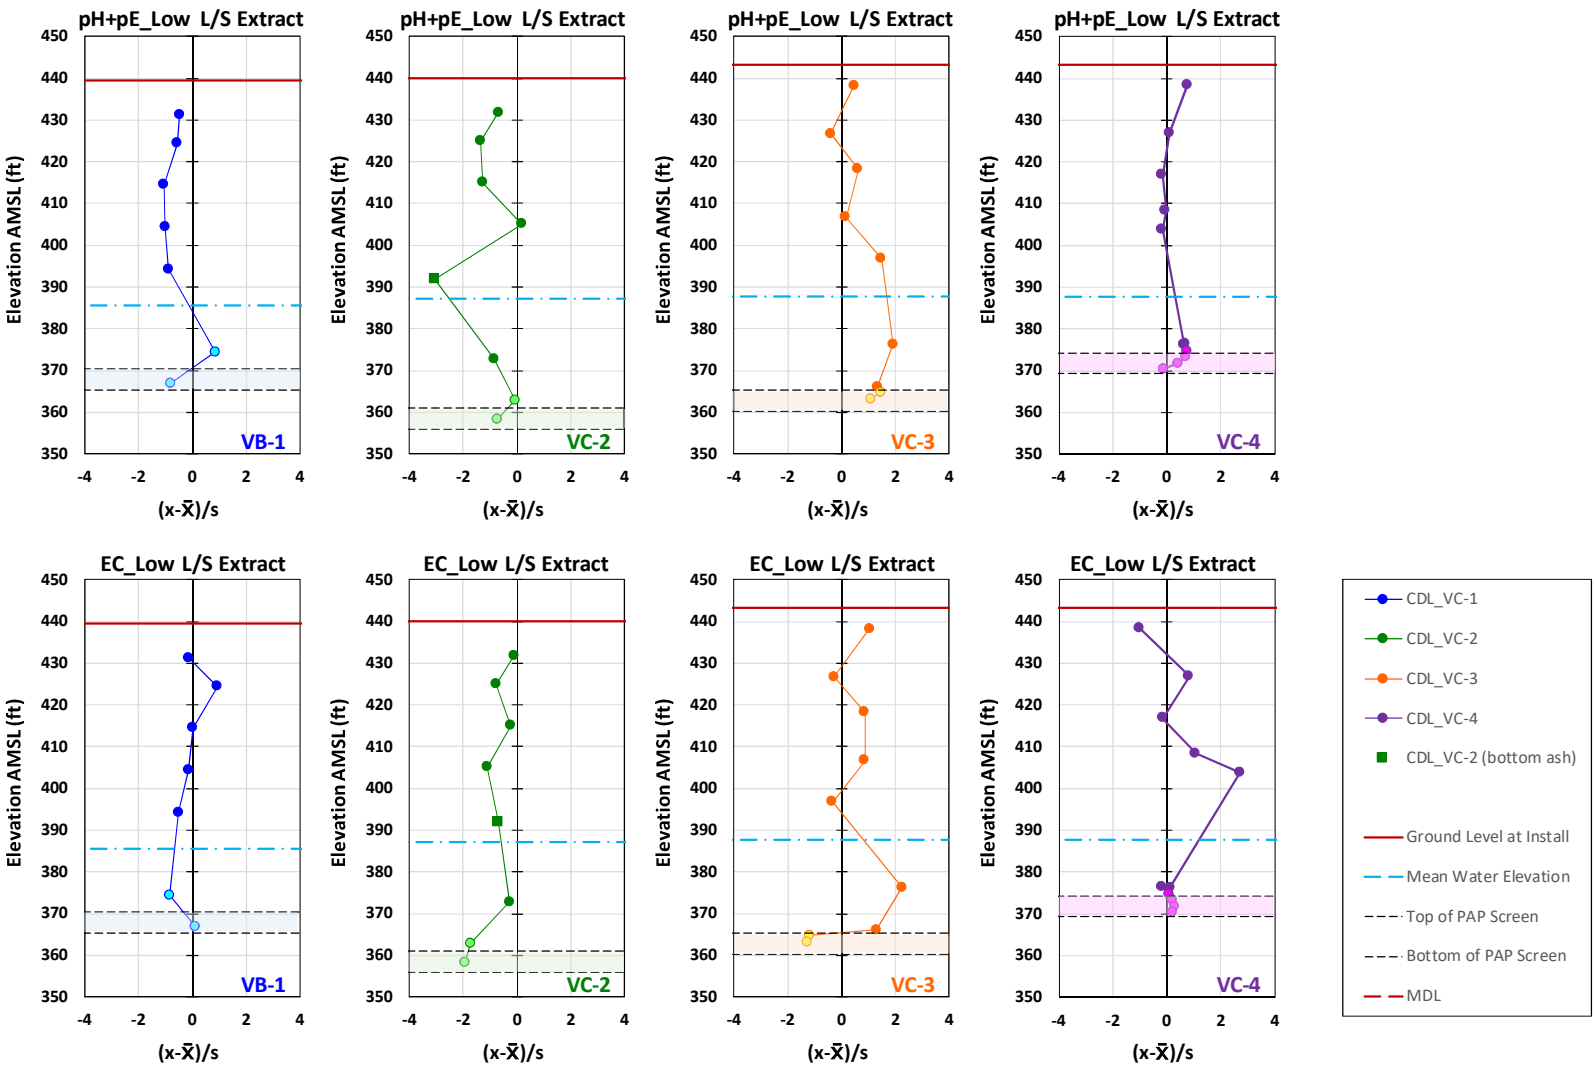

Figure B-19
Profiles from in-field low L/S extractions standardized using the global material mean and standard deviation: pH+pE and electrical conductivity

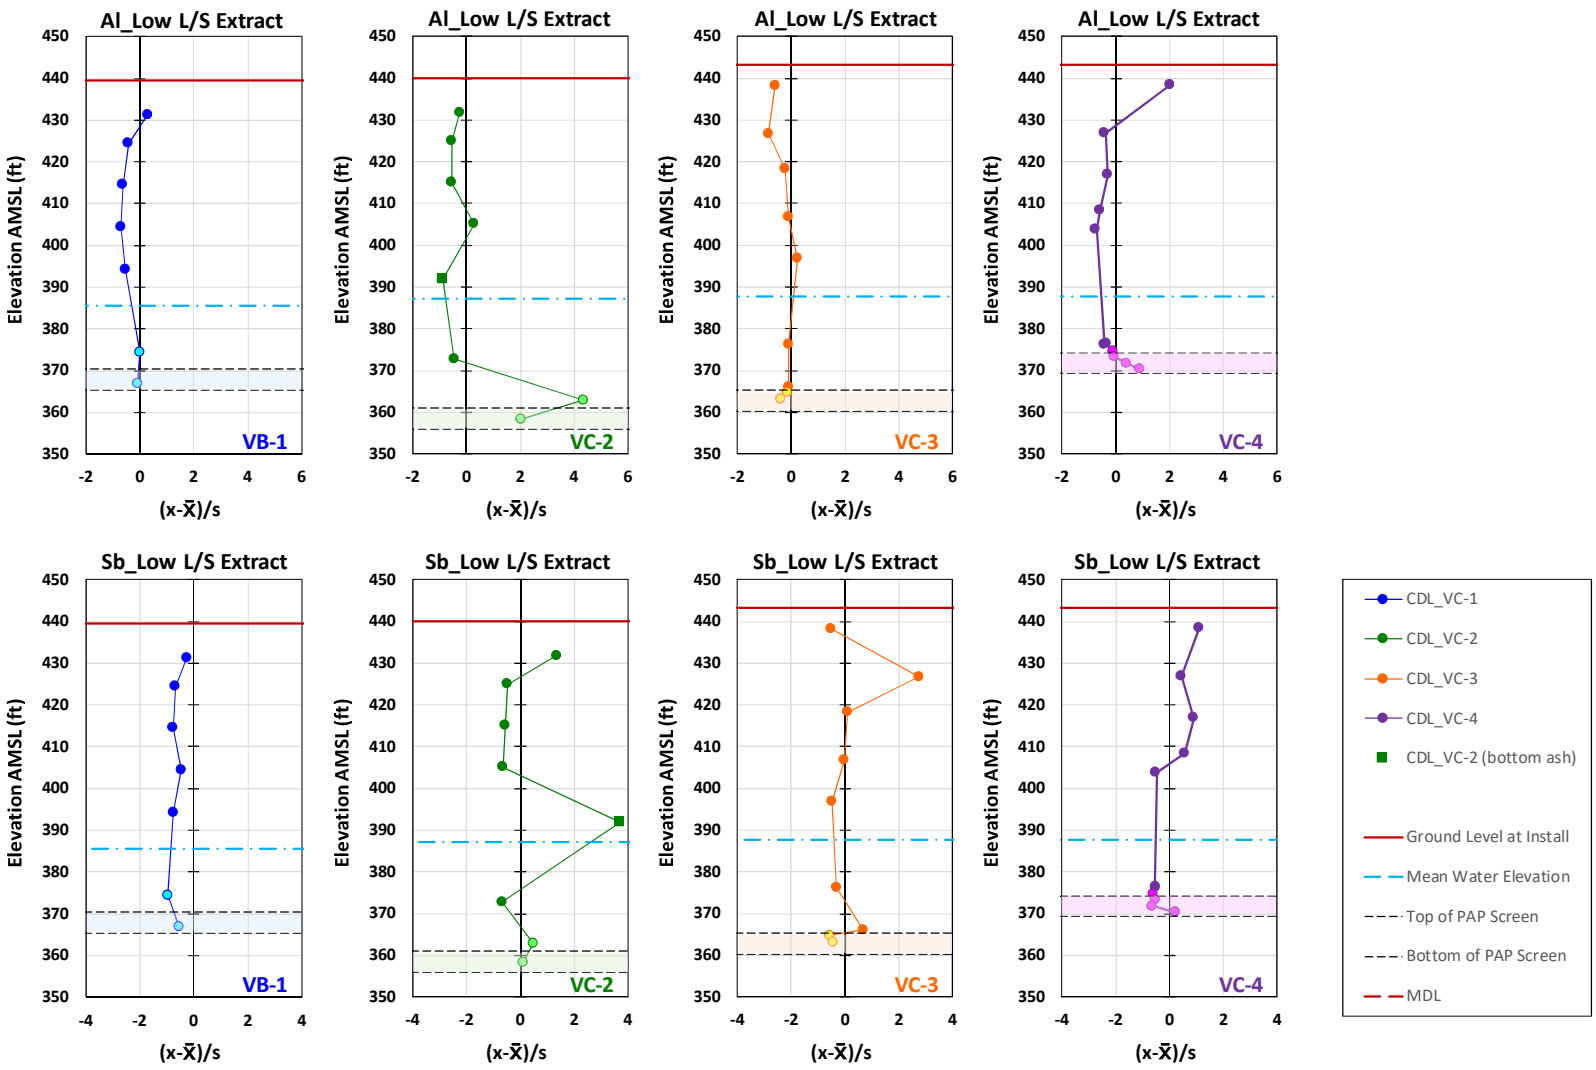

Figure B-20
Profiles from in-field low L/S extractions standardized using the global material mean and standard deviation: aluminum and antimony

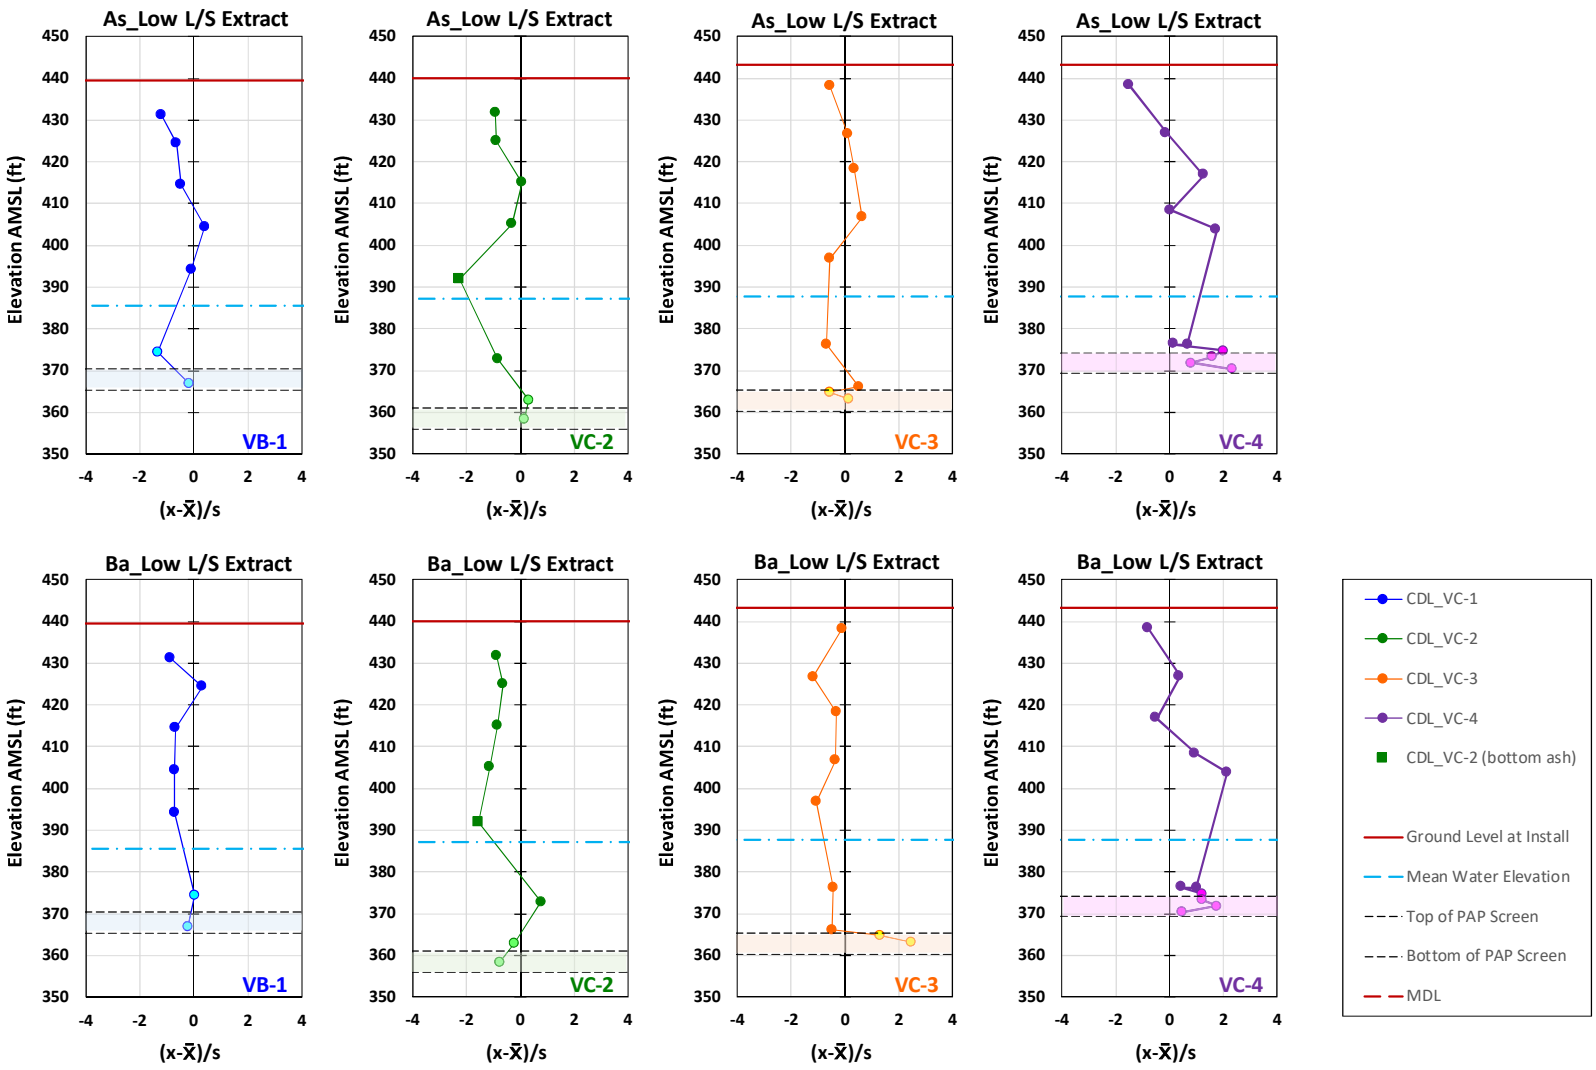

Figure B-21
Profiles from in-field low L/S extractions standardized using the global material mean and standard deviation: arsenic and barium

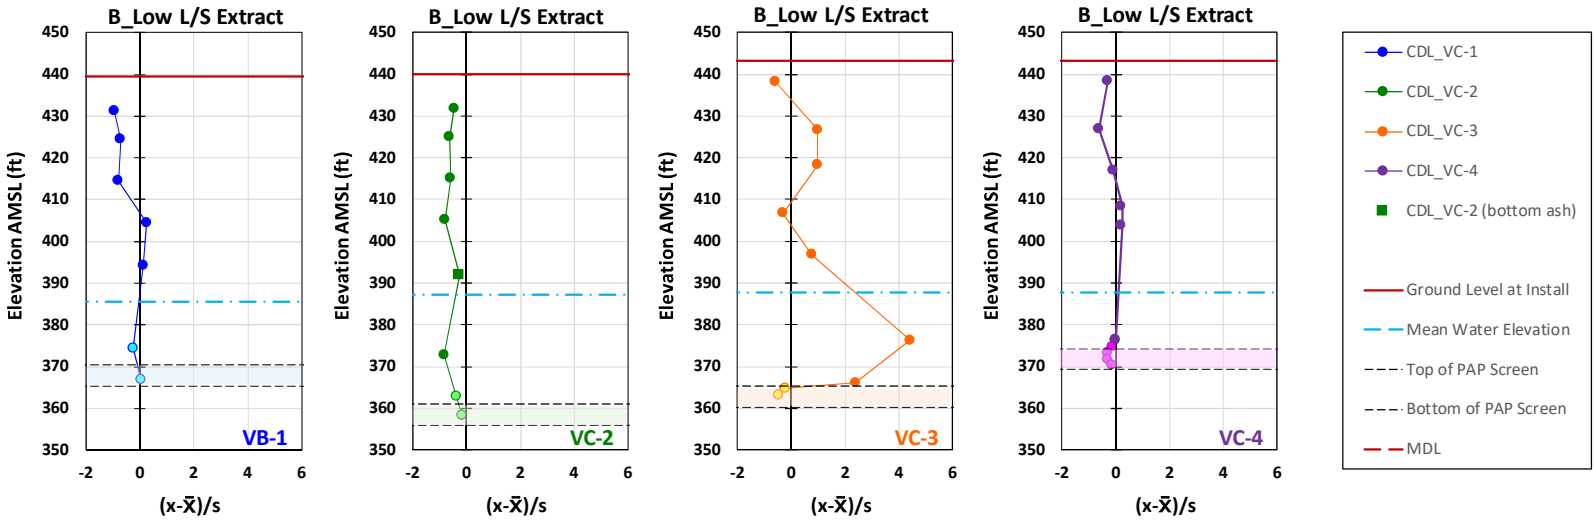

Figure B-22
Profiles from in-field low L/S extractions standardized using the global material mean and standard deviation: beryllium and boron

Profiles from in-field low L/S extractions standardized using the global material mean and standard deviation: zinc

B-3 Comparison of Standardized Release Profiles for Low L/S and L/S≈1 Extractions

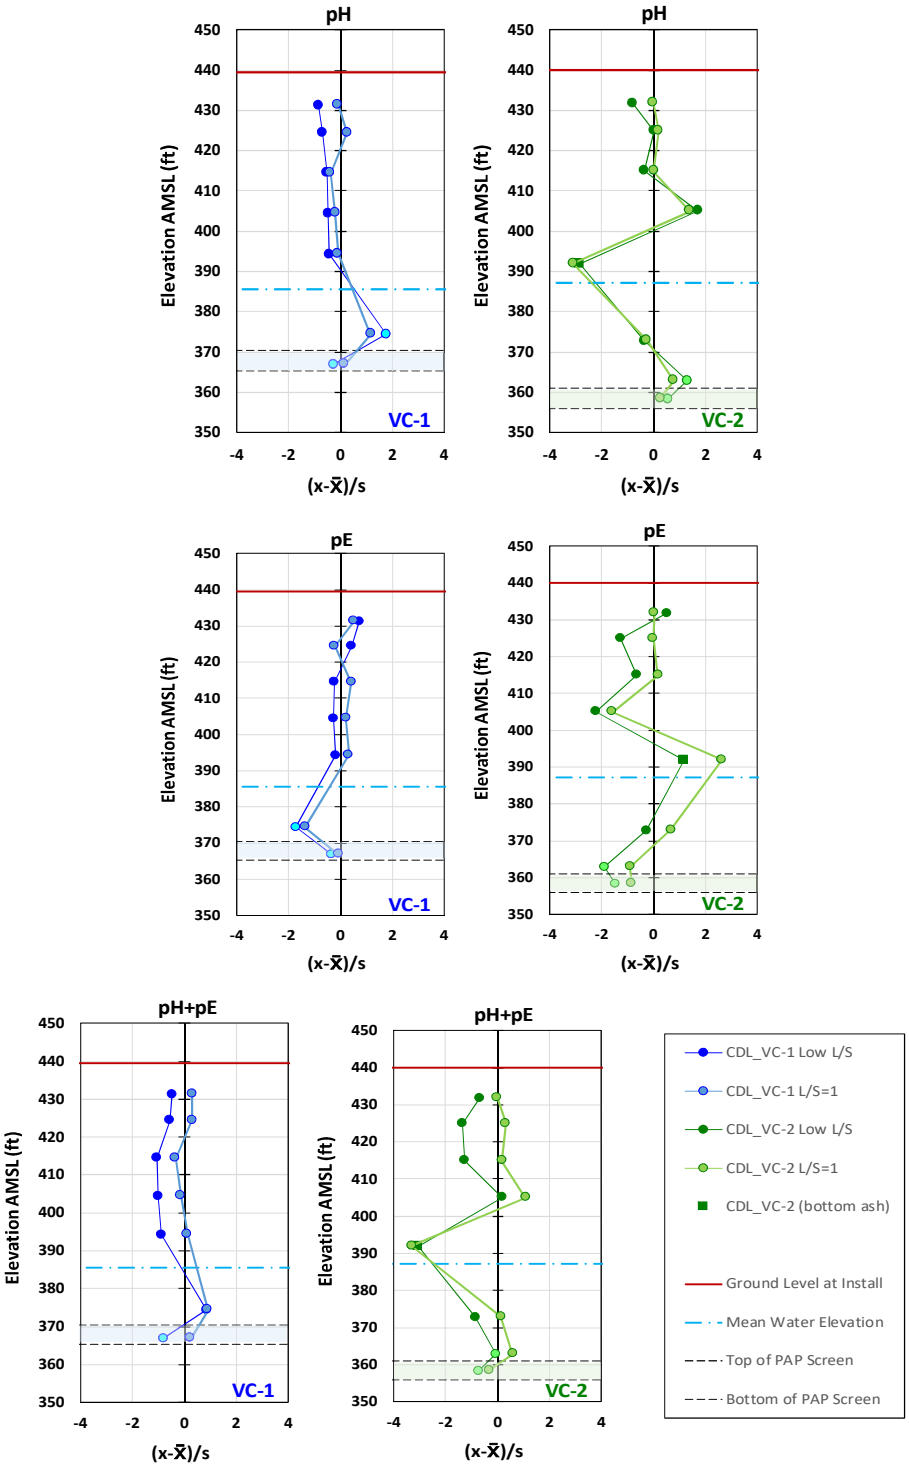

Figure B-35
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: pH, pE, and pH+pE

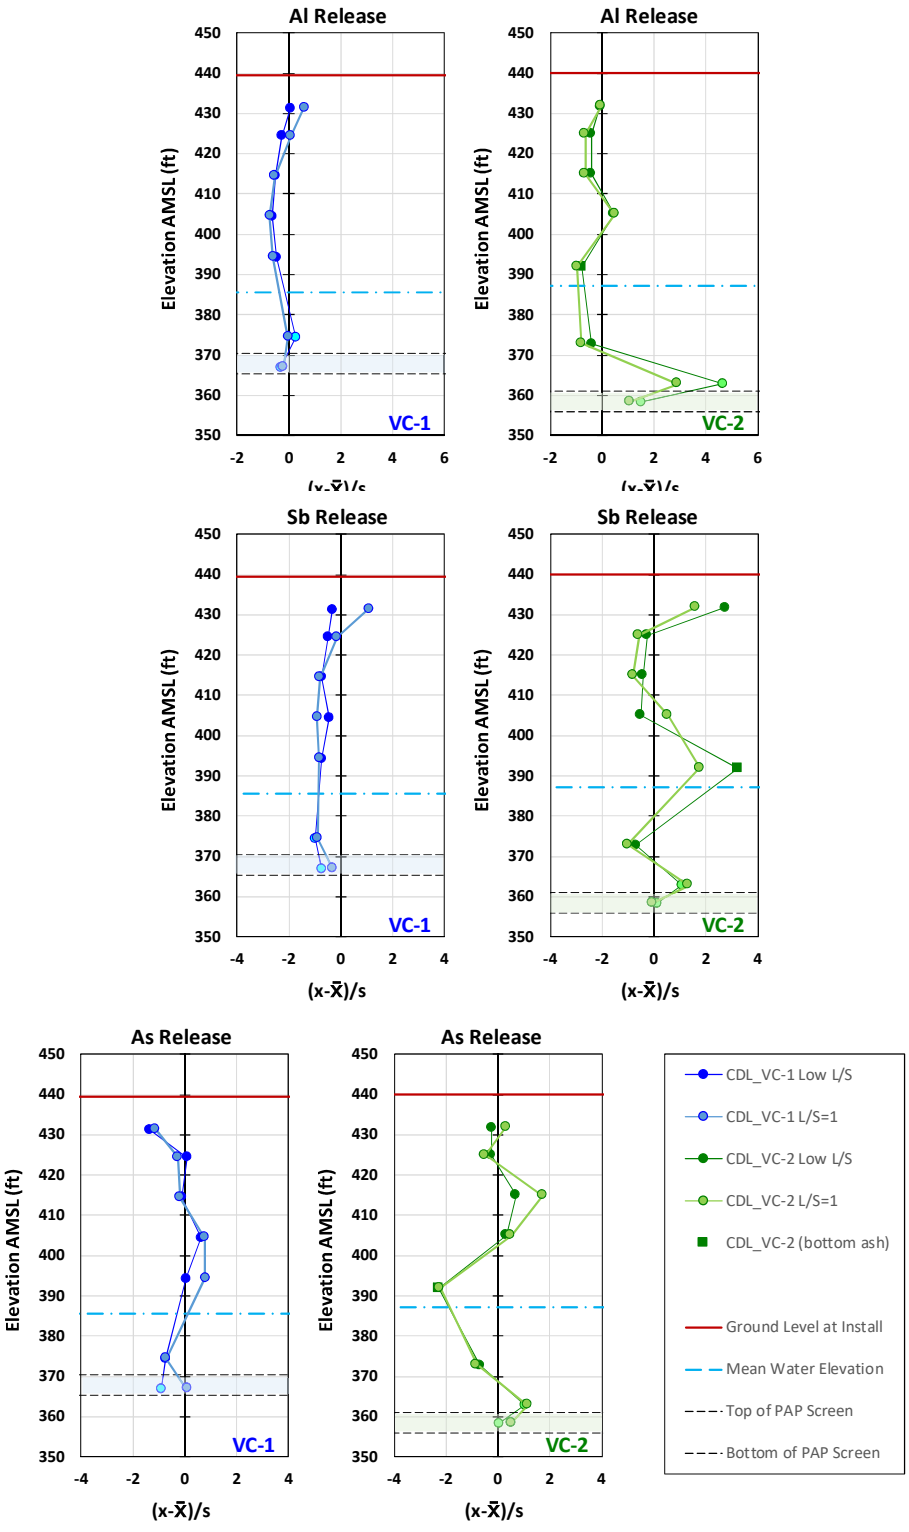

Figure B-36
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: aluminum, antimony, and arsenic

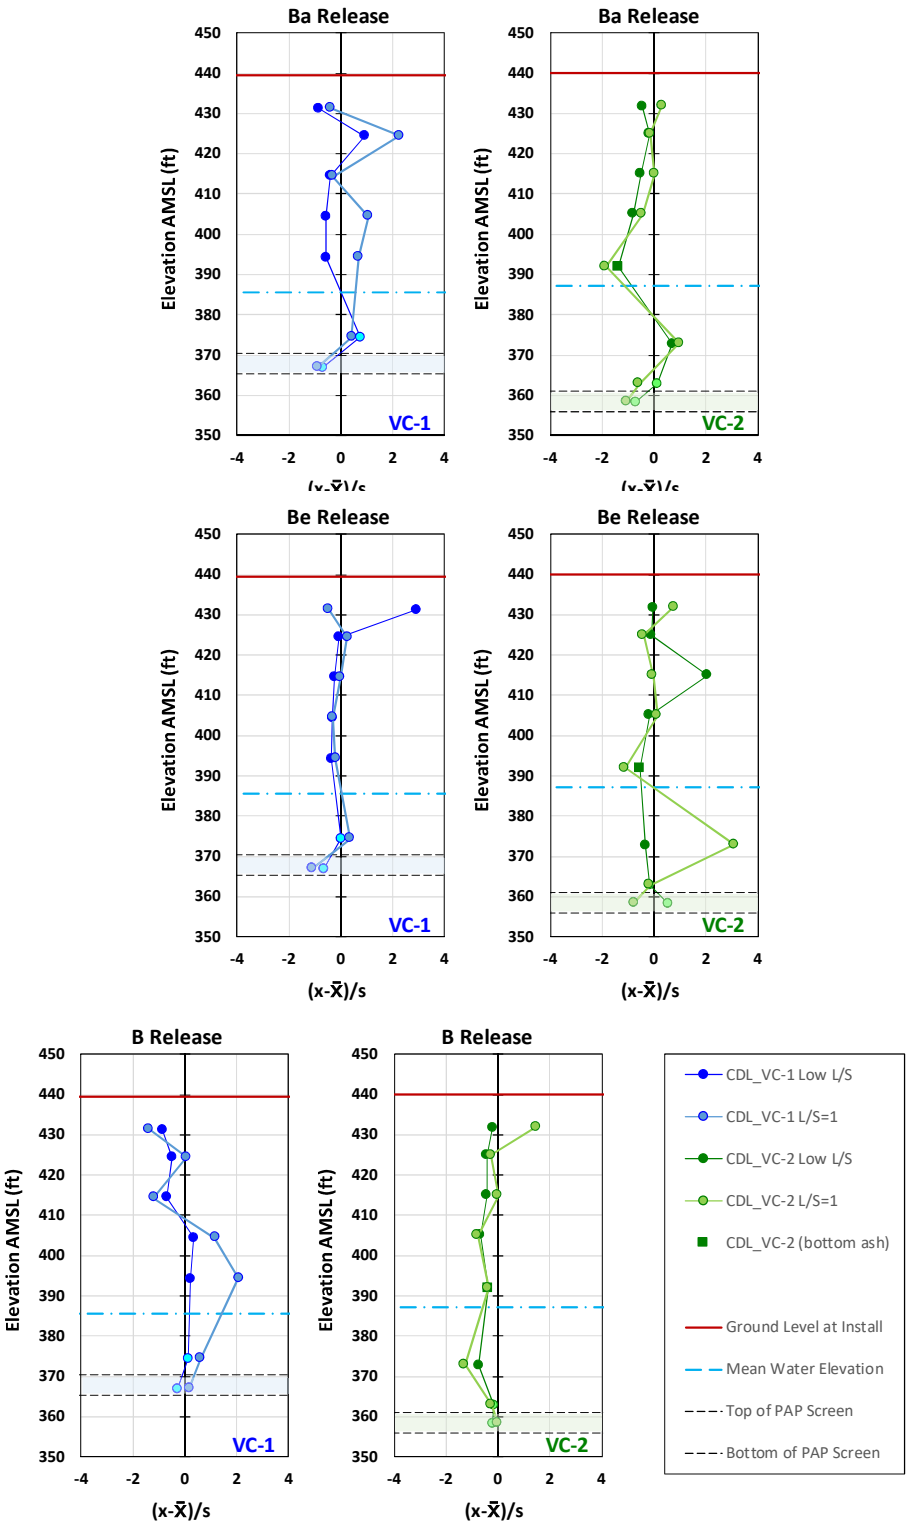

Figure B-37
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: barium, beryllium, and boron

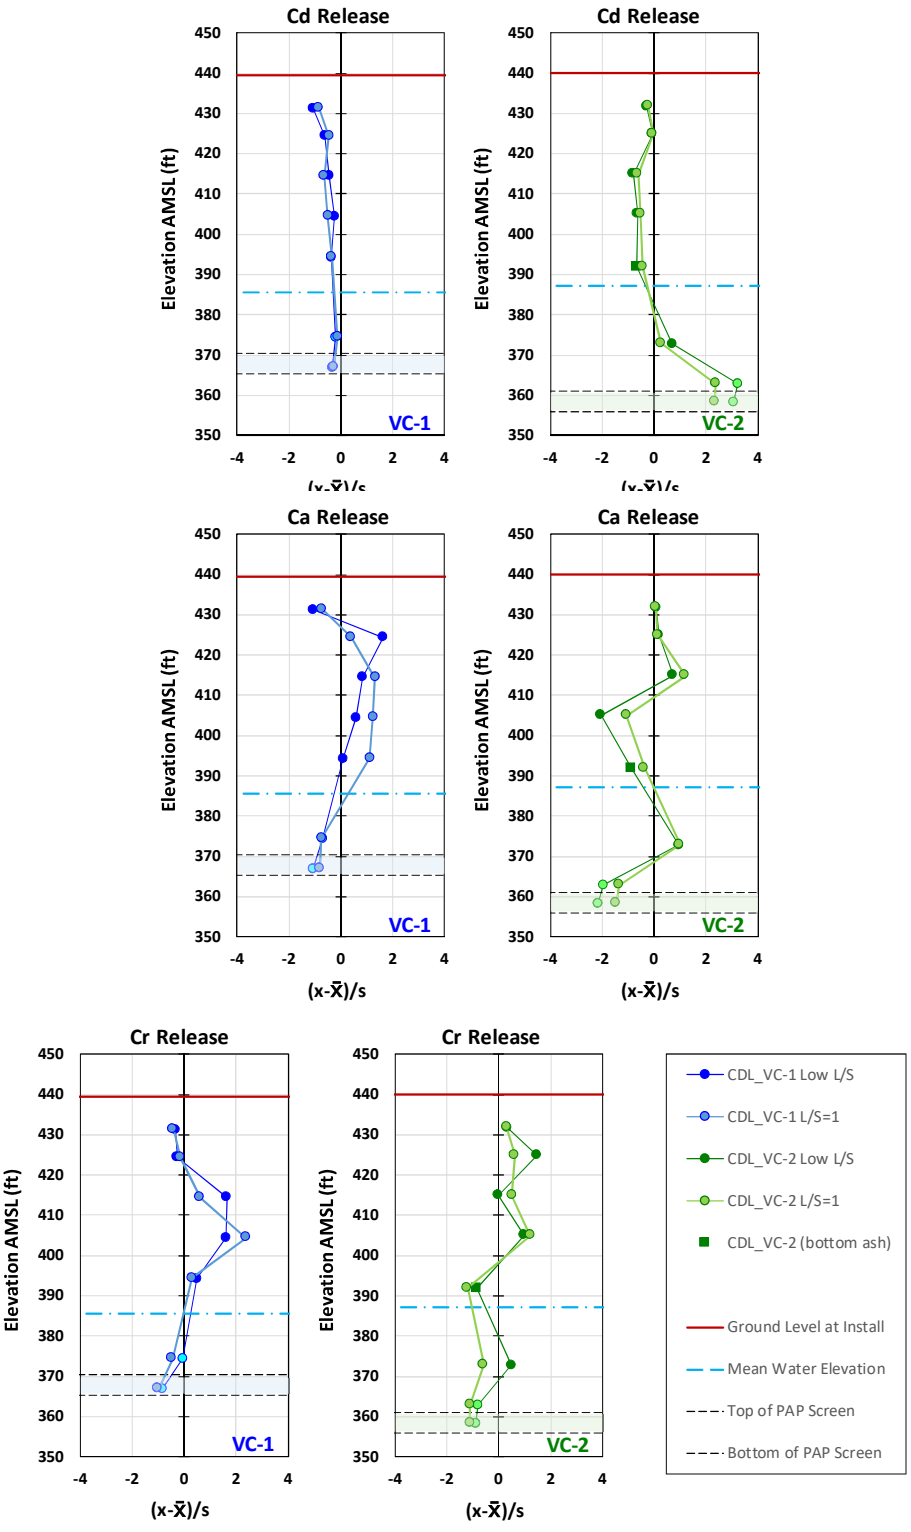

Figure B-38
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: cadmium, calcium, and chromium

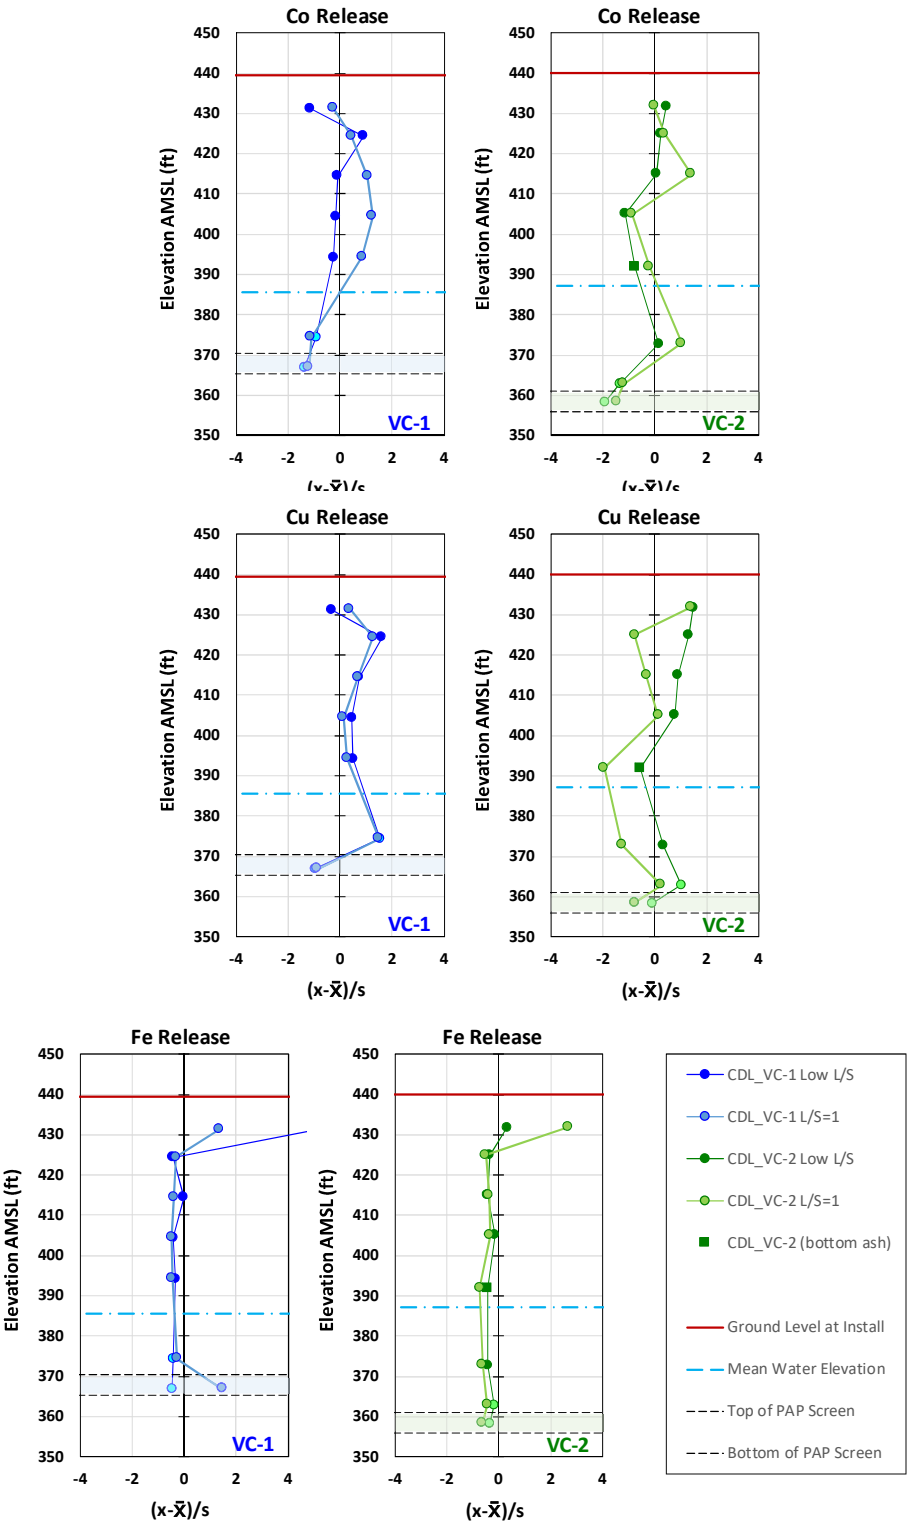

Figure B-39
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: cobalt, copper, and iron

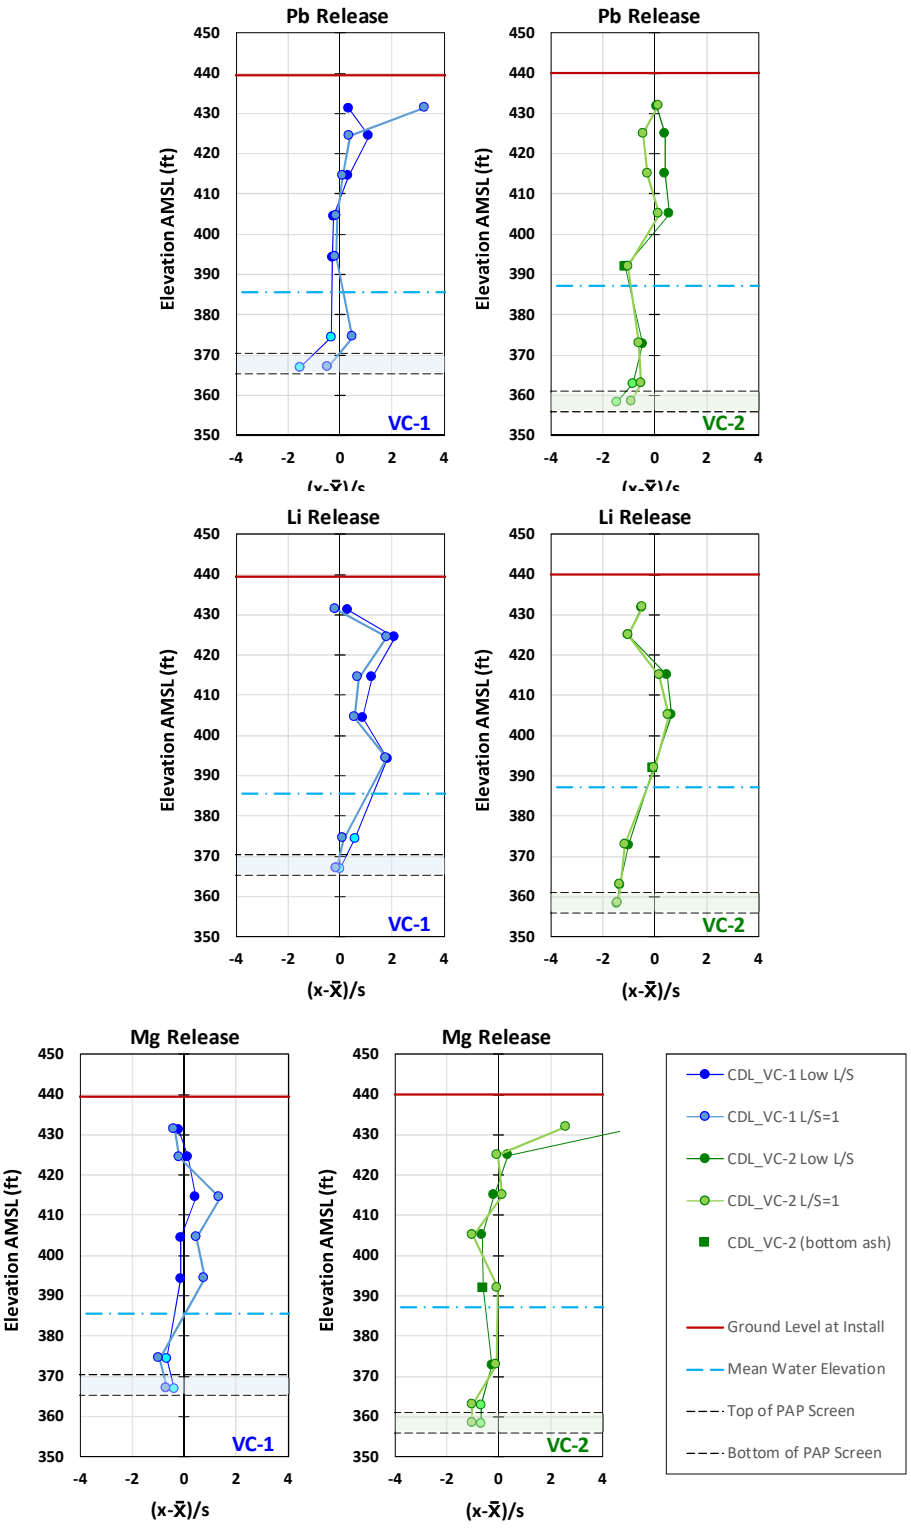

Figure B-40
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: lead, lithium, and magnesium

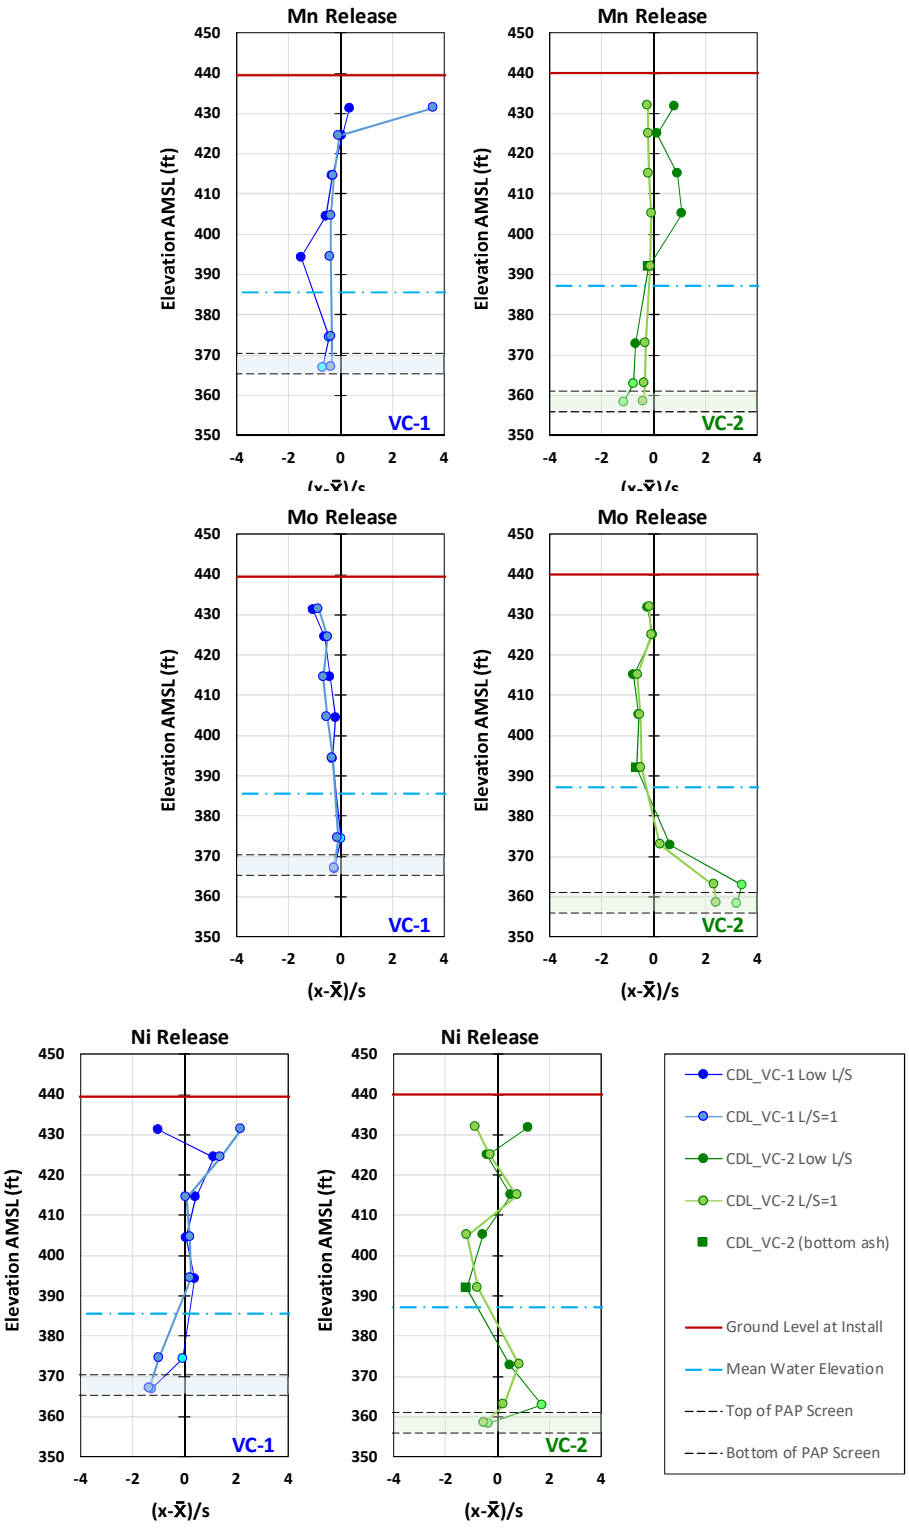

Figure B-41
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: manganese, molybdenum, and nickel

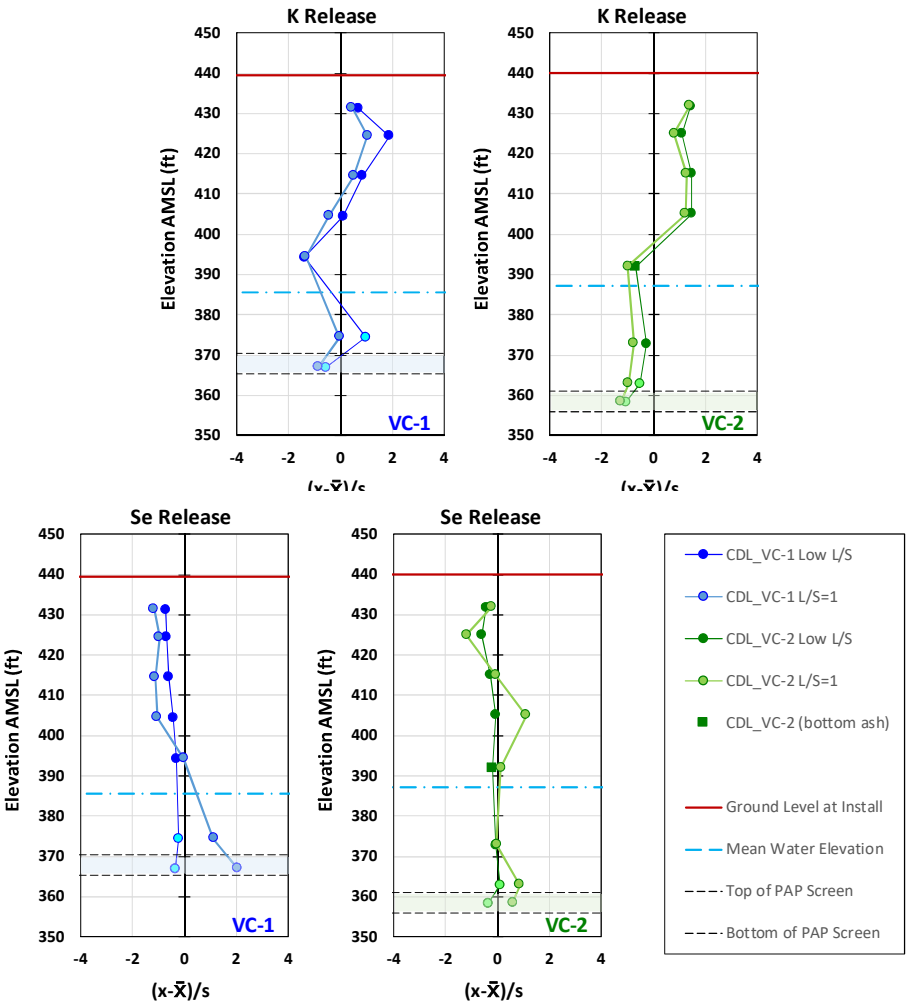

Figure B-42
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: potassium and selenium

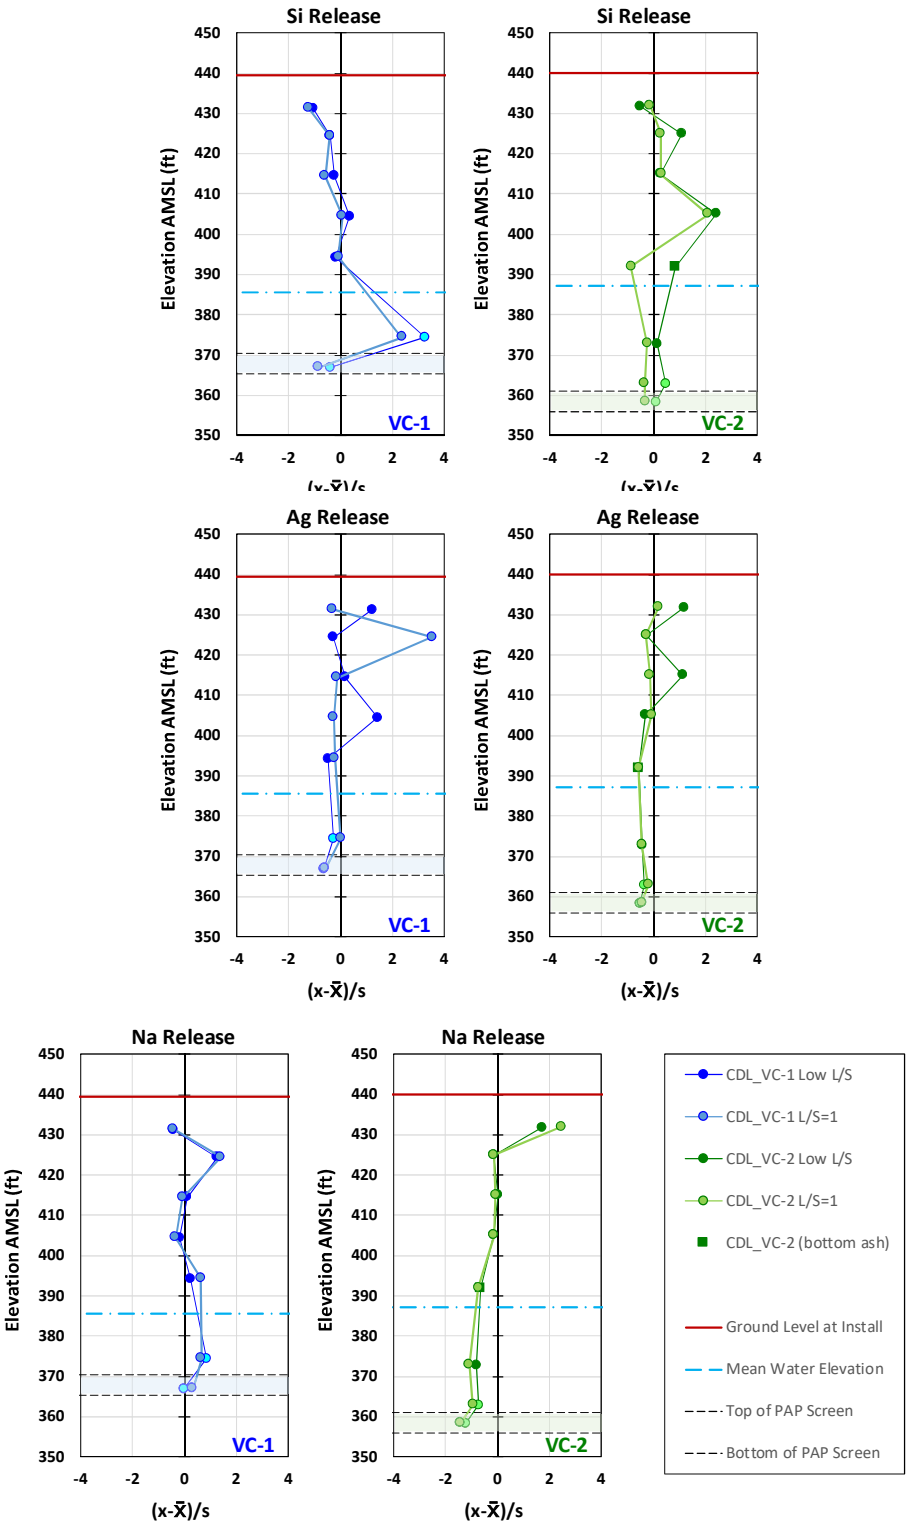

Figure B-43
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: silicon, silver and, sodium

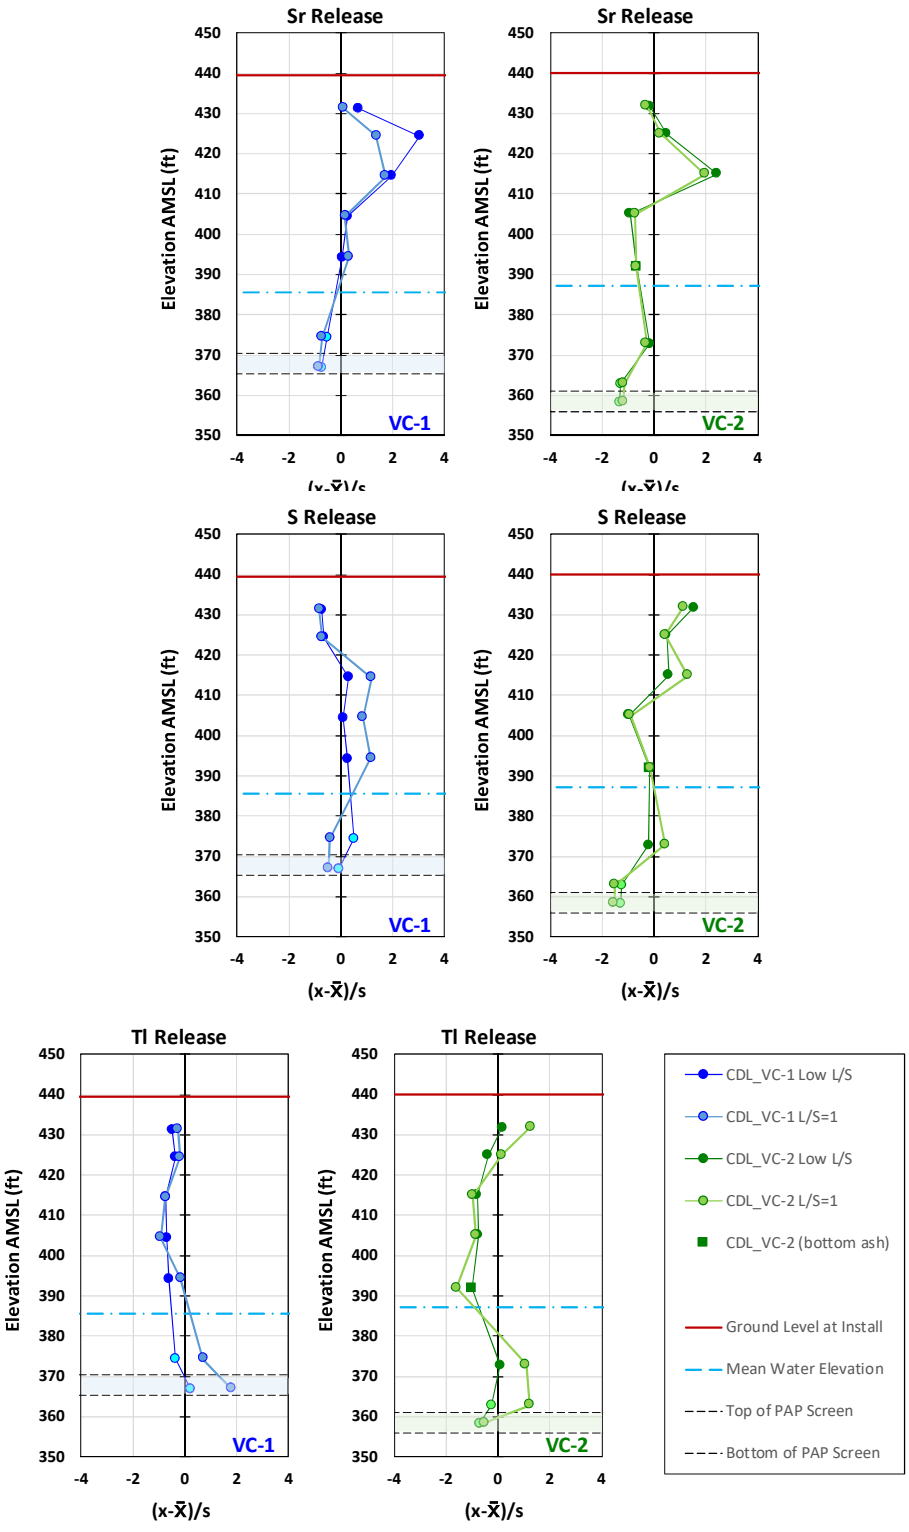

Figure B-44
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: strontium, sulfur, and thallium

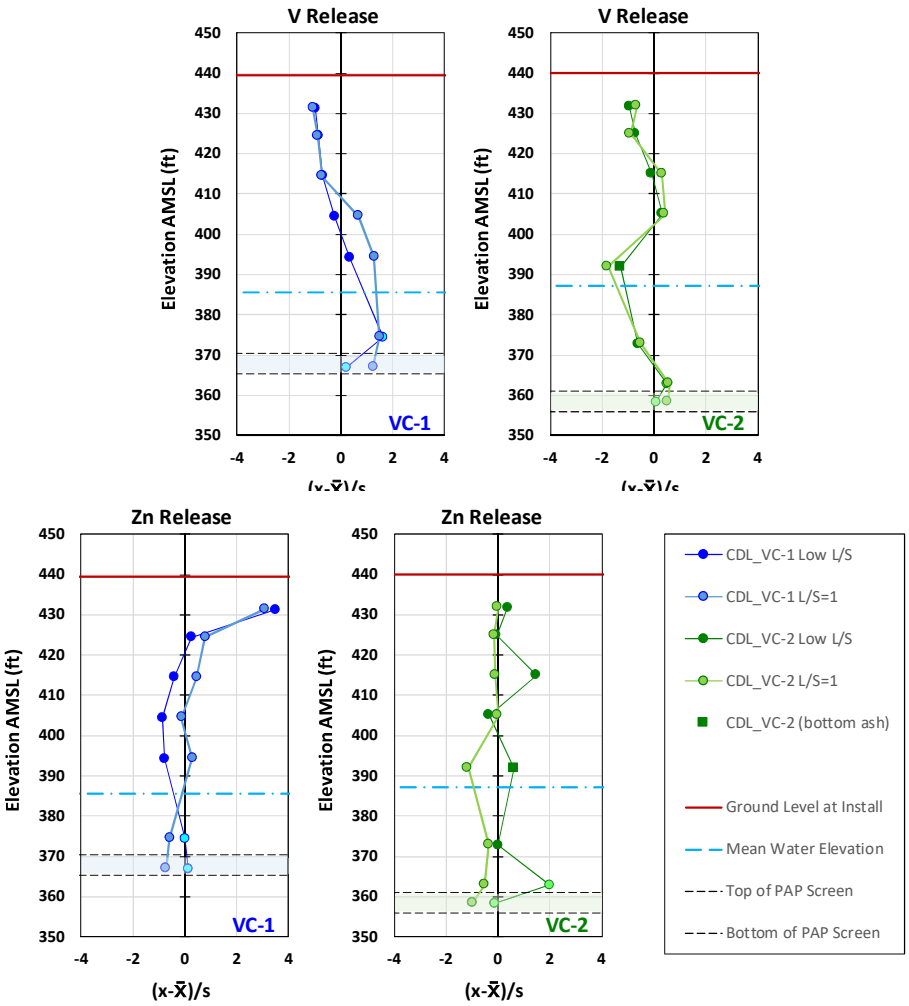

Figure B-45
Comparison of release (mg/kg-dry) from in-field extractions at low L/S and at L/S~1: vanadium and zinc

C
LEACHING TEST METHOD RESULTS

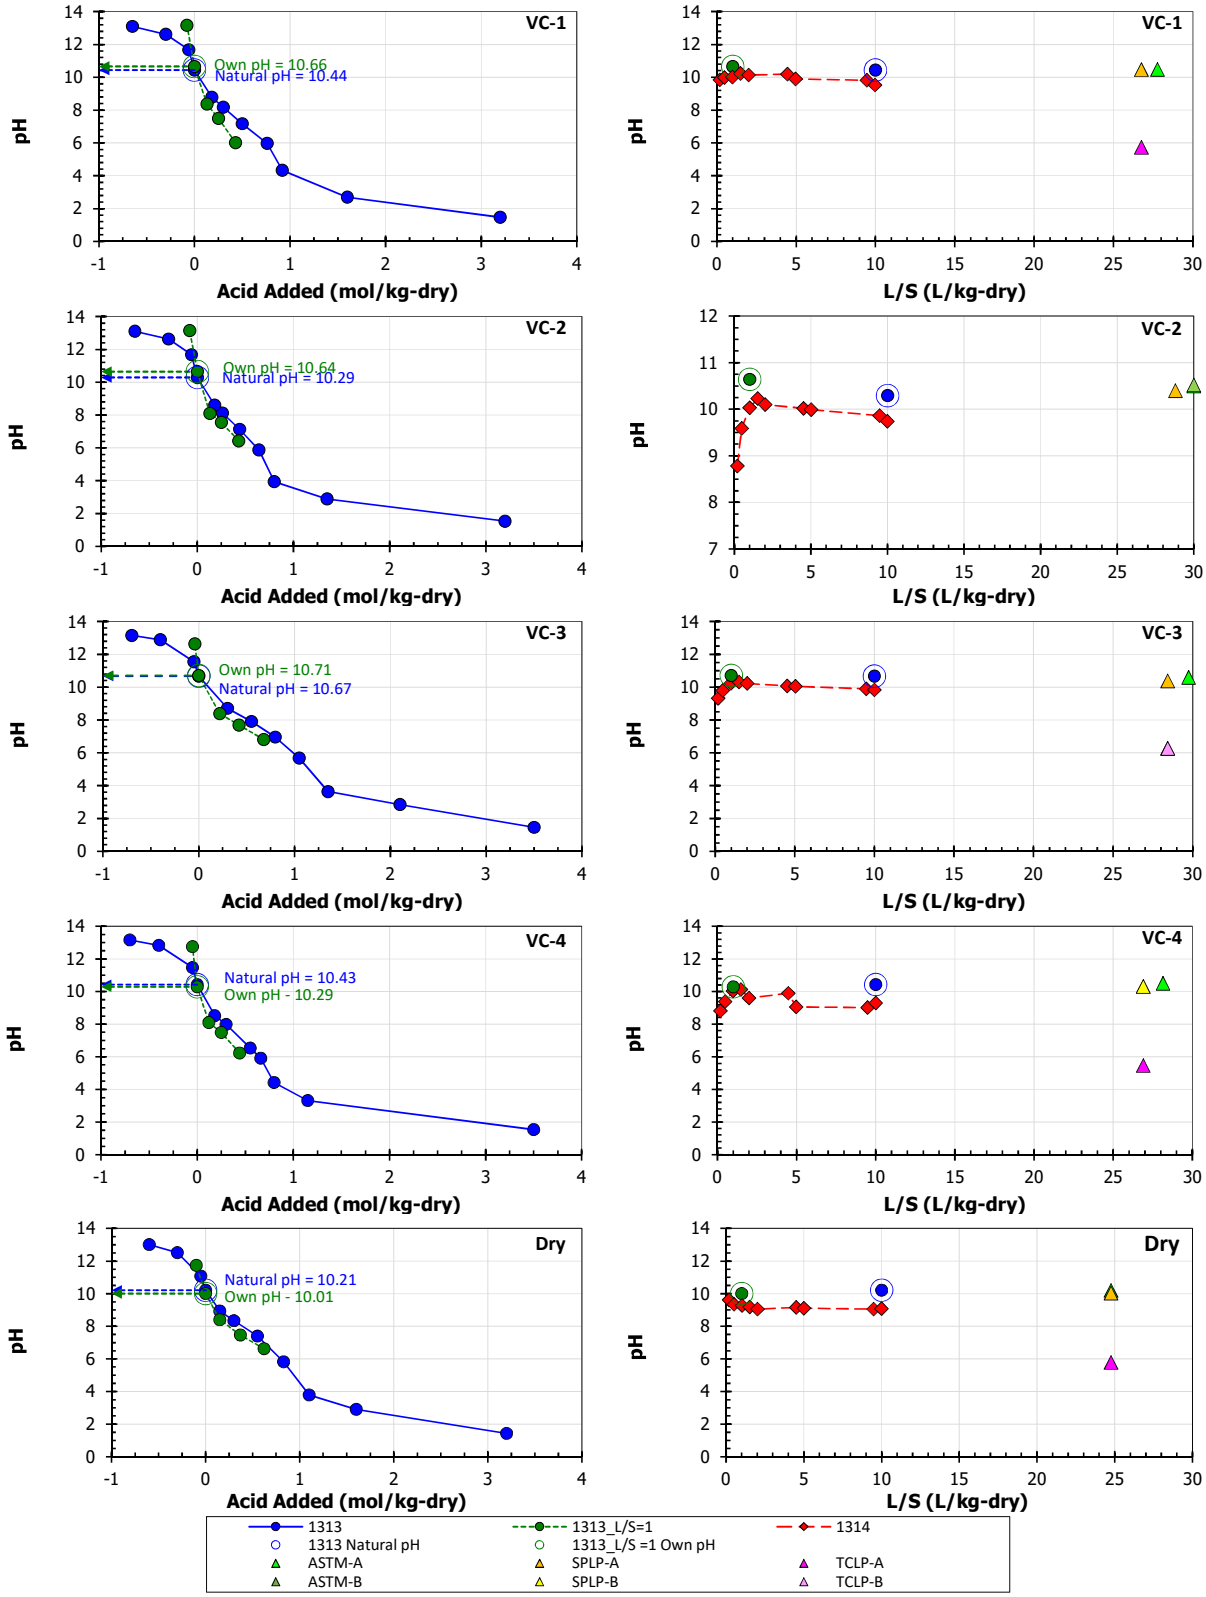

Figure C-1
Titration curve and pH results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

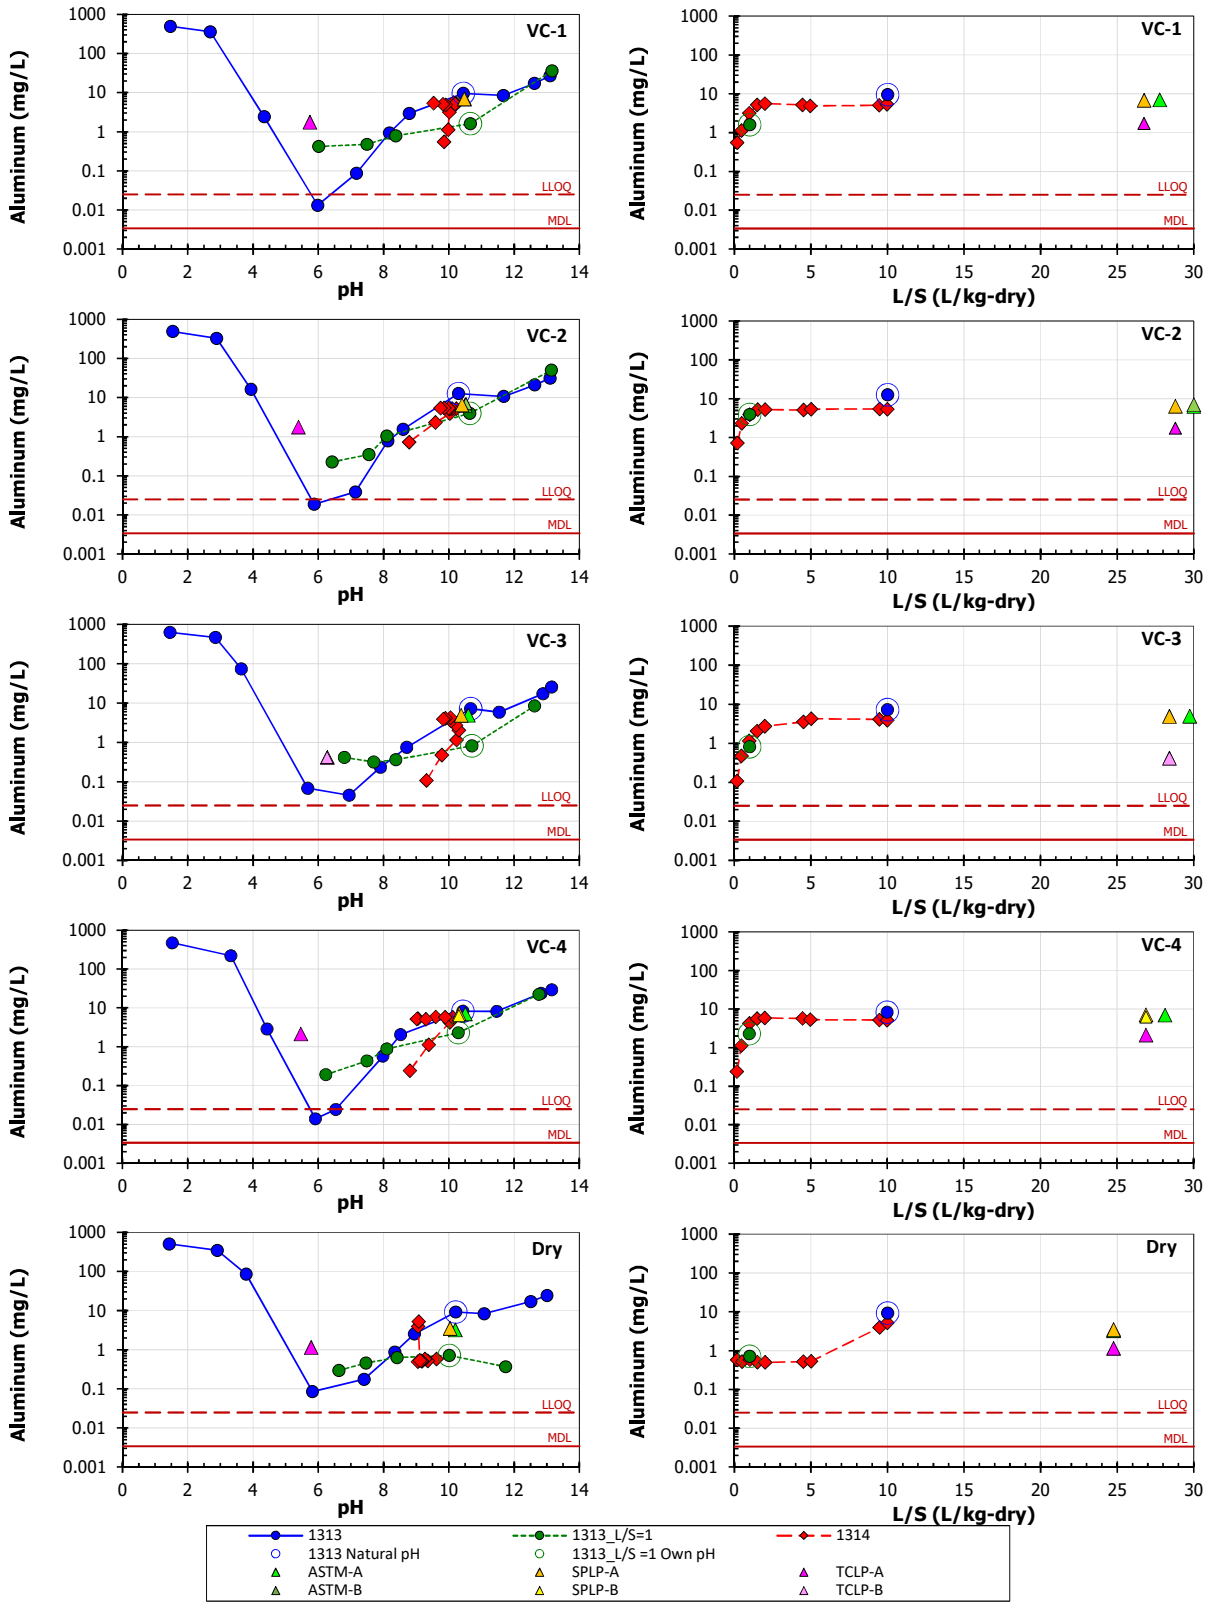

Figure C-2
Aluminum leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

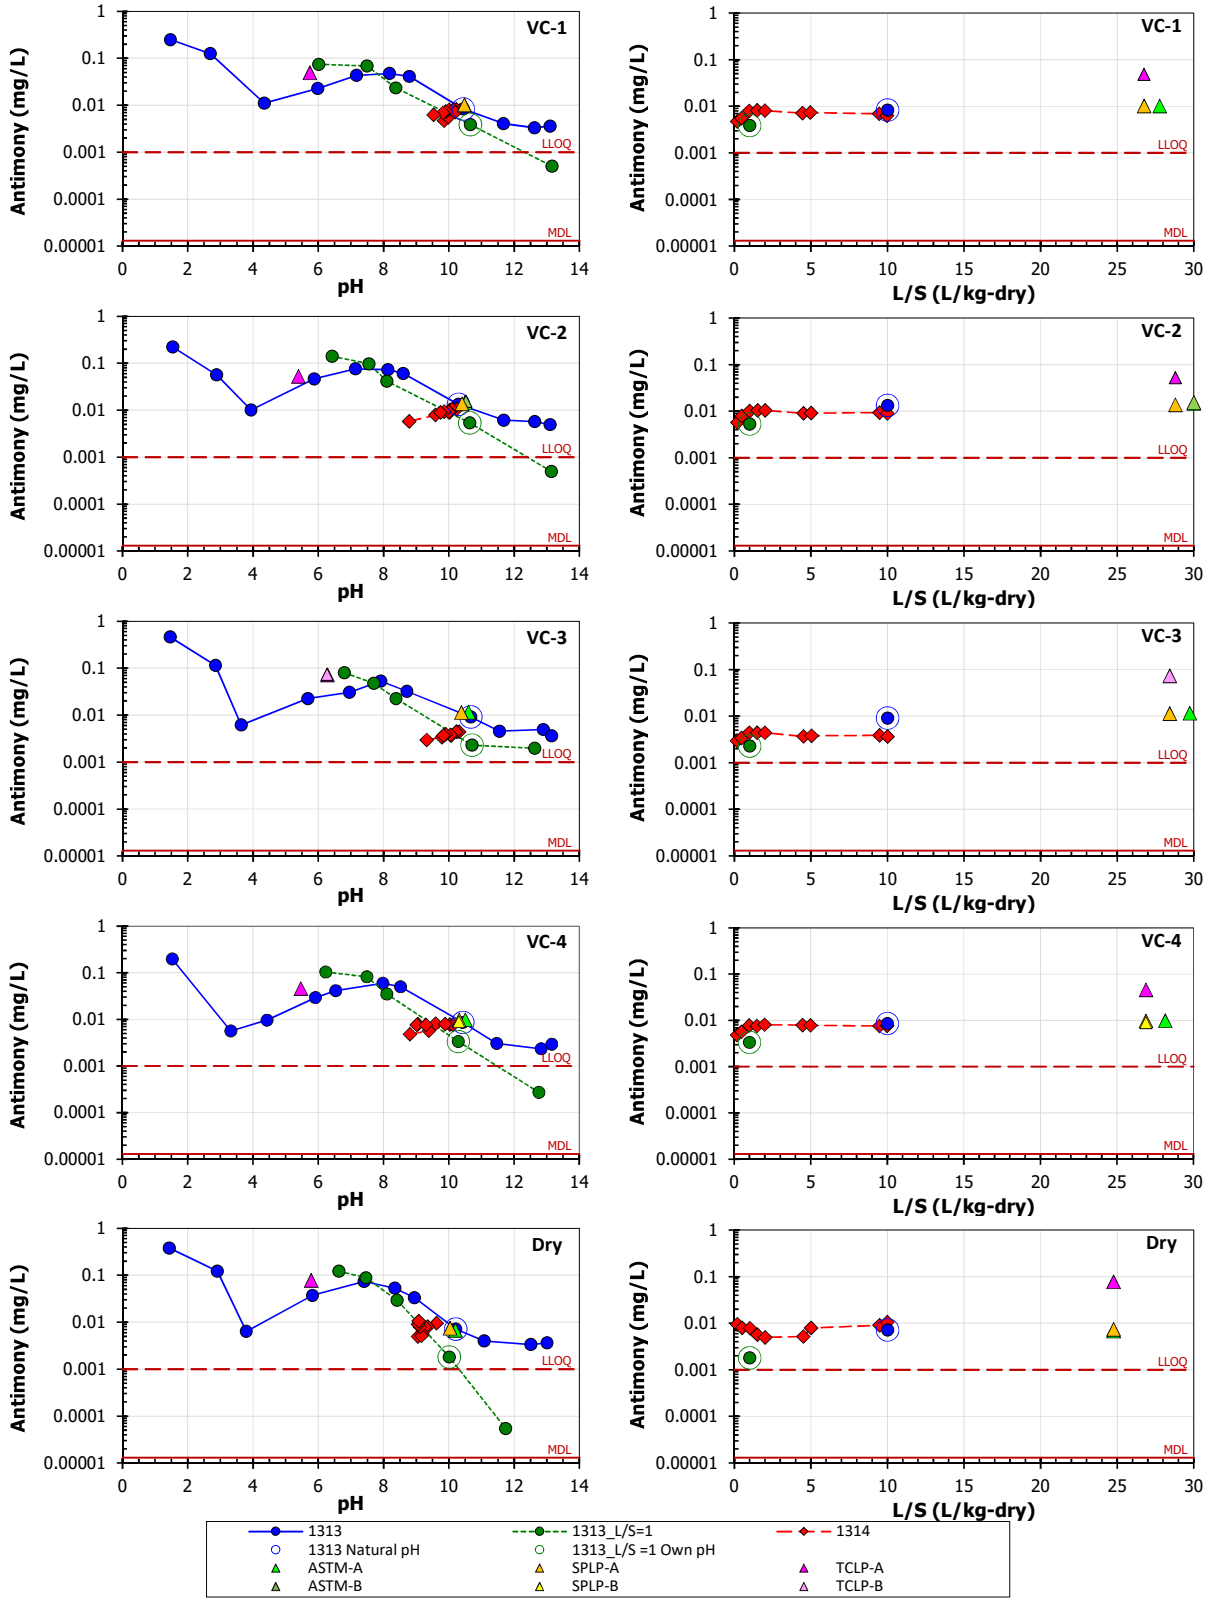

Figure C-3
Antimony leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

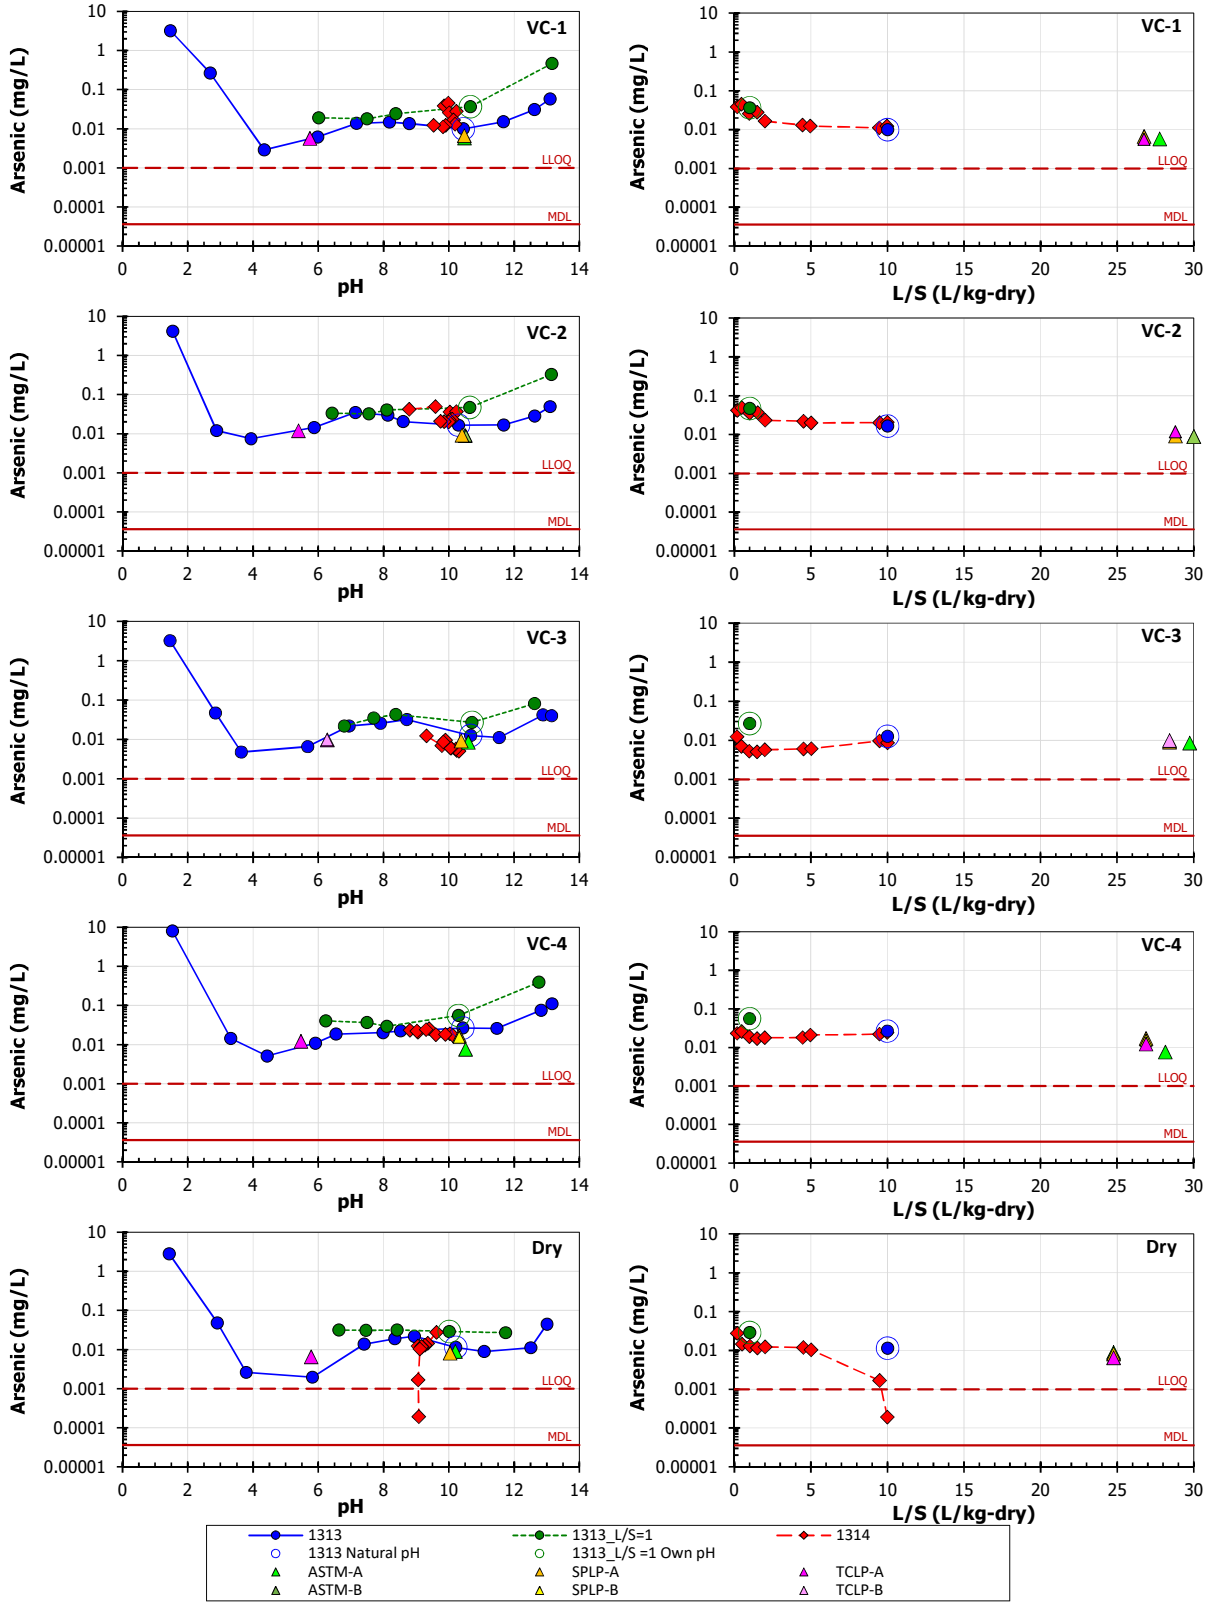

Figure C-4
Arsenic leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

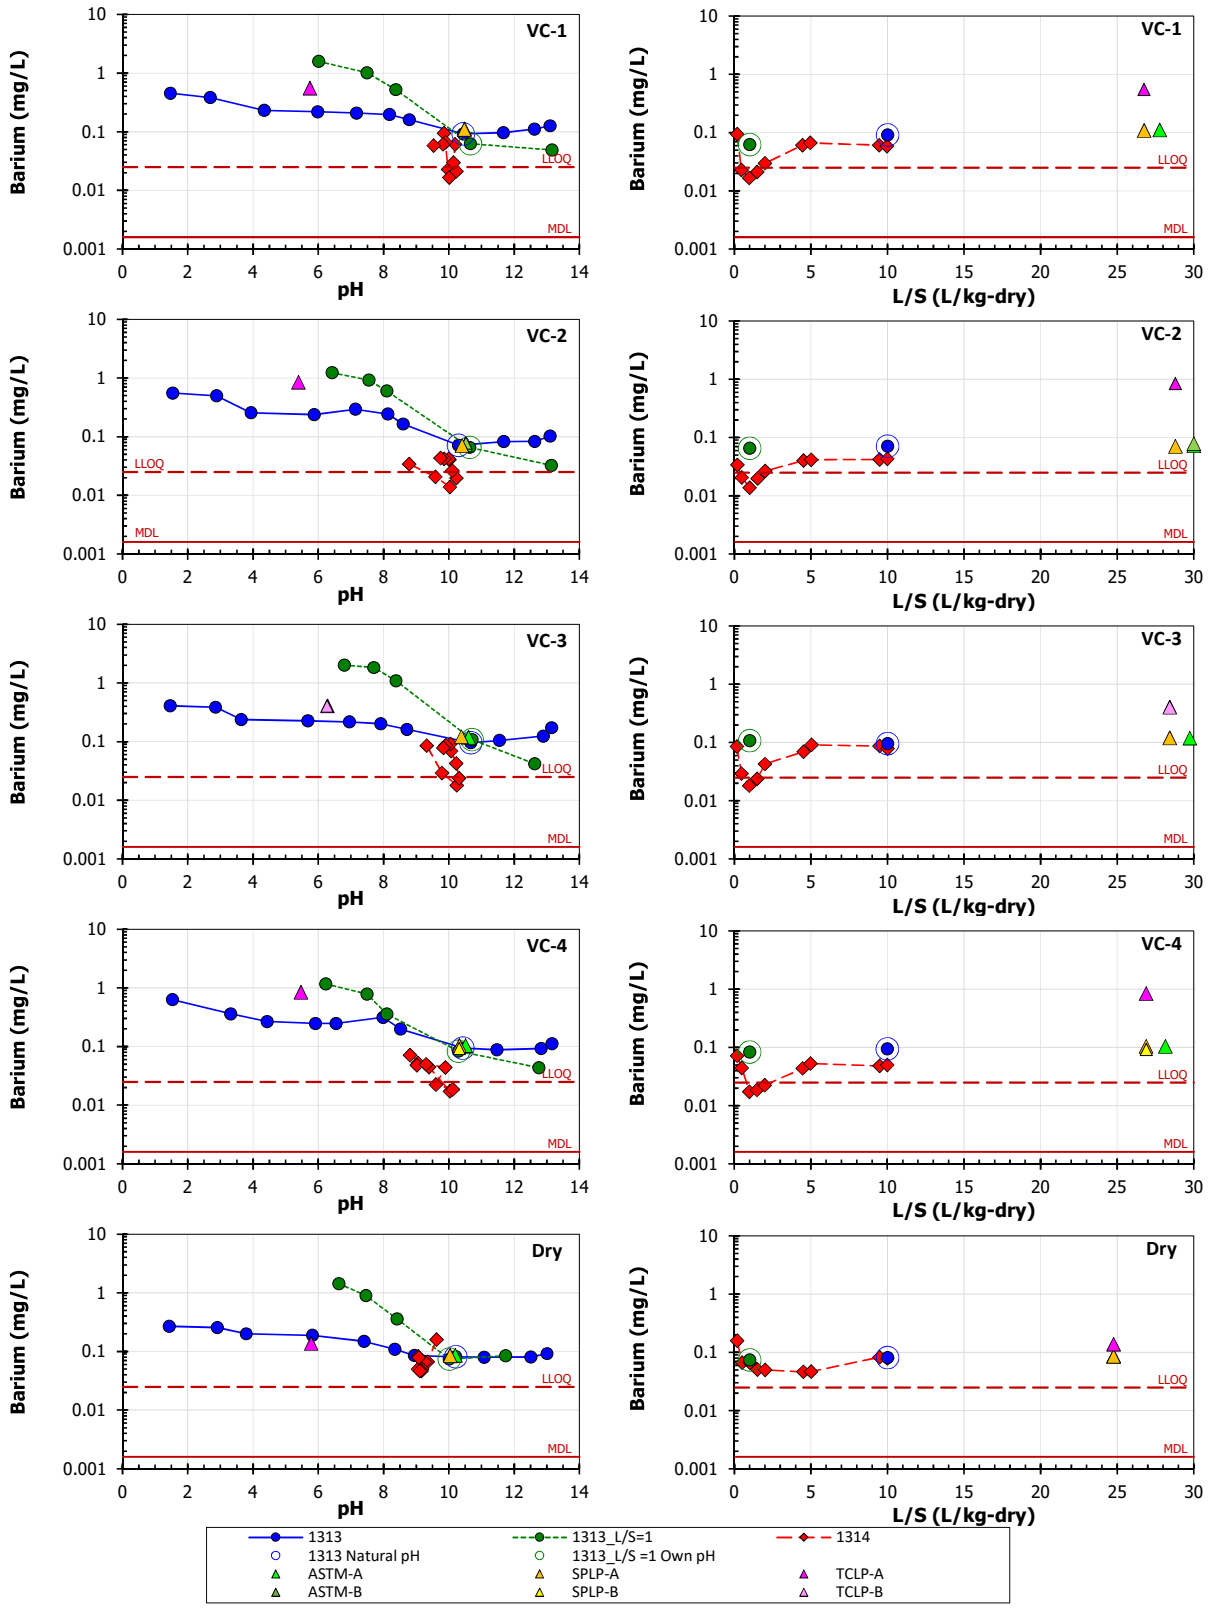

Figure C-5
Barium leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

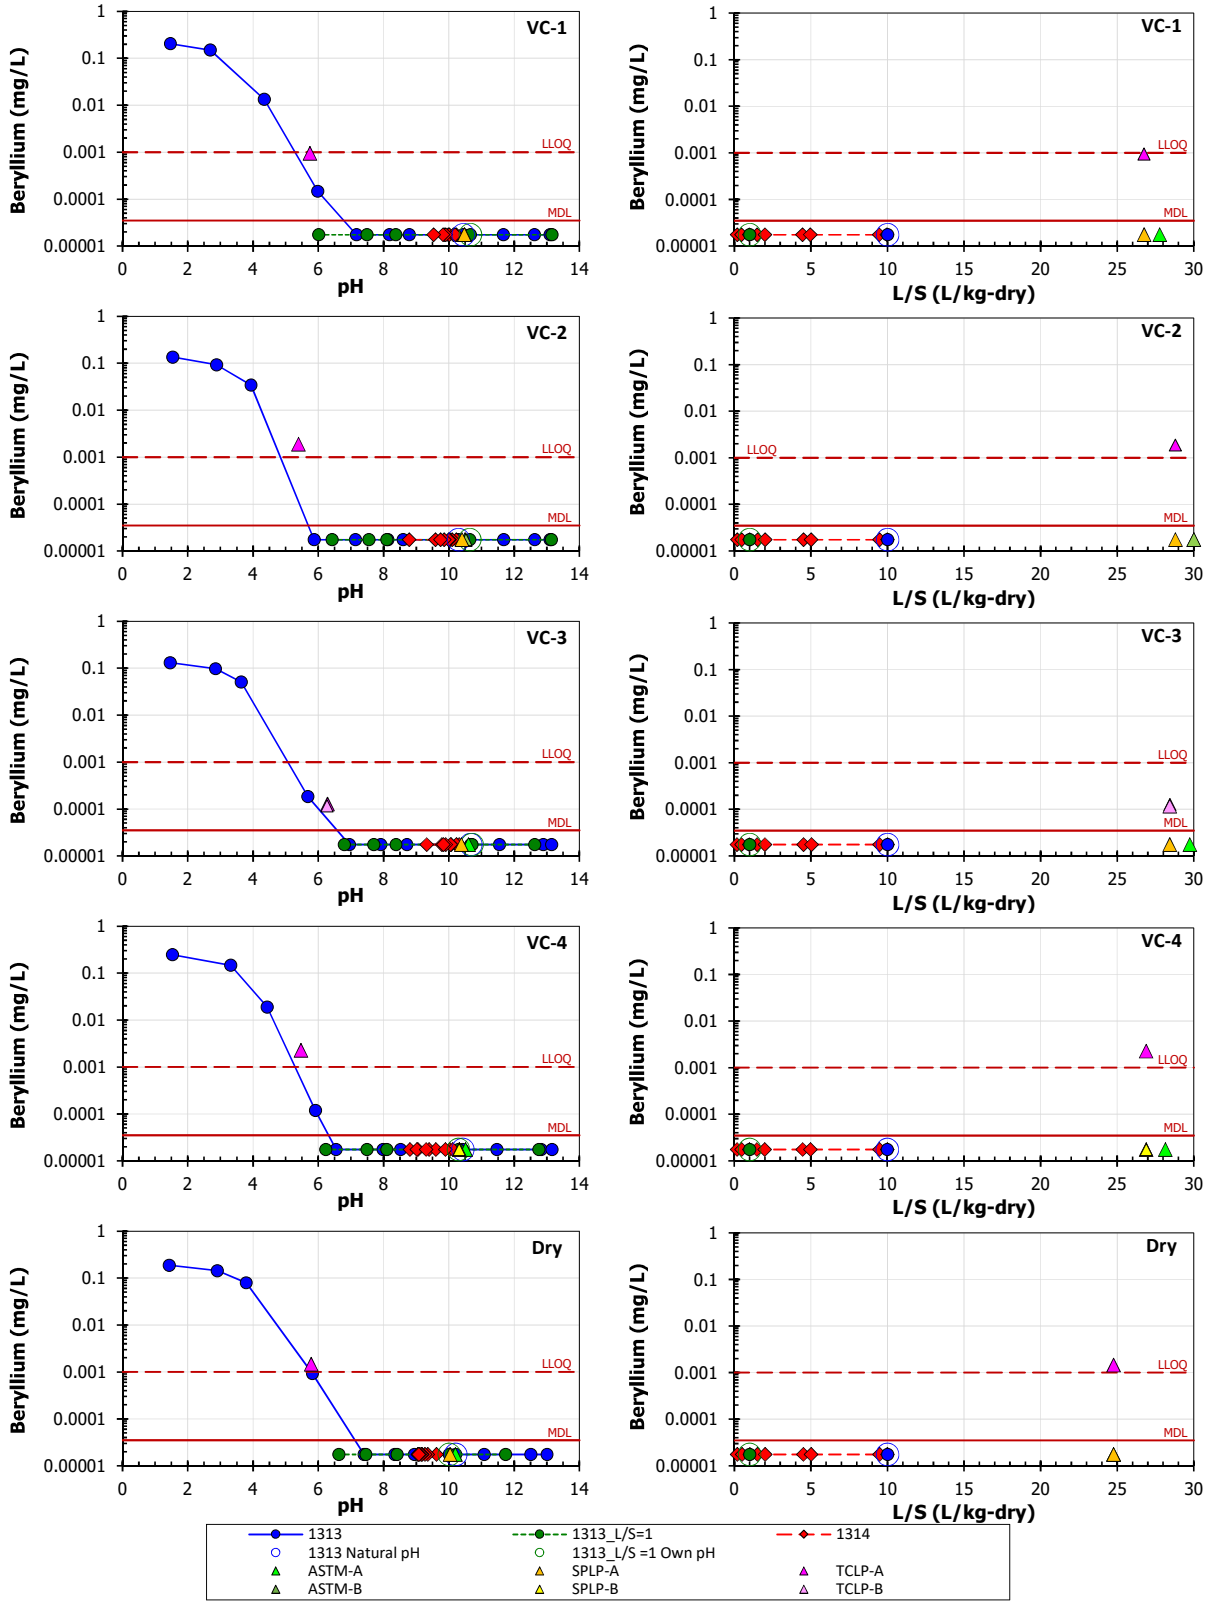

Figure C-6
Beryllium leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

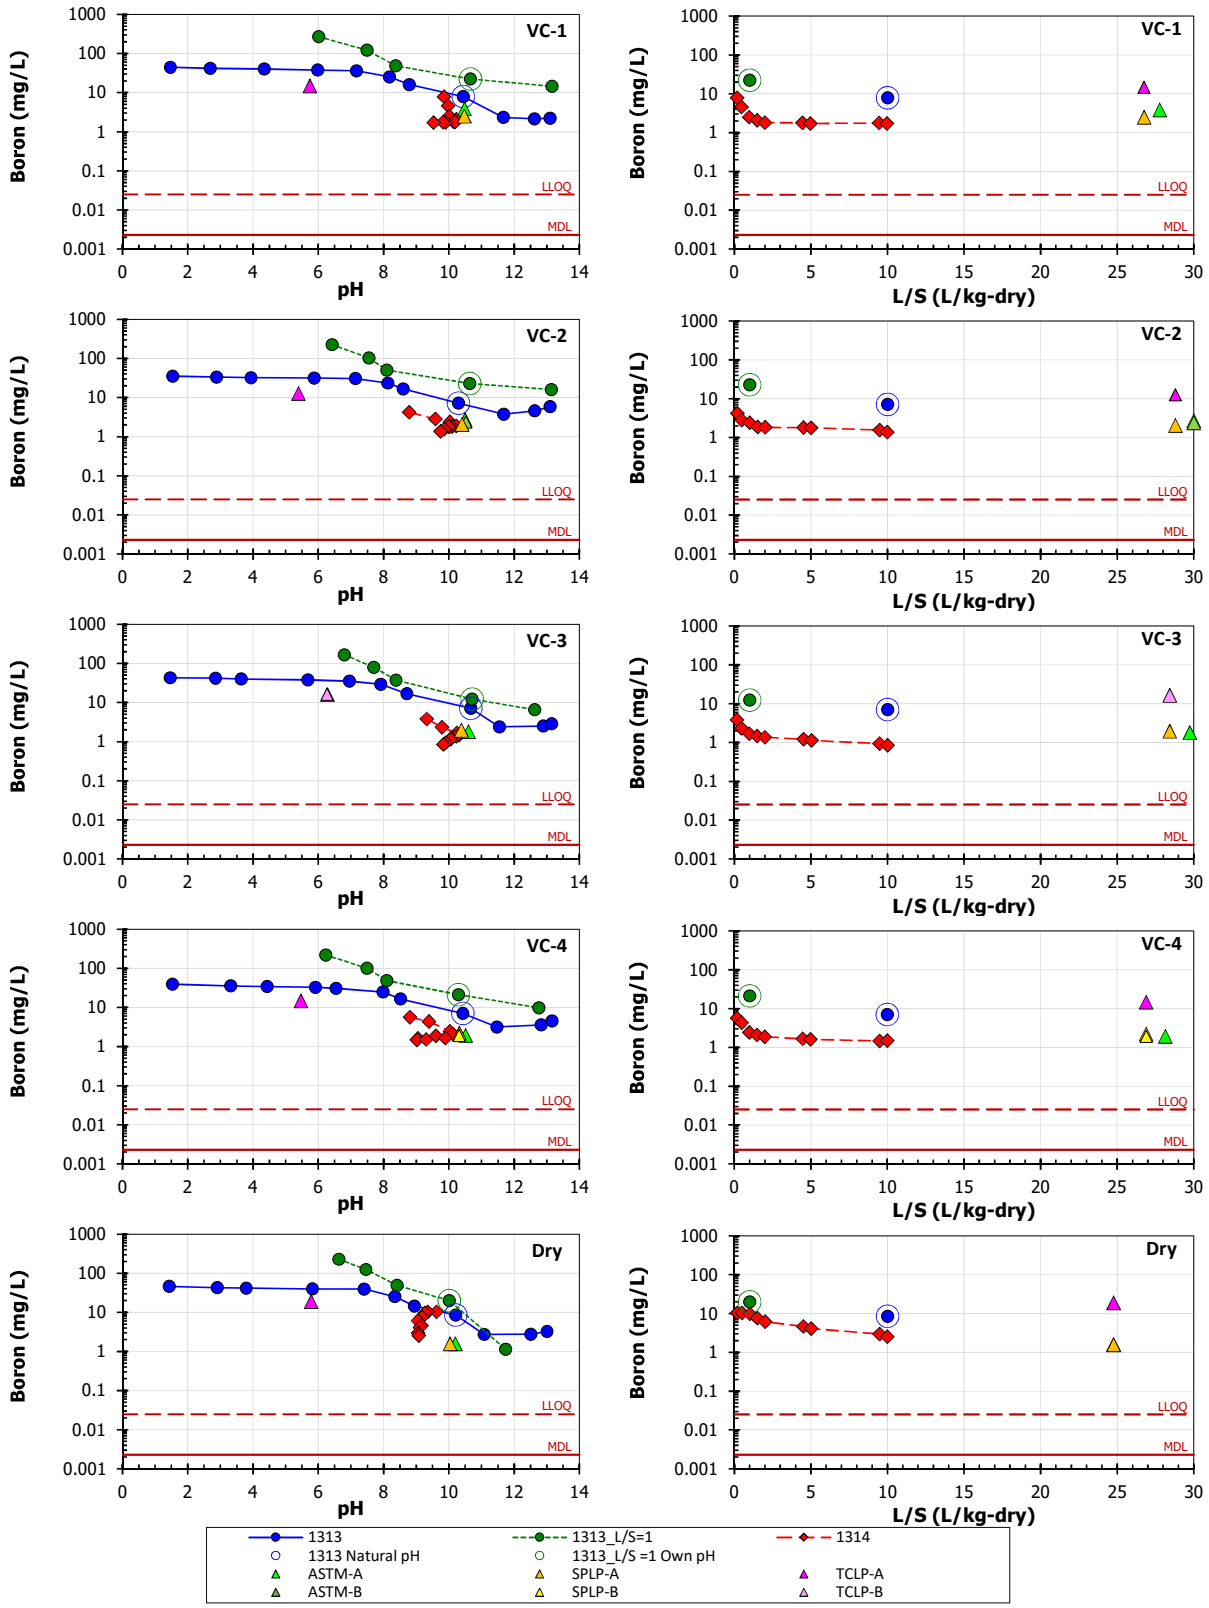

Figure C-7
Boron leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

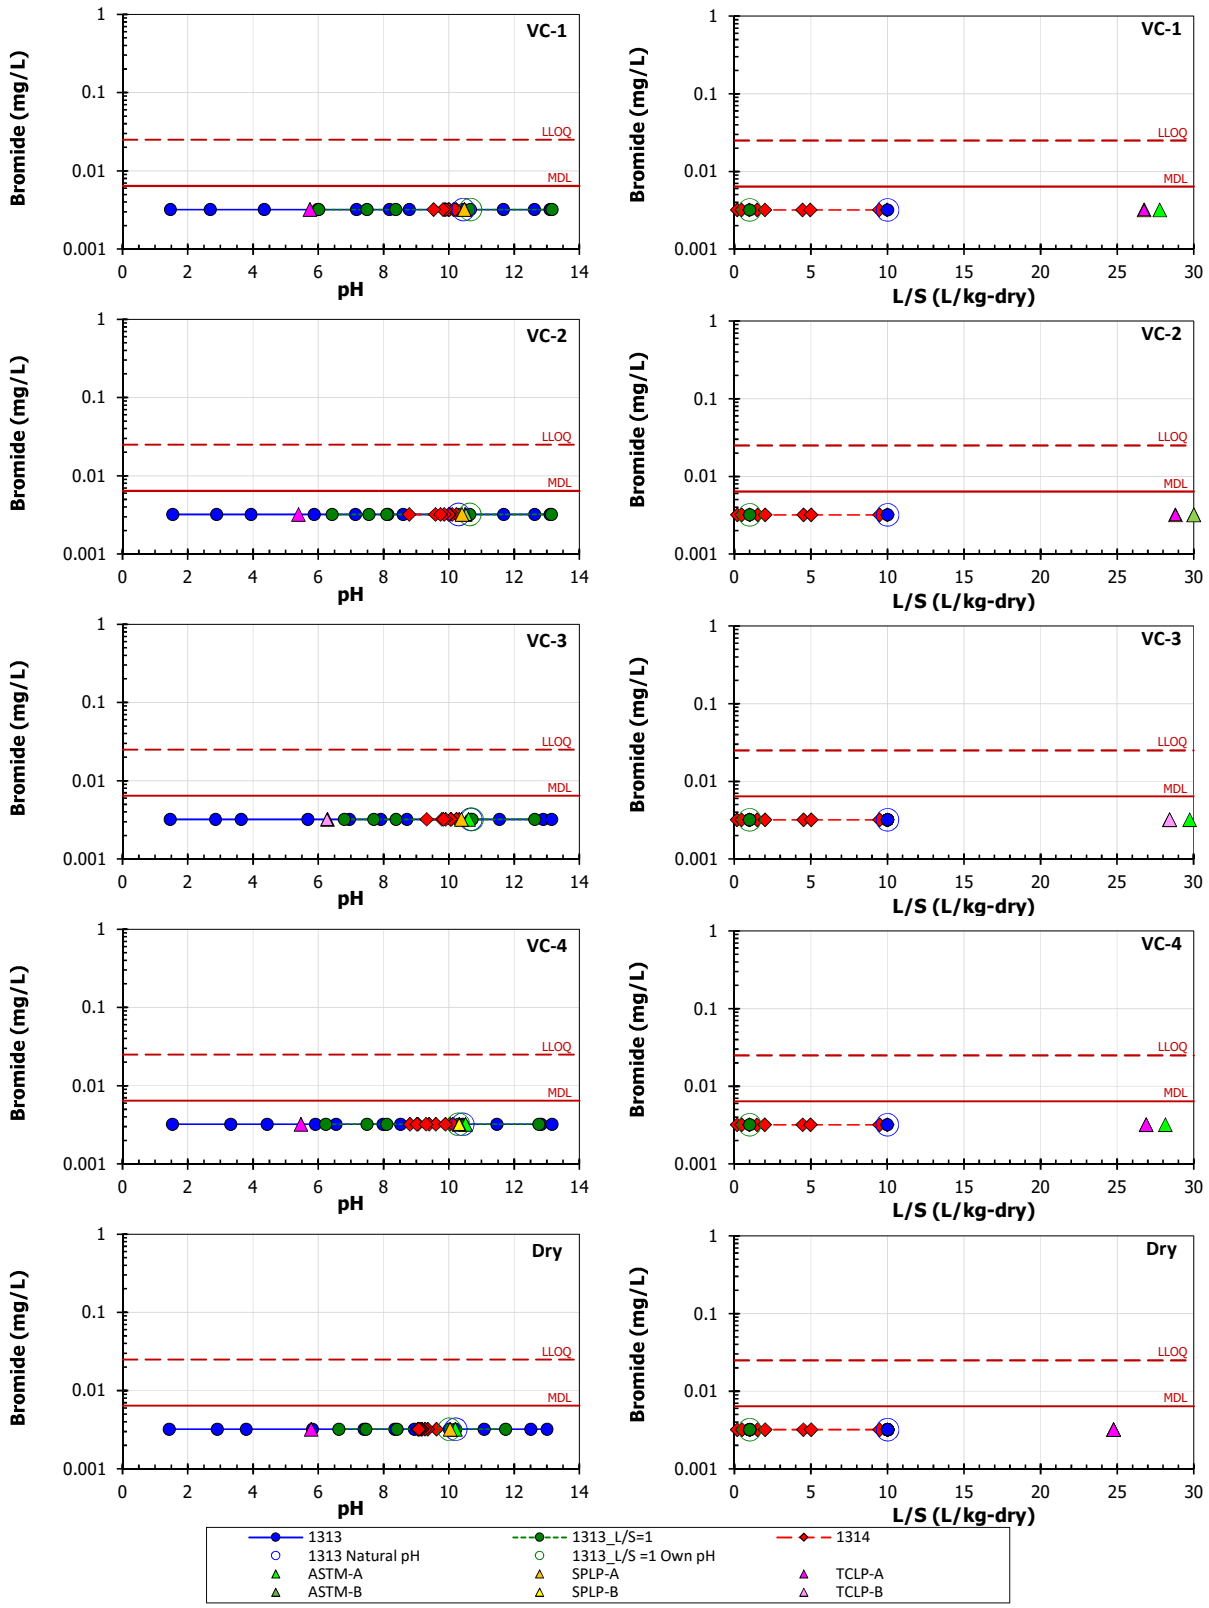

Figure C-8
Bromide leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

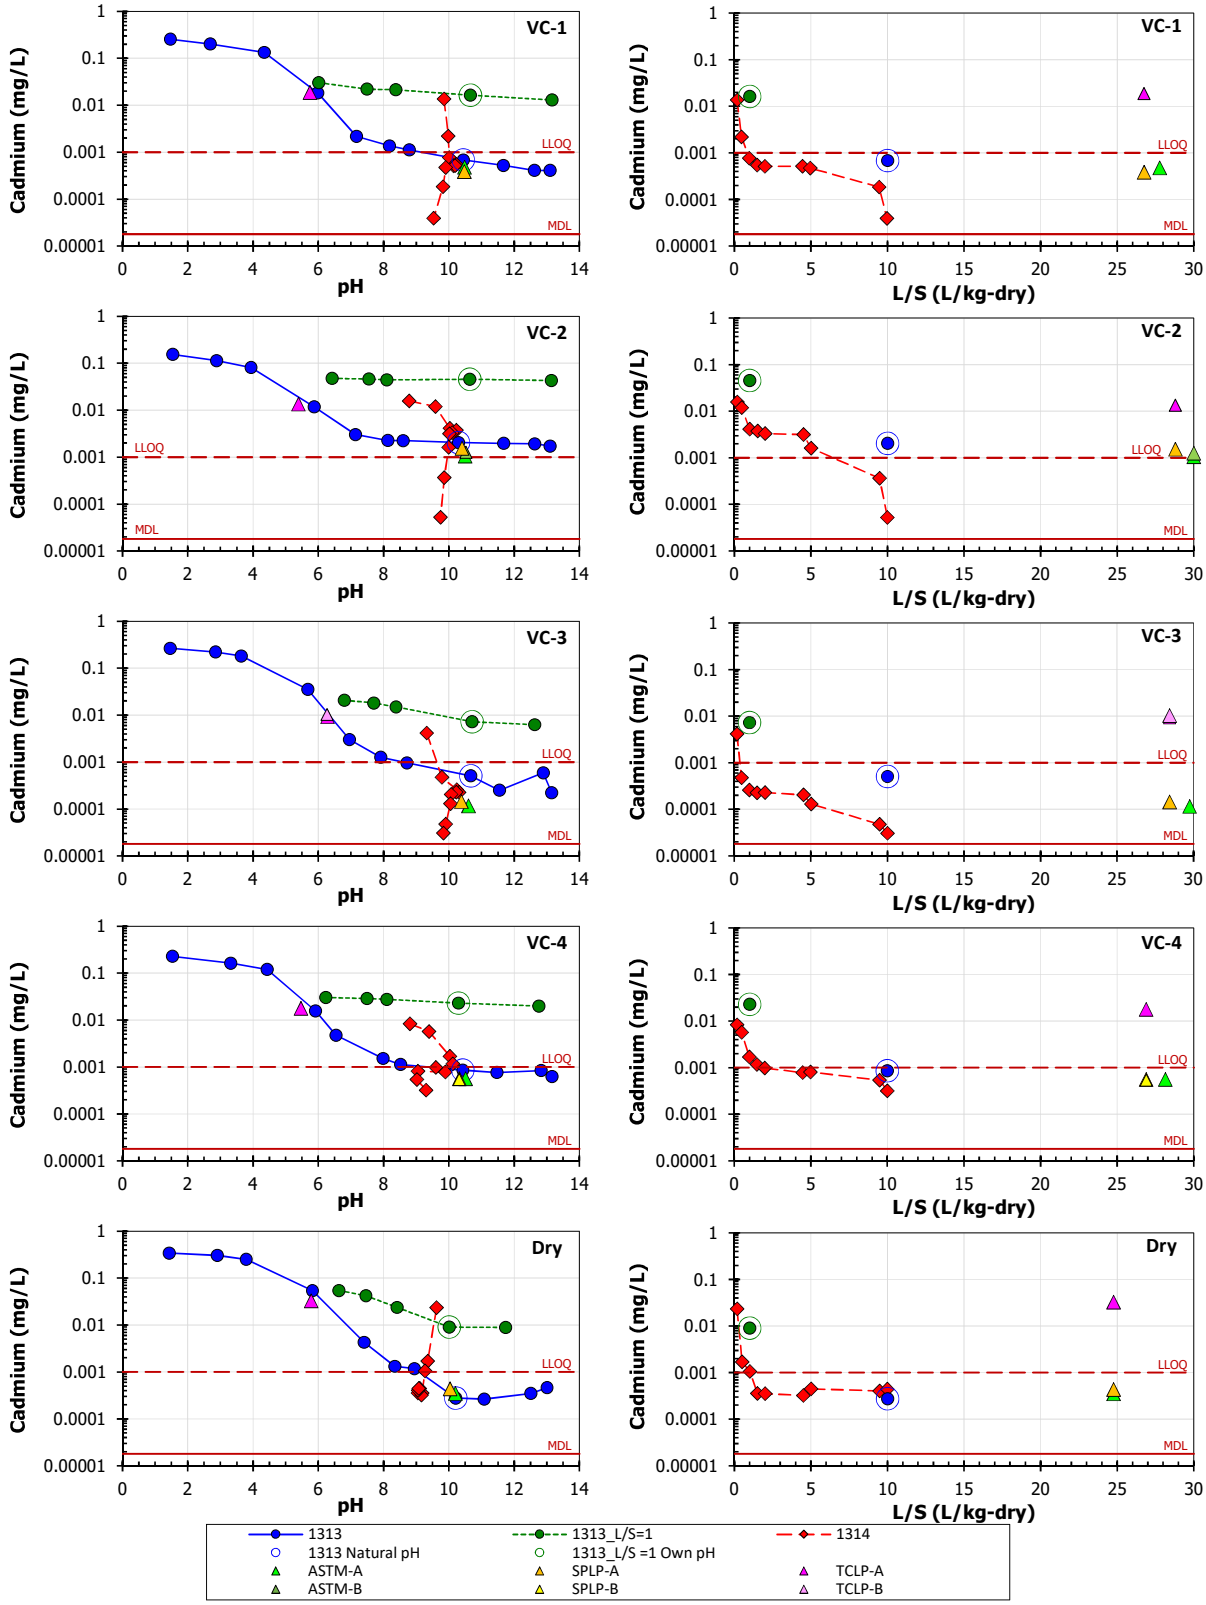

Figure C-9
Cadmium leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

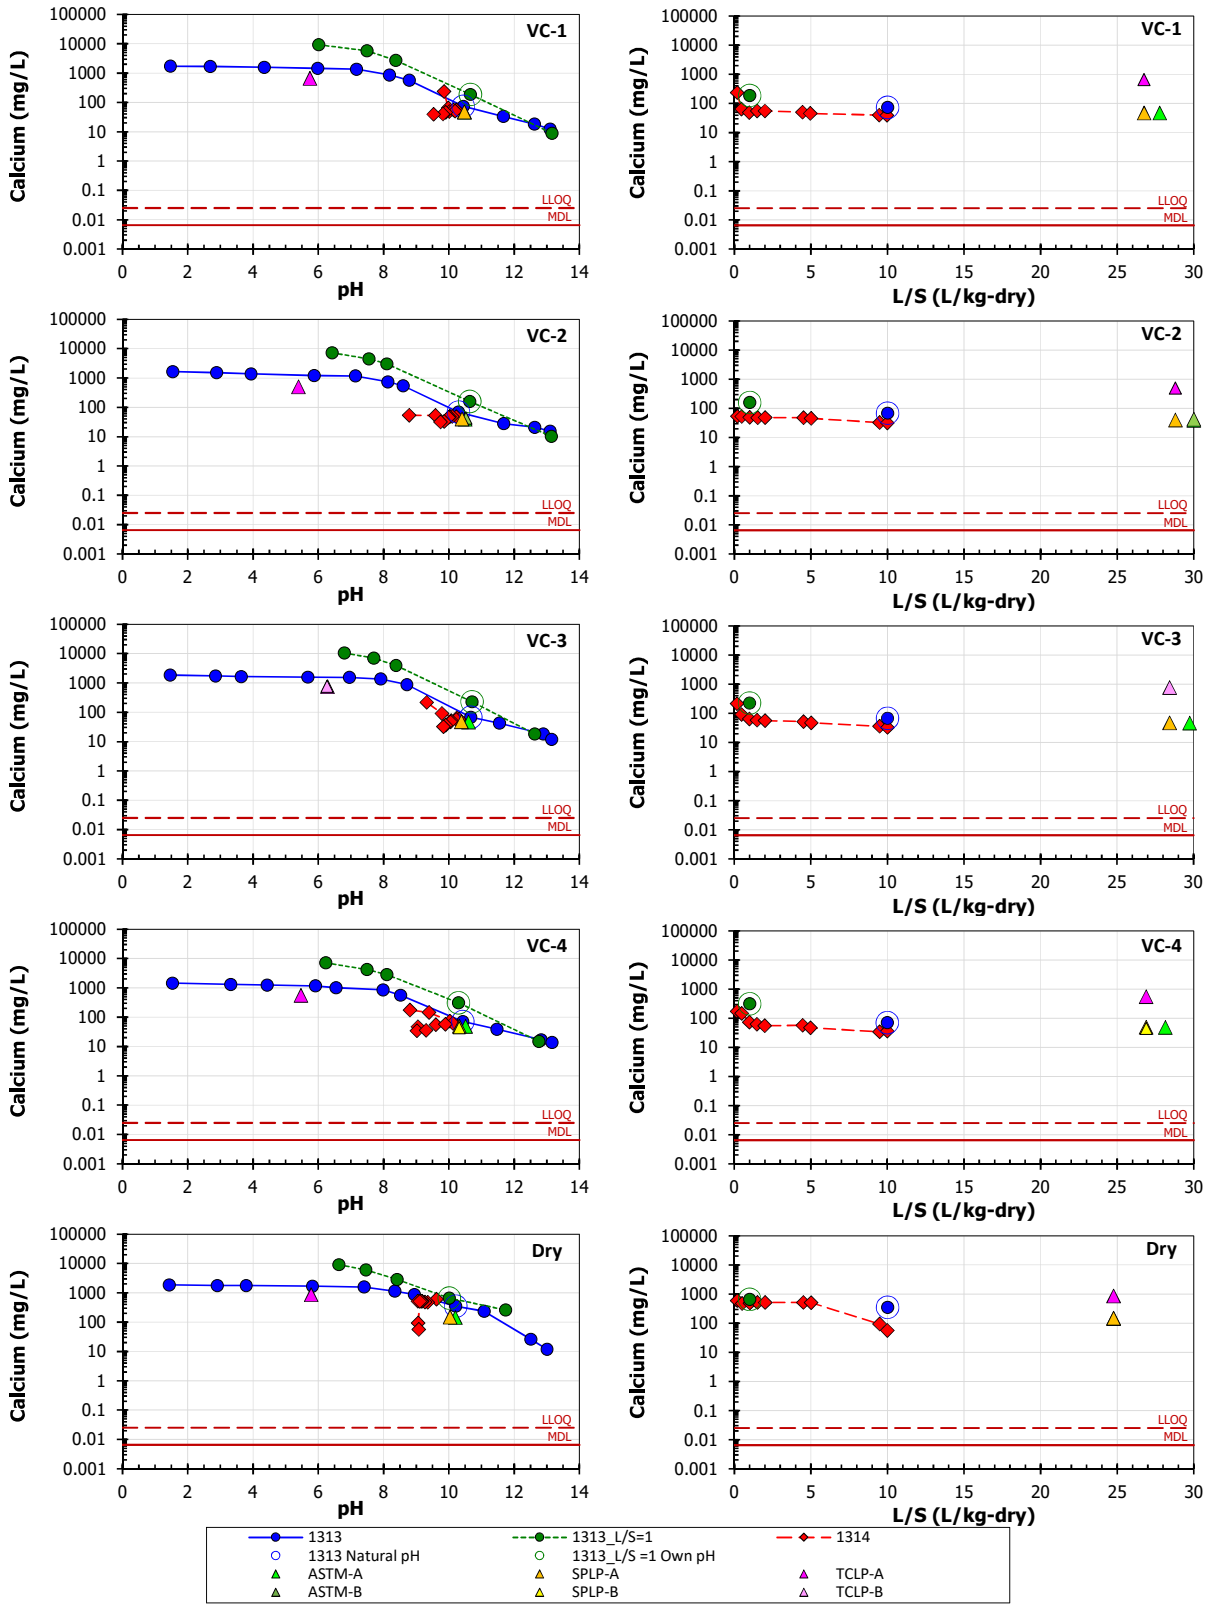

Figure C-10
Calcium leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

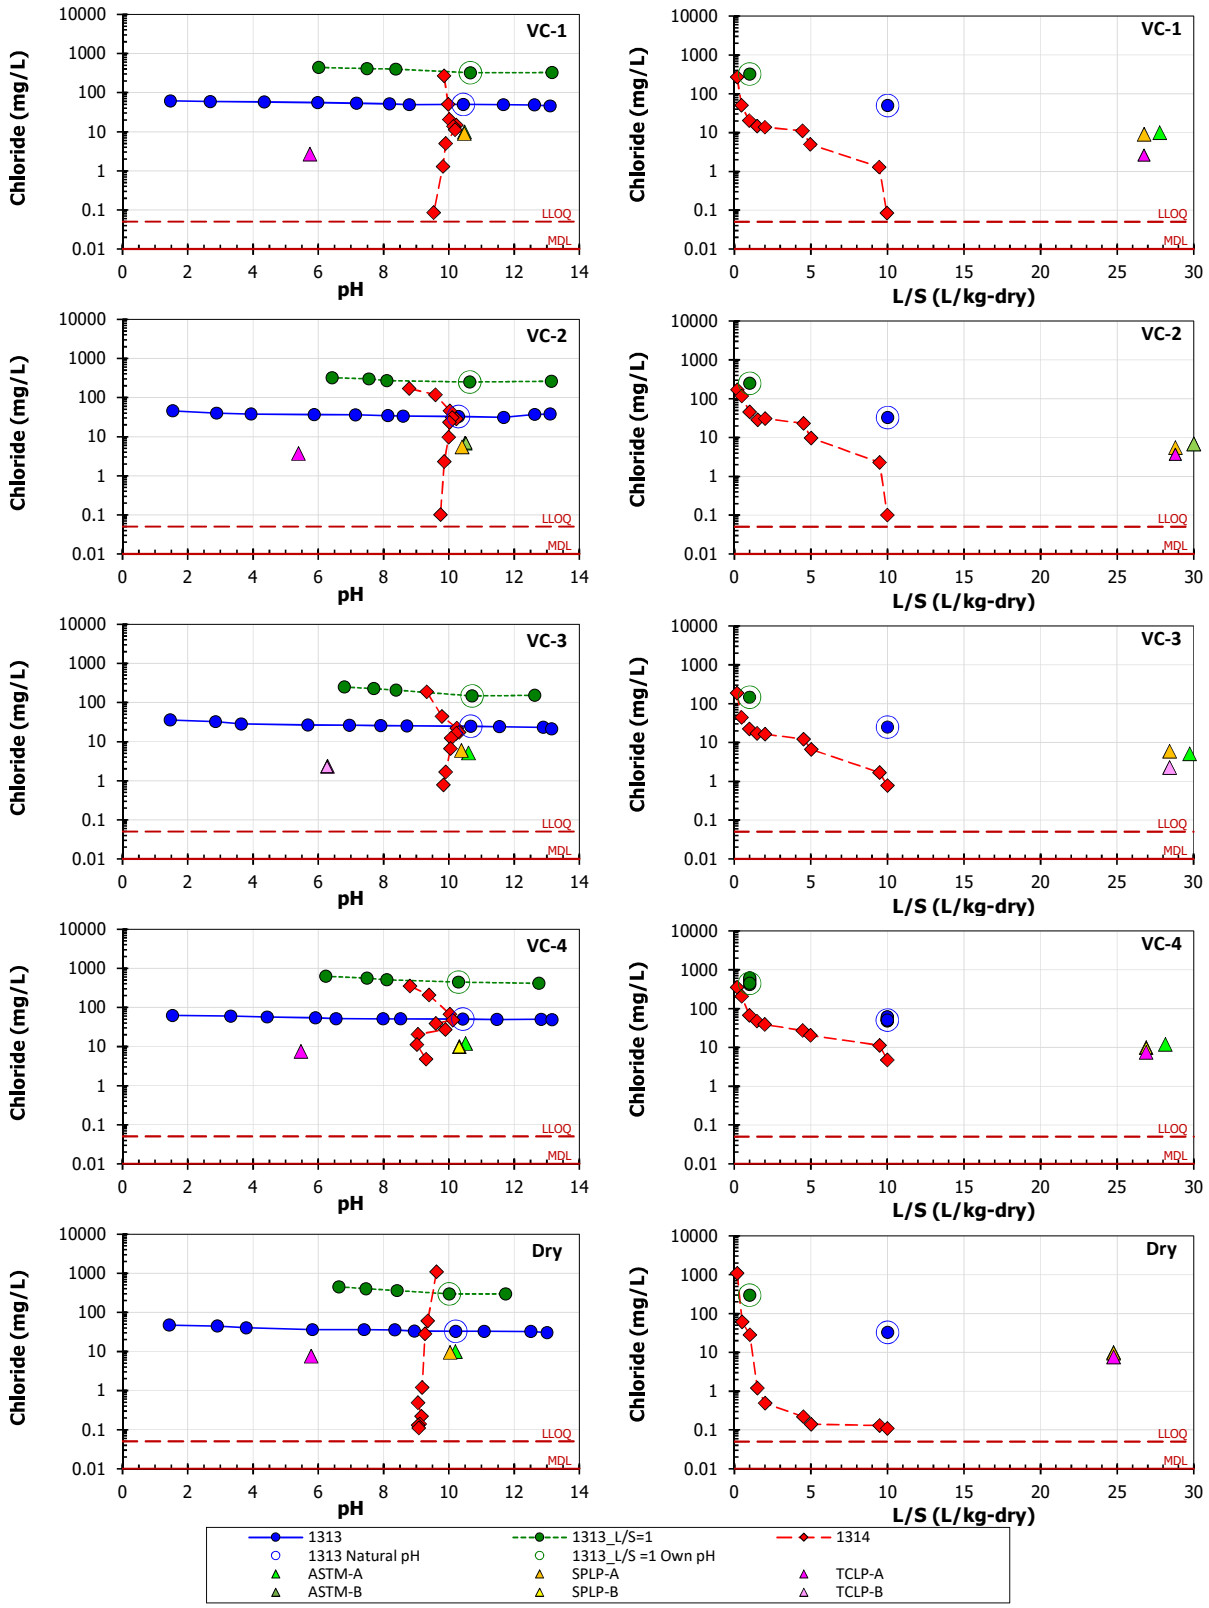

Figure C-11
Chloride leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

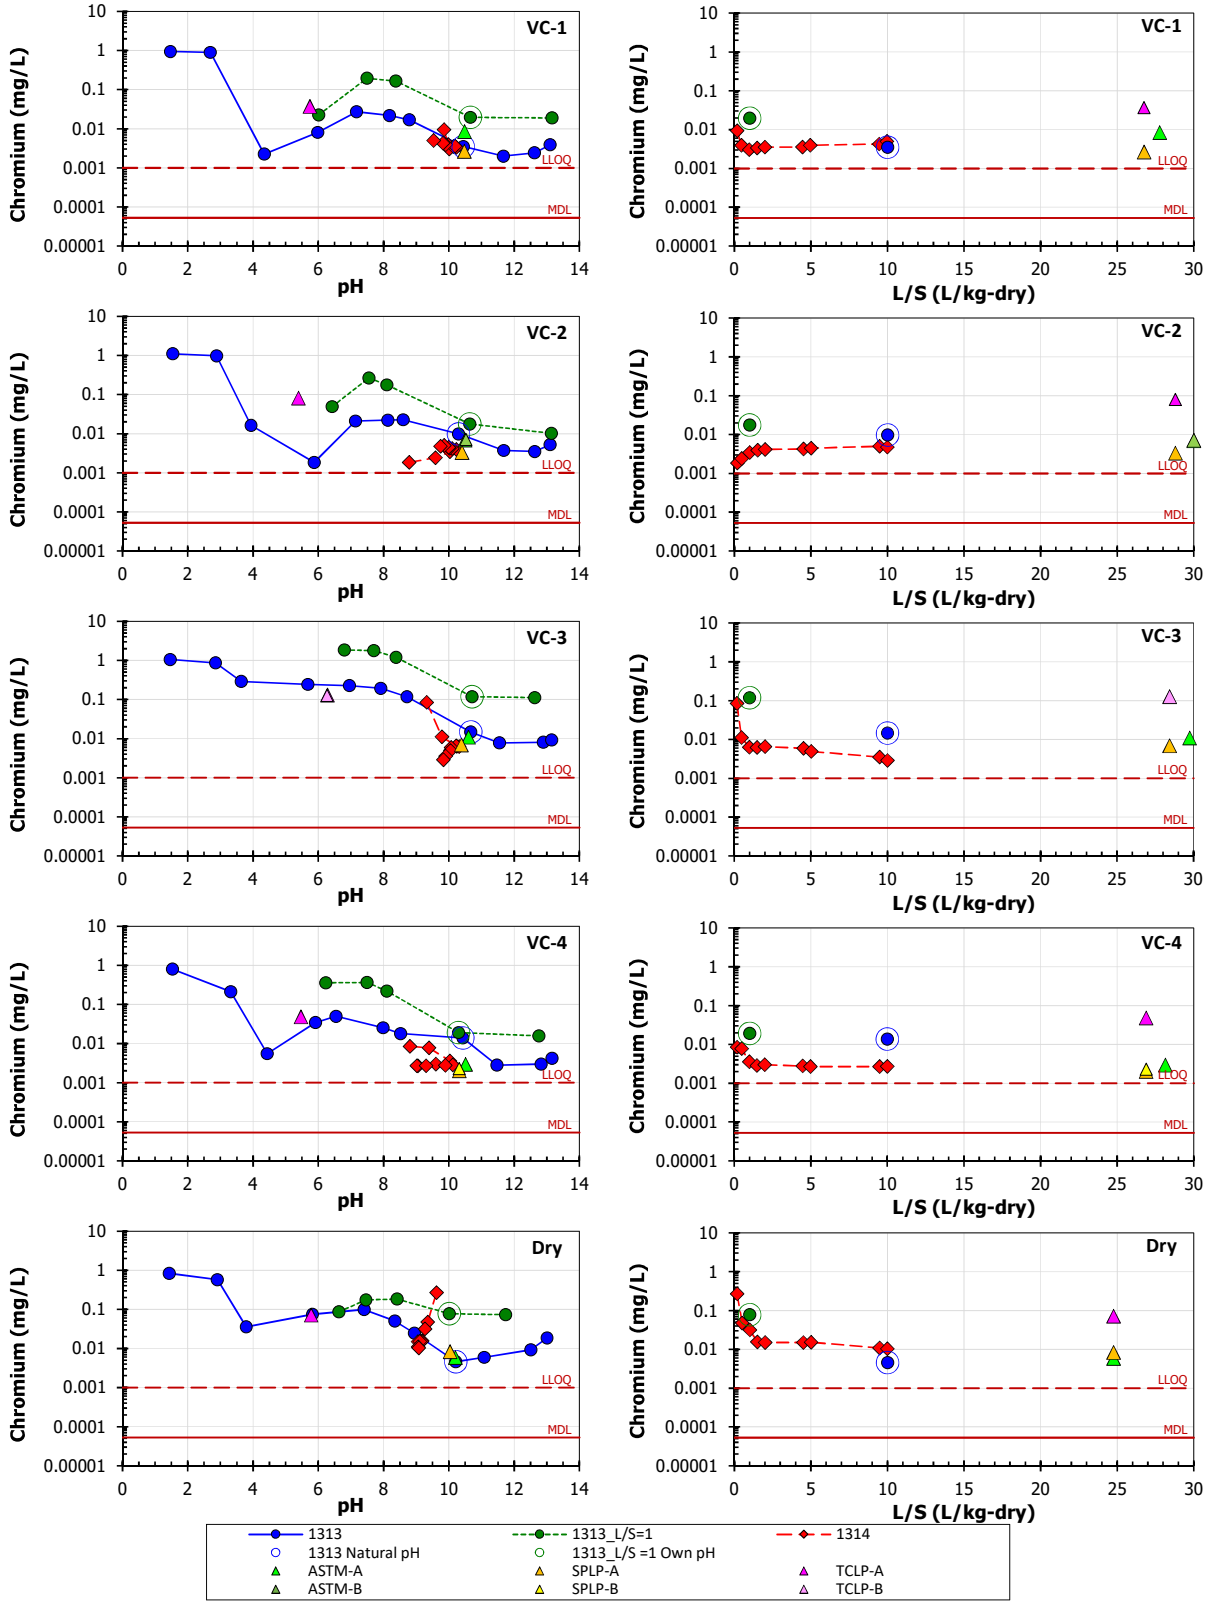

Figure C-12
Chromium leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

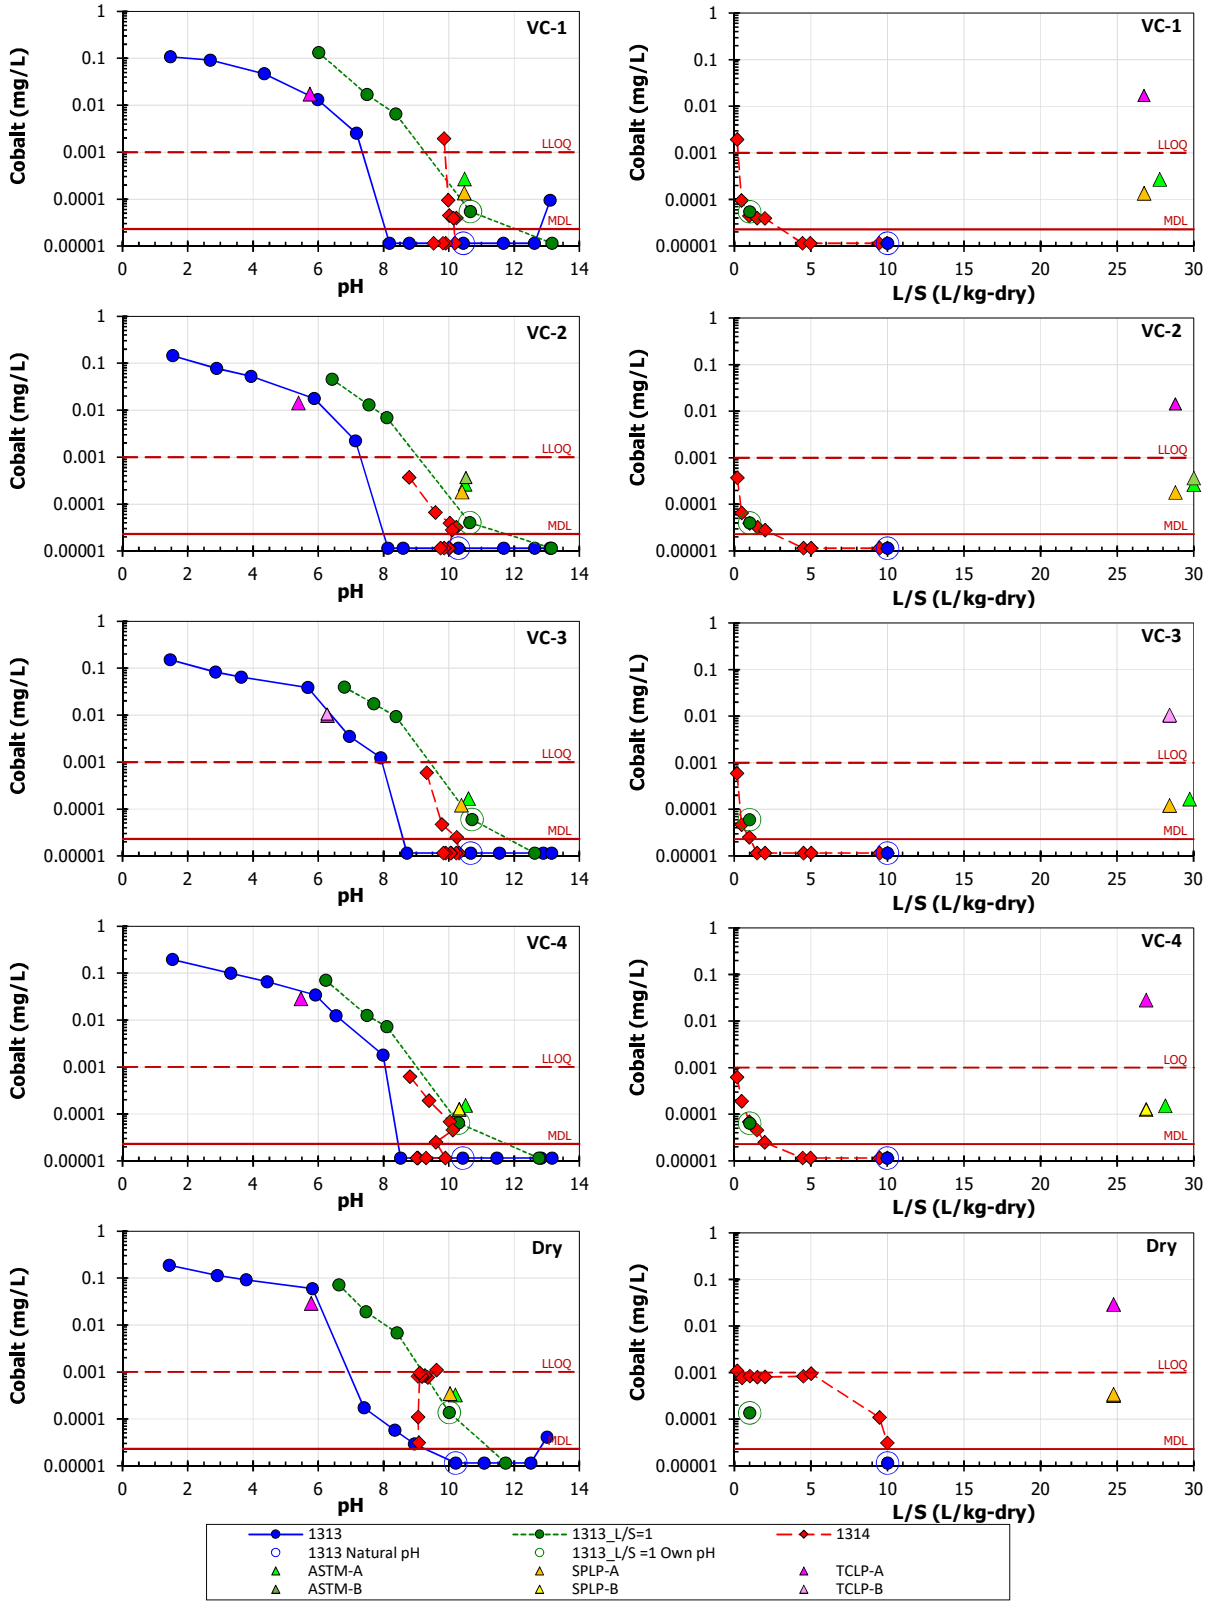

Figure C-13
Cobalt leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

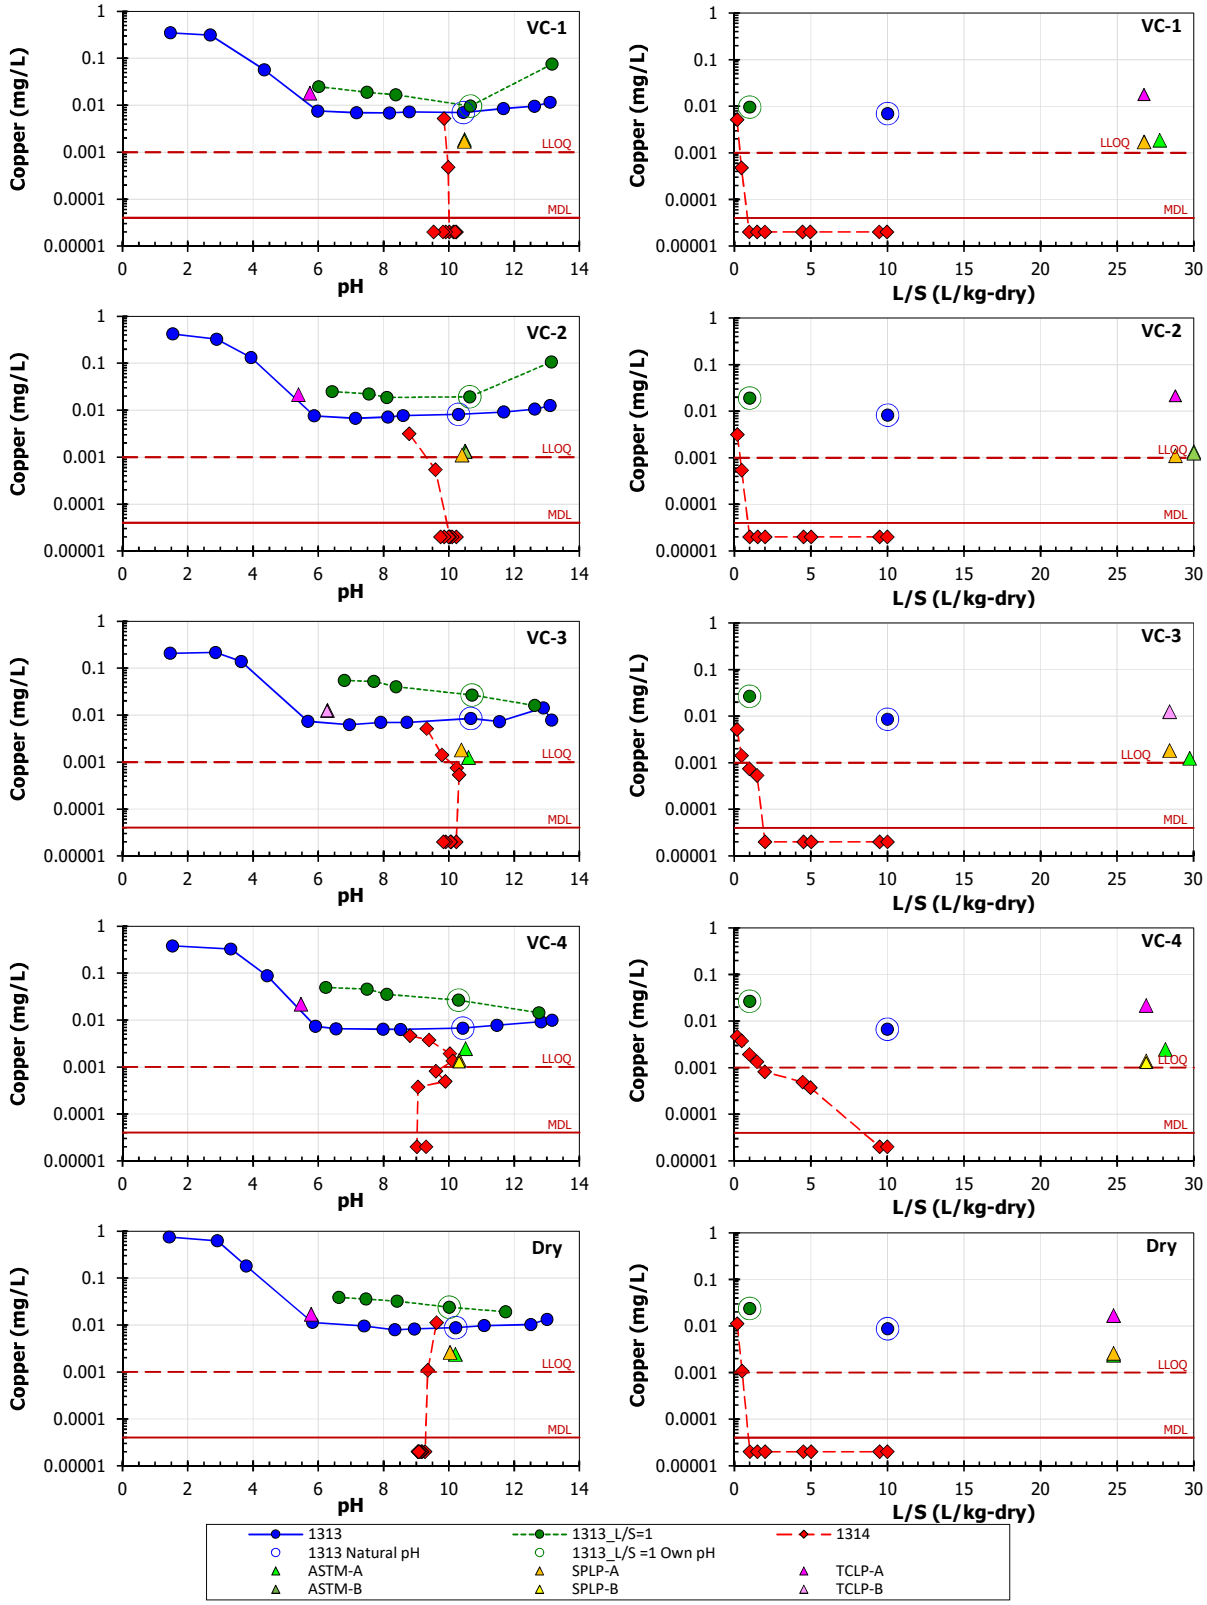

Figure C-14
Copper leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

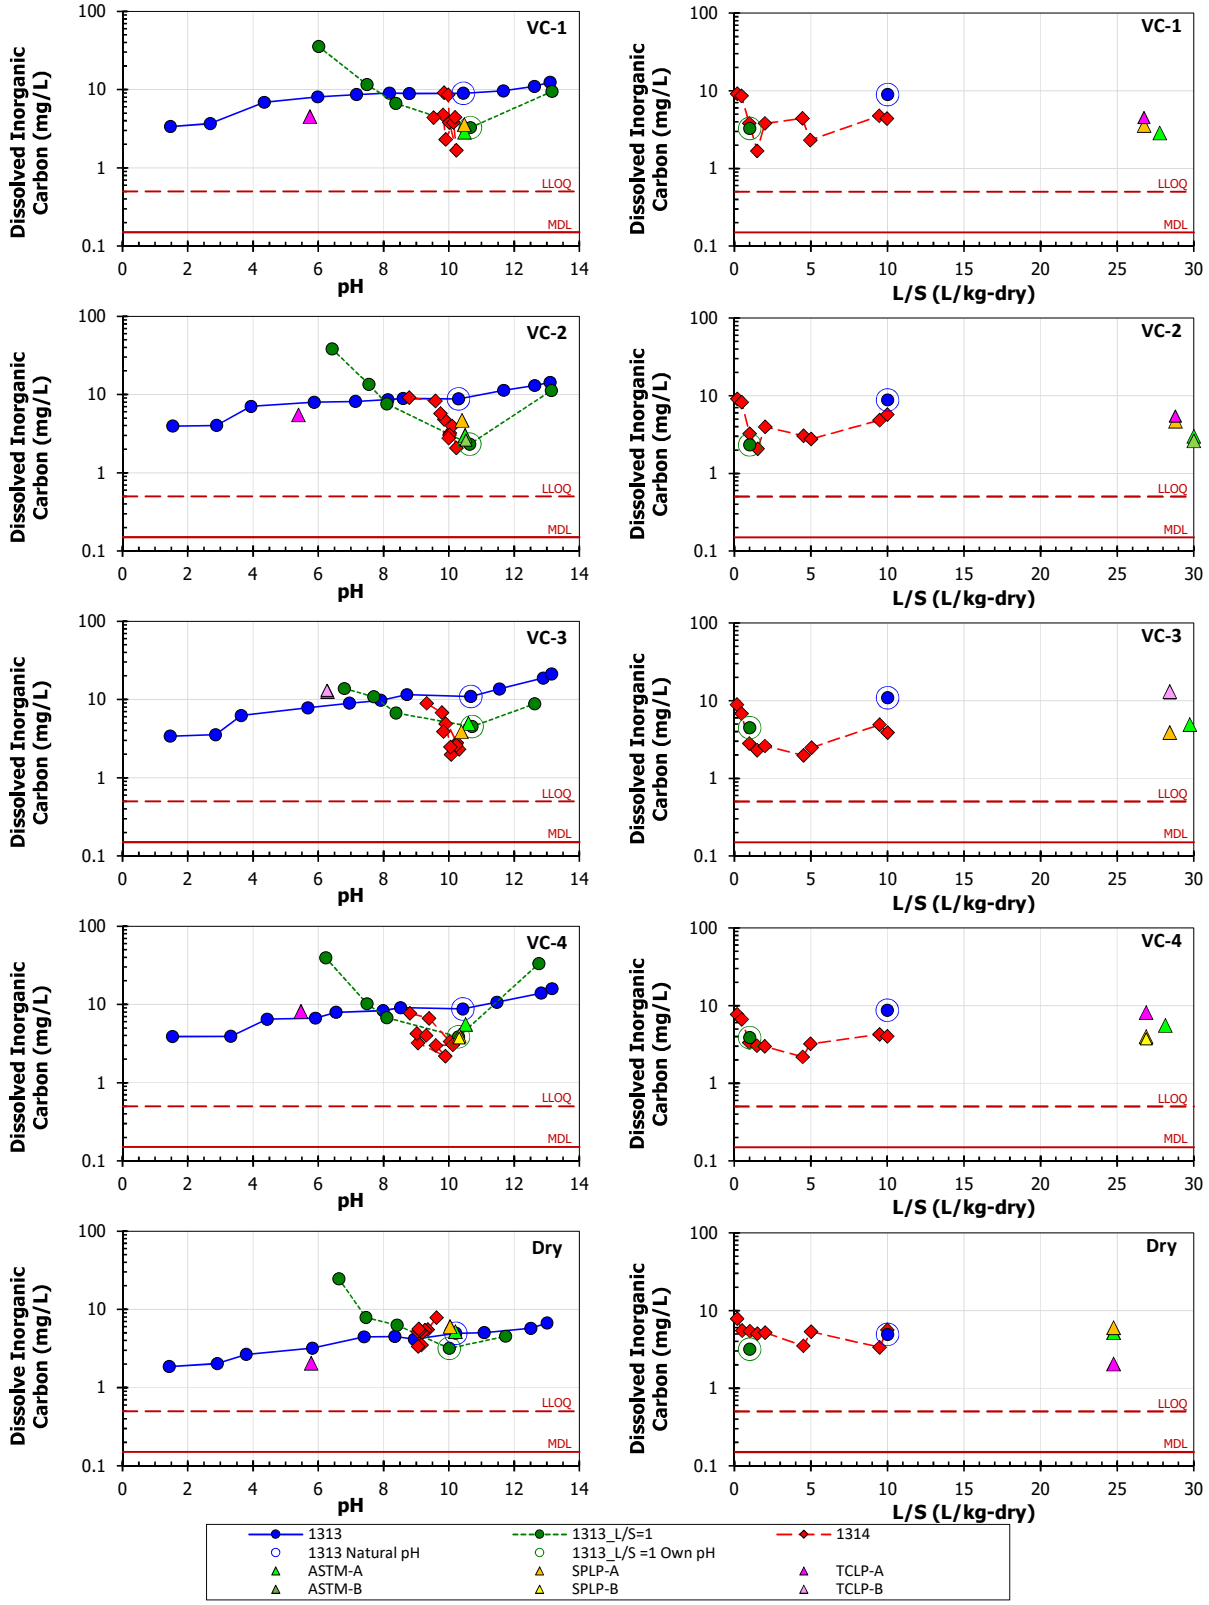

Figure C-15
Dissolved inorganic carbon leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

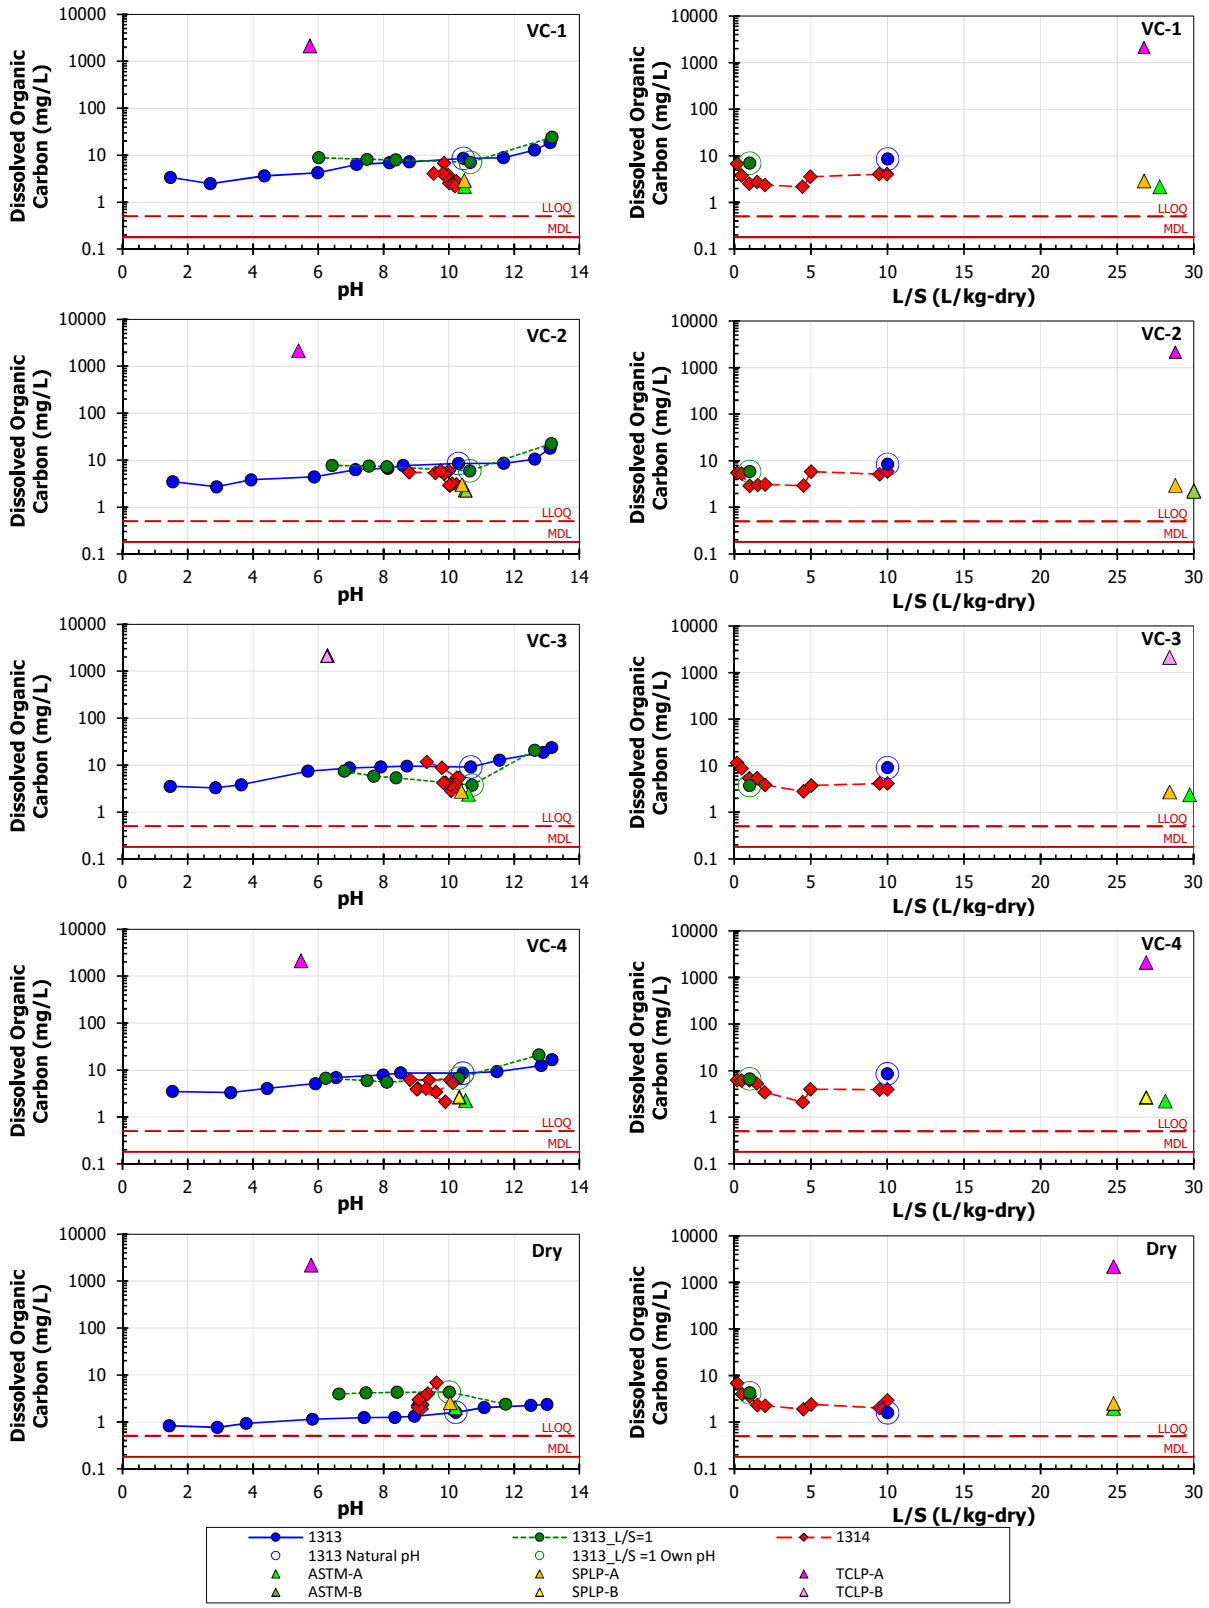

Figure C-16
Dissolved organic carbon leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

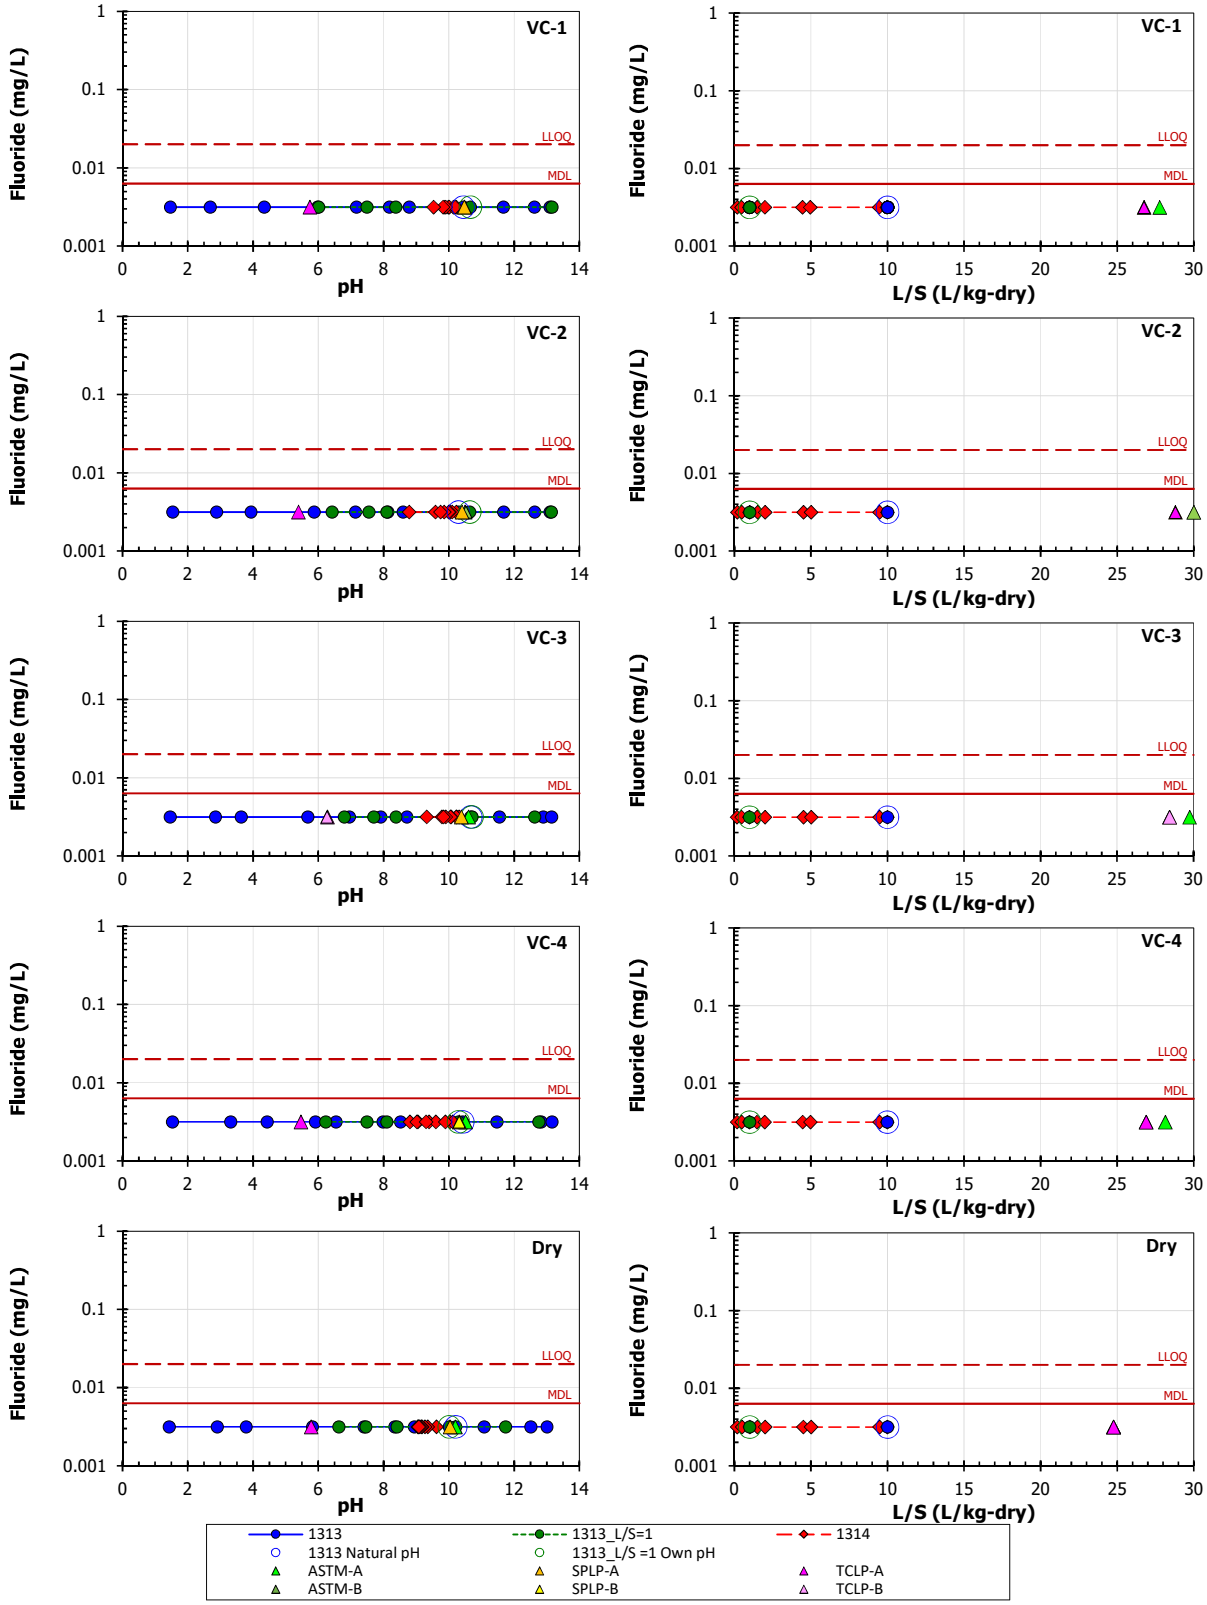

Figure C-17
Fluoride leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

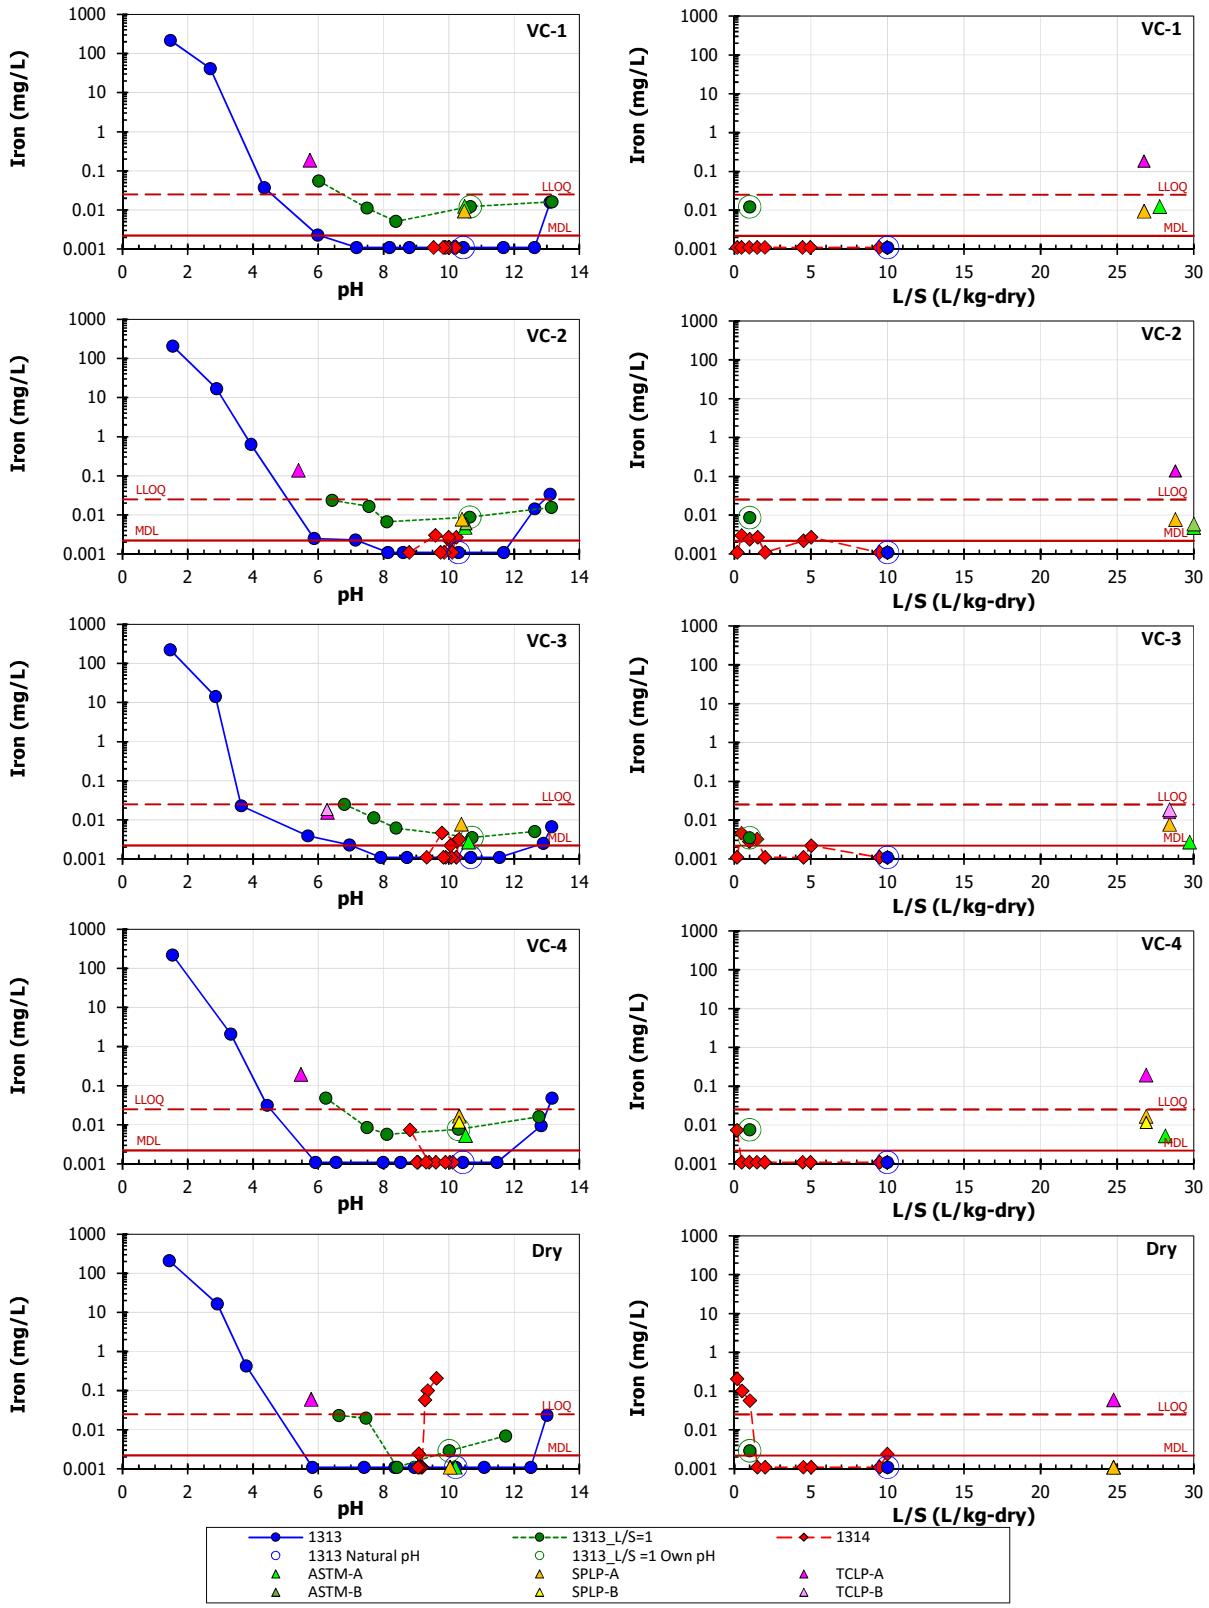

Figure C-18
Iron leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

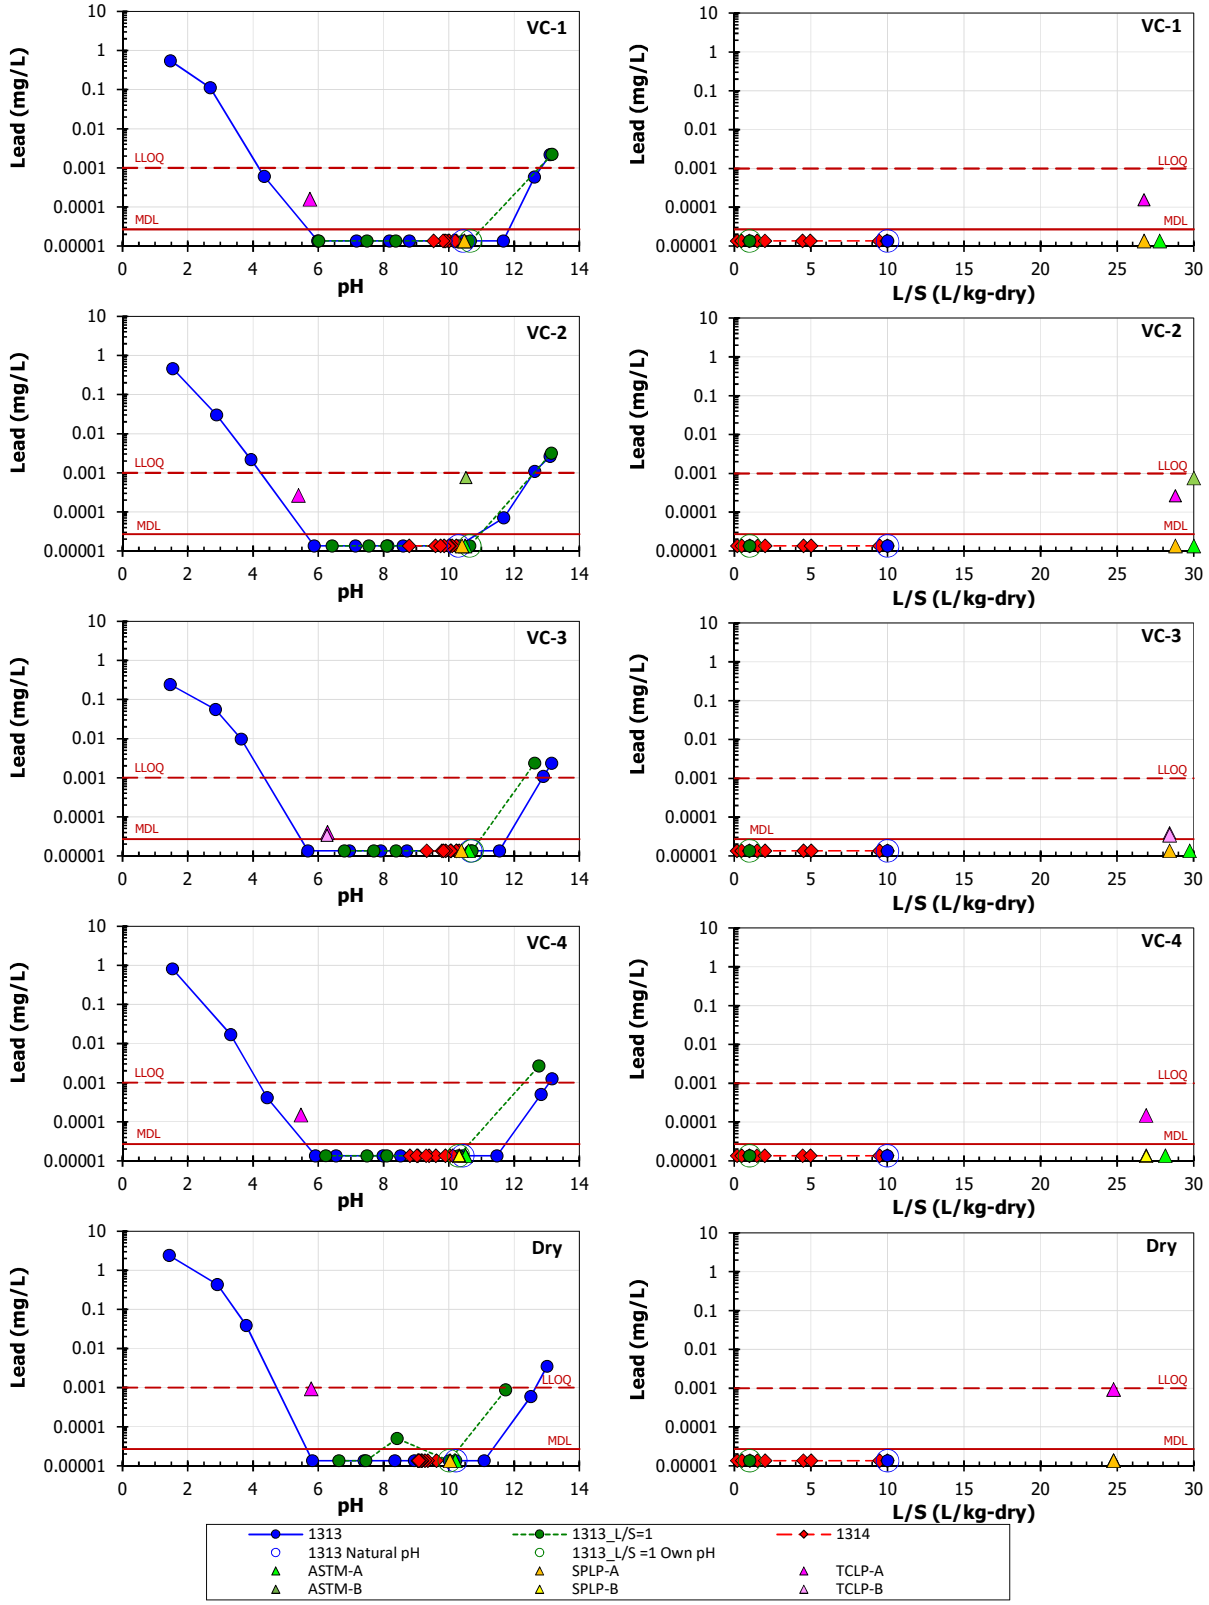

Figure C-19
Lead leaching results for LEAF tests (1313, 1313@L/S=1, 1314) and traditional tests (TCLP, SPLP, ASTM) for Plant 42197 landfill composites

ANALYTICAL QA/QC REPORTS

Analytical QA/QC reports are maintained as electronic files available upon request to EPRI.

Export Control Restrictions

Access to and use of this EPRI product is granted with the specific understanding and requirement that responsibility for ensuring full compliance with all applicable U.S. and foreign export laws and regulations is being undertaken by you and your company. This includes an obligation to ensure that any individual receiving access hereunder who is not a U.S. citizen or U.S. permanent resident is permitted access under applicable U.S. and foreign export laws and regulations.

In the event you are uncertain whether you or your company may lawfully obtain access to this EPRI product, you acknowledge that it is your obligation to consult with your company's legal counsel to determine whether this access is lawful. Although EPRI may make available on a case by case basis an informal assessment of the applicable U.S. export classification for specific EPRI products, you and your company acknowledge that this assessment is solely for informational purposes and not for reliance purposes.

Your obligations regarding U.S. export control requirements apply during and after you and your company's engagement with EPRI. To be clear, the obligations continue after your retirement or other departure from your company, and include any knowledge retained after gaining access to EPRI products.

You and your company understand and acknowledge your obligations to make a prompt report to EPRI and the appropriate authorities regarding any access to or use of this EPRI product hereunder that may be in violation of applicable U.S. or foreign export laws or regulations.

The Electric Power Research Institute, Inc. (EPRI, www.epri.com) conducts research and development relating to the generation, delivery and use of electricity for the benefit of the public. An independent, nonprofit organization, EPRI brings together its scientists and engineers as well as experts from academia and industry to help address challenges in electricity, including reliability, efficiency, affordability, health, safety and the environment. EPRI also provides technology, policy and economic analyses to drive long-range research and development planning, and supports research in emerging technologies. EPRI members represent 90% of the electricity generated and delivered in the United States with international participation extending to nearly 40 countries. EPRI's principal offices and laboratories are located in Palo Alto, Calif.; Charlotte, N.C.; Knoxville, Tenn.; Dallas, Texas; Lenox, Mass.; and Washington, D.C.

Evaluation and Comparison of Leach Test and Porewater Variability for Multiple Coal Combustion Product Management Units. EPRI, Palo Alto, CA: 2022. 3002024214.

ABSTRACT

EPRI is researching coal combustion product (CCP) porewater chemistry to improve predictions of chemical evolution over the long term, particularly post-closure. An EPRI-member company made a large volume of porewater chemistry data available to EPRI, which was used to improve our understanding of porewater chemistry and how it varies between and within CCP units. This data set also provided information on the efficacy of USEPA's SW-846 1313 and 1316 leaching methods (also known as *LEAF 1313* and *LEAF 1316*) for evaluating porewater chemistry.

The objective of this research was to provide information on the chemistry of CCP porewater and how it may vary to help inform decision making on porewater evaluations. The specific objectives of this project were to:

- Evaluate the relationship of total (unfiltered) concentrations versus dissolved (filtered) concentrations in CCP porewater
- Assess the variability of porewater properties within and between CCP units
- Identify whether there are relationships between the laboratory leaching tests and measured porewater concentrations

Keywords

CCP porewater
Coal combustion products (CCPs)

Deliverable Number: 3002024214

Product Type: Technical Report

Product Title: Evaluation and Comparison of Leach Test and Porewater Variability for Multiple Coal Combustion Product Management Units

PRIMARY AUDIENCE: Subject matter experts and project managers responsible for closure or groundwater remediation at coal combustion product (CCP) management units.

SECONDARY AUDIENCE: Groundwater and geochemical modelers responsible for predicting the long-term effects of closure or groundwater remediation at CCP management units.

KEY RESEARCH QUESTION

EPRI is researching CCP porewater chemistry to improve predictions of chemical evolution over the long term, particularly post-closure. The objective of this research was to provide information on the chemistry of CCP porewater and how it may vary to inform decision making when characterizing porewater concentration for groundwater and geochemical models. The specific objectives of this project were to:

- Evaluate the relationship of total (unfiltered) concentrations versus dissolved (filtered) concentrations in CCP porewater
- Assess the variability of porewater properties within and between CCP units
- Identify whether there are relationships between the laboratory leaching tests and measured porewater concentrations

RESEARCH OVERVIEW

CCP porewater data were collected and provided by an EPRI-member company. The porewater data were collected from porewater monitoring points (PMPs) installed at 29 CCP management units between 2015 and 2021. In addition, CCP solids samples from the same location and depth as the PMPs at four units were subjected to leach testing using USEPA SW-846 methods 1313 (LEAF 1313) and 1316 (LEAF 1316). EPRI researchers used graphical and statistical methods to evaluate the data with respect to the project objectives.

KEY FINDINGS

- A comparison of total versus dissolved porewater sample results indicated:
  - Total and dissolved measurements are generally more comparable at concentrations elevated well above the reporting limit where laboratory analytical variability is less significant relative to concentration.
  - Major ions (Ca, Mg, Na, K), certain minor ions (Ba, B, Mn, Mo, Sr, Li), and elements with low detection frequency (Cd, Hg) were least likely to be affected by sample filtration.
  - Elements most likely to be affected by sample filtration were Al, Cr, Cu, Fe, and V.
- A comparison of intra-unit and inter-unit porewater variability results indicated:
  - There does not appear to be an overall pattern to define which parameters exhibit high or low variability. However, parameters of interest—either because they are CCP tracers (B and SO_4) or potential remediation drivers (As, Sb, B, Cr, Co, Li, Mo, and Se)—mostly have medium to high intra-unit variability, which suggests that more extensive porewater evaluation may be helpful to characterize a unit when developing a source term to model these parameters. Lithium was the only remediation driver with low intra-unit variability.

  - As, B, Co, Li, Mo, Se, and SO_4 had high inter-unit variability. Sb and Cr had medium and low inter-unit variability, respectively, which was attributed to their relatively low concentration in the porewater samples.
- Comparing leach test eluates to porewater samples, EPRI researchers observed:
  - LEAF 1313 and 1316 eluate concentrations were usually more than 25% higher or 25% lower than their paired median porewater concentrations. This observation was made for 1313 eluates at natural pH and the broader pH range for all porewaters as well as for 1316 results at low and high L/S.
  - Elements often controlled by available content—such as B, Ca, Cl, Li, Sr, and SO_4—tended to be underpredicted by the LEAF tests.
  - As, Fe, and Mn were also underpredicted, even though they tend to be solubility controlled, because the LEAF testing was performed under oxic conditions when the solubility of these elements is low.
  - Conversely, Se and Cr, which are most soluble under oxic conditions, tended to be overpredicted by the LEAF testing performed under oxic conditions.
  - Sb, Tl, and V tended to be overpredicted by the leach tests while other elements were overpredicted or underpredicted depending on test-specific and site-specific factors.

WHY THIS MATTERS

This research helps stakeholders understand that LEAF tests produce valuable information for comparing CCPs and understanding their geochemistry but are not reliable for predicting in-field porewater quality. This research also helps stakeholders understand CCP porewater variability, which can be used to improve characterization of source terms used in fate and transport or geochemical models and resulting predictions of groundwater quality in response to closure or remediation alternatives evaluated with these models.

HOW TO APPLY RESULTS

The conclusions of this research are stated in this executive summary. Readers interested in more detailed information for specific constituents can reference the body of this report.

LEARNING AND ENGAGEMENT OPPORTUNITIES

INTRODUCTION

EPRI is researching coal combustion product (CCP) porewater chemistry to improve predictions of chemical evolution over the long term, particularly post-closure. The objective of this research was to provide information on the chemistry of CCP porewater and how it may vary to inform decision making when characterizing porewater concentration for groundwater and geochemical models. The specific objectives of this project were to:

- Evaluate the relationship of total (unfiltered) concentrations versus dissolved (filtered) concentrations in CCP porewater
- Assess the variability of porewater properties within and between CCP units
- Identify whether there are relationships between the laboratory leaching tests and measured porewater concentrations

2
SUMMARY OF DATA

Coal Combustion Product Units

CCP porewater and leach test data were provided for 14 power plants in North Carolina (Synterra, 2021). The 14 power plants and 29 associated CCP management units are summarized in Table 2-1. Porewater data were collected from porewater monitoring points (PMPs) installed at all 29 units between 2015 and 2021. Additional data from laboratory leaching tests were provided for four plants (Allen, BCSS, Cliffside, and Marshall), based on cores collected at the time of PMP installation in 2018. Operational periods are summarized in Table 2-1 and illustrated in Figure 2-1.

All units contain coal ash and are primarily a mix of fly ash and bottom ash. Several units were excavated within the last 15 years (that is, Asheville units 1964 and 1982, Cliffside units 1–4 and ash storage area, Dan River ash basin, Riverbend ash basin and cinder storage area, and Weatherspoon 1979 ash basin).

Leach test data were obtained by LEAF 1313[1] and LEAF 1316.[2] Synthetic precipitation leaching procedure (SPLP) was also performed, but final values for eluate pH were not available, so the SPLP results are not further considered.

Data Preparation and Refinement

Data were provided in two separate files: one containing the porewater data and the other containing LEAF leach test eluate data. Due to differences in how these two files reported data, slightly different data preprocessing and quality assurance steps were taken for the porewater data file and the LEAF eluate data file. For both data files, concentrations reported in units of µg/L were converted to mg/L for consistency across the data set. Radium activities reported as negative values were set to zero for both data files. Quality control replicate sample analyses were removed from the porewater data set to avoid bias because those results are not independent.[3] In the porewater data, non-detect results were identified as those samples flagged with a "U" qualifier, and the method detection limit was used as the result. QA/QC samples were excluded from the LEAF eluate data. In the LEAF eluate data, non-detect results were identified

[1] LEAF 1313 (SW-846, USEPA 2019) is a standardized, parallel batch extraction method used to evaluate the liquid-solid partitioning (LSP) of inorganic constituents as a function of eluate pH.
[2] LEAF 1316 (SW-846, USEPA 2019) is an equilibrium-based leaching test intended to provide eluate solutions over a range of liquid-to-solid ratios (L/S). This method consists of five parallel batch extractions of a particle-size-reduced solid material in reagent water over a range of L/S values from 0.5 to 10 mL/g-dry material.
[3] The data set included four categories of duplicate samples, which combined represented a small fraction of the data set. In the absence of information about the nature of those duplicate sample categories, they were excluded from the data set used in this analysis.

as those samples with analytical results less than method detection limit (MDL), and the MDL was used as the result.

Notes:

[1] Dry ash handling may include units constructed on top of the footprint of ash basins.

[2] Excavation of the unit has been performed (complete) or is ongoing (in progress) as of the date the information was provided.

[3] Based on review, these locations are likely within the Active Ash Basin but were kept separate because of their distinction in the database.

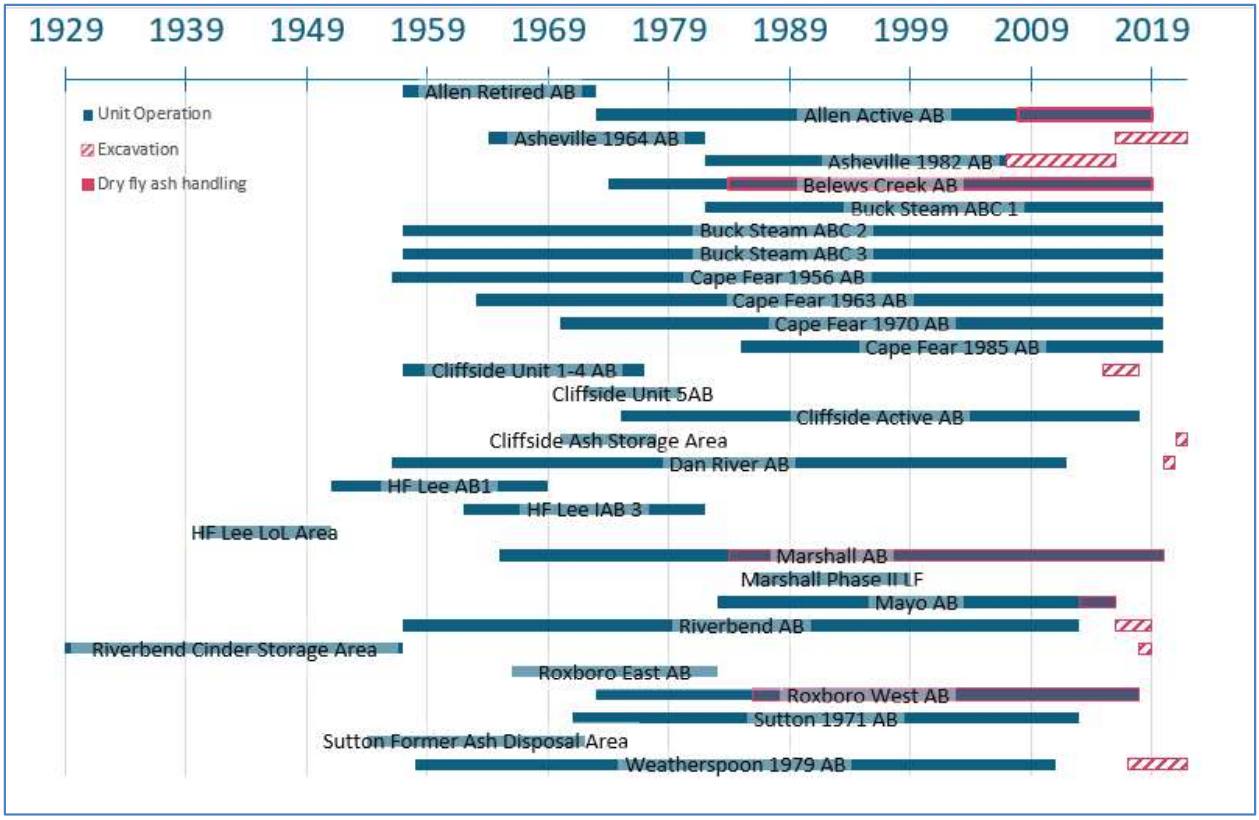

Figure 2-1
Operational history CCP units with available porewater data

Porewater Data

The porewater data set contained 111 parameters (including both total and dissolved fractions for most inorganic parameters) reported at a total of 100 individual PMPs. The porewater data set was refined prior to further analysis based on number of measurements for each parameter and degree of relevance in CCP porewater. Most parameters with fewer than 1,000 measurements were excluded from this analysis. This included redox speciation measurement, dissolved samples filtered at a 0.1 µm level, and some radioactive parameters. Some parameters with fewer than 1,000 total measurements were retained due to their relevance for CCP (fluoride, lithium, and isotopes of radium) or to facilitate comparisons between total and dissolved concentrations. In addition, dissolved oxygen (often unreliable due to contamination during sampling) and oxidation-reduction potential (ORP) (redundant with Eh) measurements were excluded. After refinement, the porewater data set contained 71 parameters measured at 100 PMPs (see Table 2-2 for a list of parameters analyzed in porewater and Appendix A for sample counts and basic statistics).

Leach Test Data

The LEAF data set contained 30 parameters and final eluate pH values for tests performed on CCP samples from 18 PMP boreholes. The LEAF and porewater data were paired based on co-location of station and depth of sample (Table 2-3).[4] For cases in which multiple LEAF samples were collected from multiple depths within the borehole spanning the corresponding porewater screen interval, the LEAF results were paired with the same porewater data. Parameters with no corresponding results in the porewater data set (U), three or fewer samples (Hg), and indicator parameters (ORP, specific conductance, and total dissolved solids [TDS]) were not included in the analysis. The combined leach test data set contained 25 parameters and final eluate pH values reported at 18 PMPs. LEAF 1313 testing was performed at pH values of about 4, 6, 8, and 10 and at natural pH. LEAF 1316 testing was performed at L/S ratios of 0.5, 1, 2, 4, 5, 6, 8, and 10.

[4] LEAF test data that did not have porewater data available from the same PMP and at the screened depth interval are not included in the analysis.

Table 2-3
Summary of leach test and porewater pairings for each PMP and depth interval

Notes:

[1] Each row represents one set of paired porewater and leach test data.

[2] Assumed to be a relevant comparison in the absence of depth interval information.

Porewater Results

An overview of the refined porewater data set is presented in Table 2-4. Sample sizes for each parameter varied from 70 samples (dissolved measurements for major ions), to between 100 and 1,000 samples (Ra isotopes, F, and Li), to over 1,000 samples (the rest of the parameters). Most of the major ions were detected in more than 90% of samples, except for NO_2+NO_3, (detected in 49% of samples) and ALK-CO_3 (detected in 12% of samples). Many minor and trace elements (total Al, total and dissolved As, Ba, B, Co, Fe, Li, Mn, Mo, Ni, Sr, and V) were detected in more than 75% of samples. Other minor trace elements were detected in between 25% and 75% of samples, including dissolved Al; total Cd and Pb; and both total and dissolved Sb, Be, Cr, Cr(VI), Cu, Se, Tl, and Zn. Total organic carbon (TOC) and total suspended solids (TSS) were also detected in between 25% and 75% of samples. Dissolved Cd, dissolved Pb, and both total and dissolved Hg were detected in 25% or fewer samples. Sulfide (S^{2-}) was also detected in very few samples (8%).

Table 2-5 shows the results of comparing porewater concentrations to a threshold value based on a regulatory standard, specifically the maximum contaminant level (MCL; 40 C.F.R.§141), secondary maximum contaminant level (SMCL; USEPA, 2022a), or regional screening level (RSL; USEPA, 2022b), where a standard was available. Although **these standards are not directly applicable to porewater data,** they provide useful thresholds for evaluating porewater concentrations. For example, if porewater concentrations are consistently below the threshold value for a parameter, the CCP unit would be an unlikely source of downgradient groundwater protection standard (GWPS) exceedances for that parameter. The statistics presented in this table are comparable to a similar tabulation by EPRI (2021a) for a larger, more widely distributed, porewater data set. However, there are differences in the tabulations. The current data set was compiled to determine the percentage of all samples with a concentration higher than a benchmark. The EPRI (2021a) data set is based on the average concentration of all porewater samples collected at a unit (range from as few as 1 to more than 100 samples per unit).

Both data sets show that As and Li have concentrations higher than a GWPS-based threshold in more than 50% of the sample and site average tabulations. In addition, Mn is greater than its SMCL-based threshold in more than 50% of the two tabulations.[5] Conversely, many of the tested constituents (Al, Sb, Ba, Be, Cr, Cu, F, Pb, Hg, Ra, Sr, Tl, and Zn) were unlikely (<15%) to have a concentration higher than their respective thresholds in both tabulations.

[5] The SMCL is based on aesthetic considerations to drinking water quality rather than on health-based considerations.

Leach Test Results

An overview of the LEAF test eluates is presented in Tables 2-6 (LEAF 1313) and 2-7 (LEAF 1316). Each individual sample represents the result for one test condition (that is, a specific pH for LEAF 1313 or a specific liquid-to-solid ratio for LEAF 1316) applied to one CCP solid sample. For summary purposes, the LEAF 1313 natural pH values (no acid/base added; sometimes referred to as the *natural pH*) and LEAF 1316 results at liquid-to-solid ratio (L/S) = 1.0 are compiled for table statistics. The proportion of detected results for all parameters in both LEAF tests is higher than those reported in the porewater measurements due to lower detection

limits used for most analytes in the LEAF tests. However, Cd was usually not detected and Hg was not detected in the LEAF 1313 samples, and Be was usually not detected and Pb and Hg were not detected in the LEAF 1316 samples.

Table 2-6

3
POREWATER ANALYSIS

Summary

This section presents an evaluation of the porewater data set that included a comparison of total and dissolved concentrations as well as an evaluation of the variability observed in porewater concentrations.

Total versus dissolved sample results:

- Total and dissolved measurements are generally more comparable at concentrations elevated well above the reporting limit where laboratory analytical variability is less significant relative to concentration.
- Major ions (Ca, Mg, Na, K), certain minor ions (Ba, B, Mn, Mo, Sr, Li), and elements with low detection frequency (Cd, Hg) were least likely to be affected by sample filtration.
- Elements most likely to be affected by sample filtration were Al, Cr, Cu, Fe, and V.

Intra-unit and inter-unit variability results:

- There does not appear to be an overall pattern to define which parameters exhibit high or low variability. However, parameters of interest—either because they are CCP tracers (B and SO_4) or potential remediation drivers (As, Sb, B, Cr, Co, Li, Mo, and Se)—mostly have medium to high intra-unit variability, which suggests that more extensive porewater evaluation may be helpful to characterize a unit when developing a source term to model these parameters. Li was the only remediation driver with low intra-unit variability.
- As, B, Co, Li, Mo, Se, and SO_4 had high inter-unit variability. Sb and Cr had medium and low inter-unit variability, respectively, which, as previously noted, can be attributed to their relatively low concentration (medians lower than 0.001 mg/L; see Appendix A) in the porewater samples reviewed in this analysis.

Analysis of Total Versus Dissolved Concentrations

Background

Porewater samples from CCP may be unfiltered or filtered[6] in the field, resulting in determinations of total or dissolved concentrations, respectively. The presence of suspended solids in porewater samples has the potential to affect total porewater measurements and can cause analytical results to not be representative of actual porewater concentrations. Geochemical modeling studies generally assume that the samples are field-filtered, while samples collected for

[6] Dissolved data represent field filtration using a 0.45-µm filter.

other purposes may not be filtered. Therefore, it is useful to understand the similarity and dissimilarity between total and dissolved measurements in CCP porewater samples.

A dissolved concentration lower than the total concentration suggests desorption of chemical constituents from small particles (>0.45 μm) in the sample when a total sample is acidified. There is no environmental explanation for a dissolved concentration higher than a total concentration. However, additional variability could be a result of heterogeneity in the samples themselves. Although paired total and dissolved samples are collected from the same location in the same sample event, they are often collected sequentially and therefore may represent slightly different fractions of porewater.

Methods

The porewater data set described in Section 2 was refined to include only samples that had both total and dissolved fractions analyzed (that is, samples with paired total and dissolved data). For samples in which either result was a non-detect, the MDL was used to calculate the ratio. The total versus dissolved concentration comparison plots are provided in Appendix B.

Data were evaluated by determining if total and dissolved concentrations were effectively similar for each sample. Total and dissolved concentrations for a sample were considered similar when the difference was within a predefined range of error. A difference of up to 20% was set as the predefined error—a percentage that is typically acceptable to meet quality control standards in a laboratory for a set of duplicate samples (USEPA, 2020). Therefore, a difference of 20% between the total and dissolved measurements was considered similar because it is within the range of accepted typical analytical variability. The overall degree of similarity for a parameter was then quantified by the percent of samples in the entire data set that had a difference of less than 20% between the total and dissolved concentrations.

Results and Discussion

The results of the total versus dissolved concentration comparison are presented in Table 3-1. For each parameter, the percentage of samples for which dissolved results were similar to totals is presented as well as the percent of samples above and below the defined range. The degree to which dissolved and total concentrations were similar ranged from 42% to 97% (Table 3-1). When there was a difference, the dissolved sample usually (63% of sample pairs with a difference) had the lower concentration, but this was not always the case.

Table 3-1
Summary of total versus dissolved concentration comparison

Parameter	Number of Samples Compared	Number Where Total and Dissolved Both Non-Detect	Dissolved Lower Than Total	Dissolved Higher Than Total	Similar Total and Dissolved Concentrations[1]
Al	1199	236	39%	10%	50%

As	1215	6	14%	6%	80%
Ba	1157	8	6%	2%	93%
Be	1164	560	20%	18%	62%
B	1216	19	3%	2%	95%
Cd	1140	794	7%	7%	86%
Ca	84	0	6%	0%	94%
Cr	1209	311	36%	22%	42%
Co	1212	163	21%	9%	71%
Cu	1076	330	28%	28%	44%
Fe	1209	64	35%	6%	59%
Pb	1078	653	19%	9%	72%
Li	136	5	2%	6%	92%
Mg	70	0	4%	0%	96%
Mn	1216	57	6%	3%	90%
Hg	1108	1037	2%	4%	95%
Mo	1162	67	6%	6%	88%
Ni	1176	122	17%	13%	70%
K	70	2	0%	4%	96%
Se	1194	569	14%	11%	75%
Na	70	0	1%	1%	97%
Sr	1216	1	2%	1%	97%
Tl	1204	403	17%	11%	72%
V	1213	41	40%	9%	52%
Zn	1081	448	18%	20%	62%

Note:

[1] Percentages may not add up to 100% due to rounding.

The similarity between total and dissolved results is visualized by plotting the dissolved concentration (y axis) against the total concentration (x axis) (Figure 3-1; Appendix B). Each sample pair is represented by one data point. If total and dissolved concentrations are identical in a sample, that point will fall on the 1:1 line. The 20% range of variability is illustrated by the dashed lines surrounding the 1:1 line. Any points that fall outside of the area between those lines are considered to have different total and dissolved concentrations. Points below the defined range of comparability have lower dissolved than total concentrations, while points above the defined range have higher dissolved than total concentrations (which, as discussed previously, is likely an artifact of sample and/or laboratory variability). The color of each point reflects the turbidity measured for that sample.

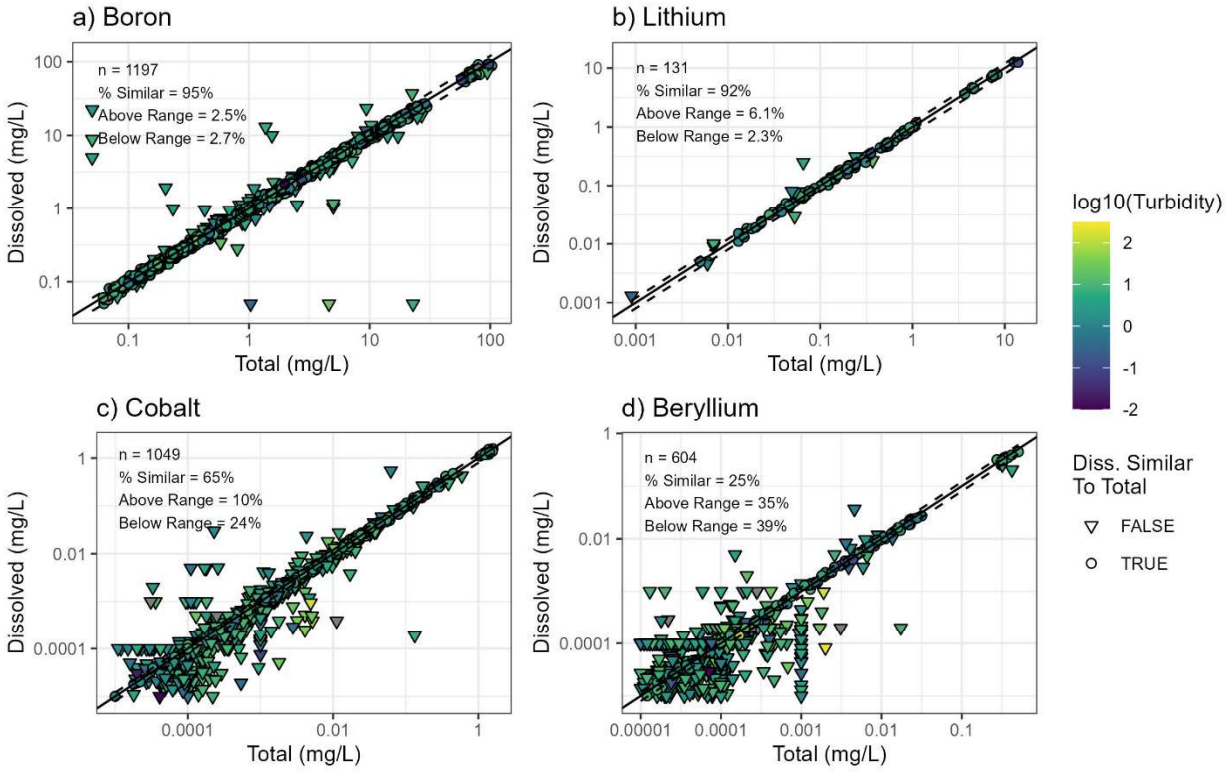

Figure 3-1
Comparison of total versus dissolved measurements for selected parameters when detected in one or both of the paired samples

The statistics on the graphs are for sample pairs where a concentration is detected in one or both samples and differs from Table 3-1 because samples where both results are non-detect were not considered.

Parameters such as Co, which sorb strongly to particulates and therefore have total concentrations more heavily influenced by the presence of turbidity, tend to have a greater proportion of samples below the defined range used for comparison. In contrast, Be does not sorb as strongly to particulates and instead has relatively equivalent proportions of points above and below the defined range. For both Co and Be, fewer samples fall outside the defined range of similarity at higher total concentrations. This suggests that total and dissolved measurements are generally more comparable at concentrations elevated well above the reporting limit (that is, where laboratory analytical variability is less significant relative to concentration).

For both Co and Be, the samples with the highest turbidity typically fall below the defined range. This observation is consistent with turbidity potentially contributing to higher total than dissolved concentrations due to the presence of sorbed ions, although this relationship is qualitative, and turbidity is not the only factor causing differences between dissolved and total concentrations (because not all samples with lower dissolved concentrations compared to totals have elevated turbidity).

Table 3-2 groups the results presented in Table 3-1. This grouping shows that major ions (Ca, Mg, Na, K), certain minor ions (Ba, B, Mn, Mo, Sr, Li), and elements with low detection frequency (Cd, Hg) were least likely to be affected by sample filtration. It is worth noting that Cd and Hg have much lower percentages for similarity (54% and 17%, respectively) when detected in one or both of the total and dissolved samples (see Appendix B). Elements most likely to be affected by sample filtration were Cr, Cu, Al, Fe, and V.

Table 3-2
Grouping of total vs. dissolved sample results

Concentration Tendency for Pairs That Were Not Similar	Percent of Paired Total and Dissolved Samples with Similar Concentration					
	40% to 50%	50% to 60%	60% to 70%	70% to 80%	80% to 90%	>90%
Dissolved more often had lower concentration	Cr	Al, Fe, V	Be, Ni	As, Co, Pb, Se, Tl		Ca, Mg, Ba, B, Mn, Sr
Similar frequency for lower and higher concentration	Cu			Sb	Cd, Mo	Na
Dissolved more often had higher concentration			Zn			K, Li, Hg

Analysis of Variability in Porewater

Background

Porewater composition variability between different CCP units (inter-unit variability) and within the same CCP unit (intra-unit variability) was evaluated in this task. Variability between different units may be due to different operational histories and different CCP source materials. Variability within a single unit may reflect different CCP composition if more than one CCP is managed in the unit (particularly for landfills), differences associated with chemical evolution over time for older vs. newer portions of the unit (particularly for landfills), and, in the case of

sluiced CCPs, the differences in chemistry associated with particle size, because coarse CCP particles will settle near the discharge pipe into the pond, and fine CCP particles will settle near the outfall structure where water exits the pond. This section uses porewater data from 29 CCP units of different sizes and ages (Section 2) to characterize inter-unit and intra-unit variability for a wide range of porewater parameters. The aim of this analysis is not to identify individual causes of variability within and between each of these CCP units; instead, the goal is to describe the variability of different parameters to help inform the characterization of porewater variability within other CCP units.

Methods

Figure 3-2 illustrates how inter-unit and intra-unit variability were evaluated for each parameter. Inter-unit differences were quantified by comparing the highest and lowest medians calculated at the units. Intra-unit differences were quantified using the 25th and 75th percentiles of the data. The 25th and 75th percentiles of the data are visually represented by the lower and upper bounds of the box in a boxplot, and the interquartile range (the difference between the 25th and 75th percentiles) is often used to characterize variability of data.

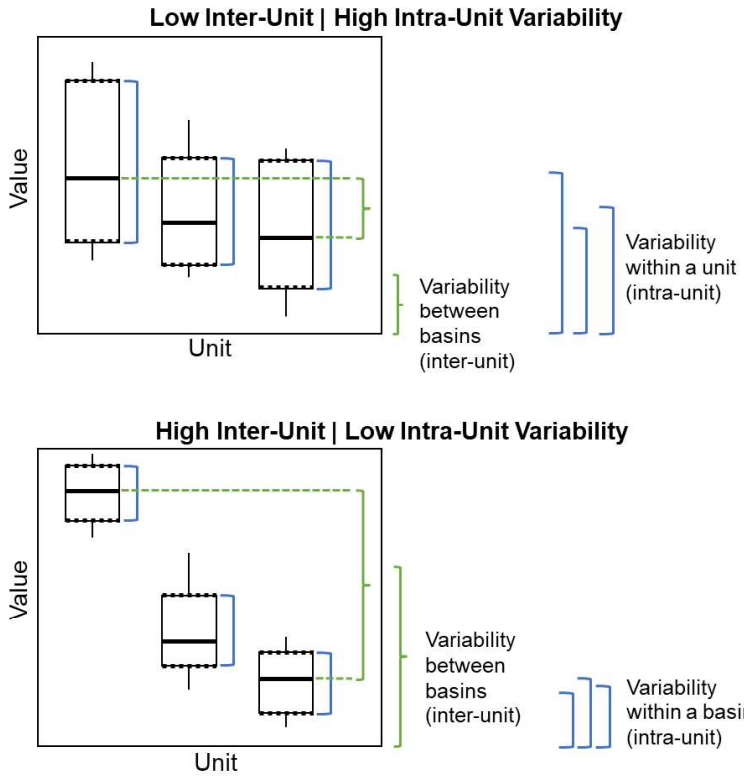

Figure 3-2
Conceptual drawing illustrating how inter- and intra-unit variability were assessed

A median range ratio (MRR) was calculated by taking the ratio between highest and lowest medians to allow for comparison of inter-unit variability across different parameters. For example, an MRR of 10 indicates an order of magnitude difference between the highest and lowest medians regardless of the actual concentrations of a given parameter. One MRR was calculated for each parameter based on the medians for all the units. An MRR could not be meaningfully calculated for Eh because the lowest median was a negative value, resulting in a negative ratio.

Intra-unit variability was quantified by taking the ratio between the 25th and 75th percentile of the data (interquartile ratio [IQR]). By calculating the IQR instead of the interquartile range, differences due to absolute concentration measurements are removed. Because IQRs were calculated by unit, as many as 29 IQRs are calculated for each parameter. The median IQR for each parameter is used in this comparison to represent the overall intra-unit variability.

For parameters with both total and dissolved concentrations available, this analysis uses only total concentrations. Data for most parameters were available for all 29 units, although some parameters were not available for all units (Table 3-3).

Results and Discussion

A summary of inter- and intra-unit variability is presented in Table 3-3. The MRR ranges from 1.6 to 80,000, with half the parameters having an MRR between 14.75 and 150. The IQR ranges from 1.0 to 5.0, with half the parameters falling between 1.4 and 2.6. High, moderate, and low variability were categorized based on approximately the top, middle, and bottom third of results, as shown in Table 3-4.

Table 3-3
Results of inter- and intra-unit variability analysis

Category	Parameter	Number of Units	Sample Count	MRR[1]	Median IQR
Field parameters	Eh	29	1390	NA	2.8
	pH	29	1390	2.0	1.1
	EC	29	1390	15	1.4
	TEMP	29	1390	1.6	1.3
	TURB	29	1388	5.9	2.4
Major ions	F	23	440	82	1.5
	NO_2 + NO_3	29	1333	16	2.0

	Hg	29	1145	4.0	1.0
	Mo	29	1287	80000	2.2
	Ni	29	1317	65	3.1
	Se	29	1353	130	1.9
	Sr	29	1383	17	1.7
	Tl	29	1368	46	2.3
	V	29	1381	360	4.7
	Zn	29	1135	18	1.8
Other	S^{2-}	29	1105	22	1.0
	TOC	29	1281	74	1.3
	TSS	29	1118	54	2.1
Radiologic	^{226}Ra	23	393	26	3.0
	^{228}Ra	23	393	9.8	2.9
	Ra	8	114	3.3	2.4

Note:

[1] The MRR describes the inter-unit variability, and the median IQR describes the intra-unit variability. A higher value indicates greater variability. Dark green indicates low variability, light green indicates moderate variability, and yellow indicates high variability according to the ranges described in Table 3-4.

Table 3-4
Values for variability group cutoff

Value Type	Range[1]	Quantitative Assessment	Parameter Count
Median IQR	[1 to 1.5]	Low intra-unit variability	15
	(1.5 to 2.3]	Medium intra-unit variability	15
	(2.3 to 5]	High intra-unit variability	15
MRR	(1 to 20]	Low inter-unit variability	16
	(20 to 100]	Medium inter-unit variability	14
	(100 to 80,000]	High inter-unit variability	14

Note:

[1] Square brackets are inclusive of the number shown; round brackets are exclusive

Figure 3-3 illustrates examples of low and high values of inter- and intra-unit variability using boxplots for the results from each unit, ordered based on each unit's median value. The units are identified in the x axis by numerical code (the numbers are non-sequential and were derived from the database provided to EPRI). Results for selected parameters are presented and discussed in the text. Similar figures for all parameters that were evaluated are provided in Appendix C.

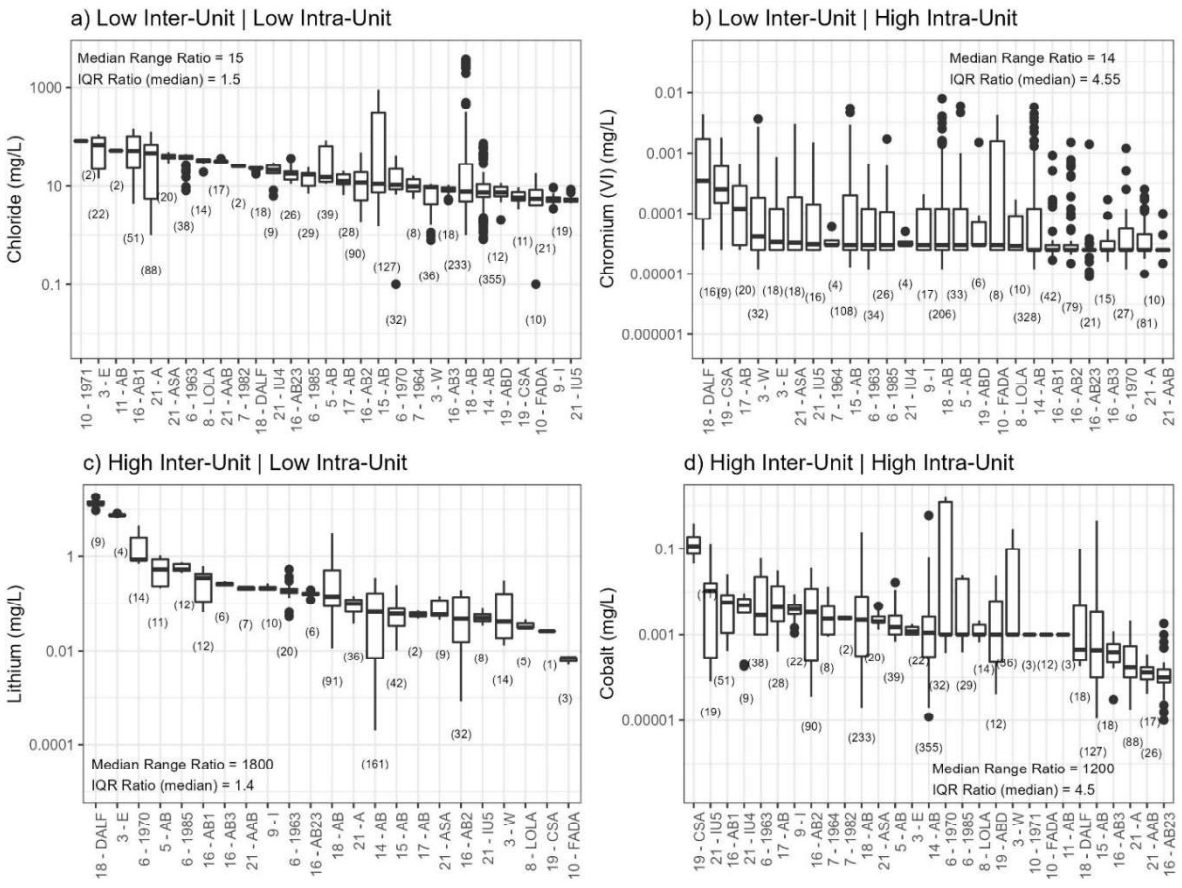

Figure 3-3
Boxplots illustrating both high and low inter- and intra-unit variability for selected parameters

Cl is presented as an example of low inter-unit and low intra-unit variability. An MRR of 15 indicates less than two orders of magnitude variability across all the units. A median interquartile ratio of 1.5 shows that Cl concentrations are relatively consistent within each unit, with units having less than twofold difference in concentration. Few parameters have low inter-unit and intra-unit variability; others with low variability include several field parameters (pH, specific conductance, and temperature) in addition to ALK-CO_3 and Hg, both of which were detected infrequently (Table 3-5).

Cr (Figure 3-3) and Cr(IV) have low inter-unit variability but high intra-unit variability, which may be attributed to the very low concentrations of these parameters. Other parameters with this pattern of variability include Cu, ^{228}Ra, and total Ra (Table 3-5). The maximum and minimum medians are similar because most individual sample results are non-detects, while the occasional detection creates high variability within each unit.

Li is presented as an example of high inter-unit and low intra-unit variability (Figure 3-3). The highest and lowest medians span three orders of magnitude (MRR of 1,800), while concentrations within a unit generally have less than a twofold difference in concentration. This indicates that within a unit there is generally little variability in Li concentration, so a small number of porewater samples may sufficiently characterize Li concentrations. Although no other parameters were observed to have high inter-unit and low intra-unit variability (suggesting that it may be an artifact of a small Li sample size), B and SO_4 (common CCP indicators) along with Mo, alkalinity, and Se had high inter-unit variability and medium intra-unit variability (Table 3-5).

Co is presented in Figure 3-3 as an example of high inter-unit and high intra-unit variability. The medians span three orders of magnitude (MRR of 1,200), and there is over fourfold variation within most units. This suggests that concentrations of Co in porewater may be difficult to predict for a CCP unit and that they may change over time or vary spatially throughout the unit. Other parameters with this distribution include As, Fe, V, Al, and Mn (Table 3-5).

Table 3-5
Inter-unit and intra-unit variability parameter groups

Intra-Unit Variability	Inter-Unit Variability		
	Low (MRR <=20)	**Medium (MRR >20 and <=100)**	**High (MRR >100)**
Low (IQR <=1.5)	pH, EC, TEMP, ALK-CO_3, Cl, Hg	F, Ca, K, Na, Cd, Pb, S^{2-}, TOC	Li
Medium (IQR >1.5 and <=2.3)	NO_2+NO_3, Be, Sr, Zn	Sb, Ba, Tl, TSS	ALK, ALK-HCO_3, Mg, SO_4, B, Mo, Se
High (IQR >2.3)	TURB, Cr, Cr(VI), Cu, ^{228}Ra, Total Ra	Ni, ^{226}Ra	Al, As, Co, Fe, Mn, V

Note: Eh is not shown because MRR was not calculated for this parameter.

There does not appear to be an overall pattern to define which parameters exhibit high or low variability, likely because the porewater concentrations are determined by a combination of the composition of the stored CCP, the operating history of the unit (for example, degree of sluicing), and the *in situ* geochemical conditions as well as the geochemical characteristics of each parameter. Of particular interest are the results for the common CCP tracers (B and SO_4), as well as potential remediation drivers (As, Sb, B, Cr, Co, Li, Mo, and Se; as defined by EPRI, 2021b).

Most of the tracers and remediation drivers have medium to high intra-unit variability, suggesting that more extensive porewater evaluation may be helpful to characterize a unit when developing a source term to model these parameters. Li was the only remediation driver with low intra-unit variability. Except for Sb and Cr, the tracers and potential remediation drivers had high inter-unit variability. Sb and Cr had medium and low inter-unit variability, respectively, which, as previously noted, can be attributed to their relatively low concentration (medians lower than 0.001 mg/L; see Appendix A) in the porewater samples reviewed in this analysis.

4
COMPARISON OF LEAF LEACH TEST ELUATE CONCENTRATIONS TO POREWATER CONCENTRATIONS

Summary

LEAF 1313 (pH-dependent) and 1316 (L/S-dependent) eluate concentrations were compared to median porewater concentrations taken from PMPs screened at the same location and depth as samples used in the LEAF testing for 18 PMPs spread across four CCP management units. This analysis indicated:

- LEAF 1313 and 1316 eluate concentrations were usually more than 25% higher or 25% lower than their paired median porewater concentrations. This observation was made for 1313 eluates at natural pH and the broader pH range for all porewaters and for 1316 results at low and high L/S.
- Elements often controlled by available content—such as B, Ca, Cl, Li, Sr, and SO_4—tended to be underpredicted by the leach tests.
- As, Fe, and Mn were also underpredicted, even though they tend to be solubility controlled, because the LEAF testing was performed under oxic conditions when the solubility of these elements is low.
- Conversely, Se and Cr, which are most soluble under oxic conditions, tended to be overpredicted by the LEAF testing performed under oxic conditions.
- Sb, Tl, and V tended to be overpredicted by the leach tests while other elements were overpredicted or underpredicted depending on test-specific and site-specific factors.
- No bias was detected for Hg because most porewater and all the LEAF test results were non-detect.
- Overall, these observations confirm the observations from EPRI 2020 and 2021c that LEAF tests do not reliably predict porewater concentrations observed in the field.

Background

Laboratory leaching tests can be used to estimate how environmental conditions, the length of exposure to leaching conditions, and material composition affect the release of inorganic constituents from CCP. However, the ability of leaching tests to predict concentrations of inorganic constituents in field porewater depends on the intended purpose of the leaching test, the applied test conditions, individual constituent geochemistry, and the ability of the test to address the principal conditions that control leaching in the field (EPRI, 2020 and 2021c).

Traditional leach tests expose a solid material to a single eluent, which is intended to be representative of *in situ* porewater concentrations. These traditional leach tests include USEPA Method 1311 (Toxicity Characteristic Leaching Procedures; TCLP), USEPA Method 1312 (Synthetic Precipitation Leaching Procedure; SPLP), and ASTM D3987 (Shake Extraction of Solid Waste with Water; ASTM). A more robust approach to leaching tests is the Leaching Environmental Assessment Framework (LEAF) (USEPA, 2019), which uses a gradient of eluent compositions designed to evaluate leaching behavior across a range of environmental conditions. Different LEAF methods alter different controlling variables (for example, pH, liquid-to-solid ratio [L/S]) in their experimental design.

In 2020 and 2021, EPRI published research that compared the results of traditional leaching tests (TCLP, SPLP, and ASTM) to two of the four LEAF leaching methods: USEPA Method 1313 (Liquid-Solid Partitioning as a Function of Eluate pH Using a Parallel Batch Procedure) and USEPA Method 1314 (Liquid-Solid Partitioning as a Function of Liquid-Solid Ratio Using an Up-Flow Percolation Column Procedure) (EPRI, 2020 and 2021c). The 2020 and 2021 research compared porewater to leach test eluates from samples collected from the screened intervals of the PMPs. The results indicated that traditional leaching tests were not reliable predictors of measured porewater concentrations because of the relatively high L/S used in these tests and because they do not necessarily reproduce field pH and redox conditions within a CCP unit.

LEAF testing is designed to span the range of pH and L/S encountered in the field although it can be difficult to determine in advance which pH or L/S will best predict the field concentration—and that point varies by element. In general, EPRI (2020 and 2021c) found that low L/S eluates from USEPA Method 1314 were better indicators for constituents where liquid-solid partitioning (LSP) is limited by the content in the CCP solids (available content LSP). Examples of constituents controlled by available content LSP are B, Cl, Mo, and SO_4. Traditional leaching methods and USEPA Method 1313 use higher L/S ratios and tended to underpredict these constituents. Constituents with porewater concentrations controlled by their solubility (solubility-controlled LSP), such as As and Sb, were better predicted by USEPA Method 1313 although the pH at which the test best predicted field conditions did not always correspond to the field pH, in part because redox also affects leaching of these elements and because it is challenging to duplicate field redox conditions in the laboratory—especially for strongly reducing conditions. EPRI (2020 and 2021c) also found that site-specific conditions influence whether some constituent concentrations are available content–controlled, solubility-controlled, or controlled by wash-off (present in an easily dissolved form that is rapidly removed by initial contact with water).

This research expands on the previous findings by evaluating the effectiveness of two LEAF test methods (1313 and 1316) at predicting porewater concentration across multiple CCP storage units using paired LEAF and porewater data (as described in Section 2). Similar to EPRI (2020 and 2021c), the laboratory leaching tests were performed on solid samples extracted from the location and depth interval within the CCP deposit where the screened interval of the PMP was placed.

Methods

Eluate concentrations from the LEAF tests were normalized by dividing by the median porewater concentration for the paired samples. Due to the high variability in the resulting ratios, the $\log_{10}$ of each ratio was used for analysis and visualization. If a leach method predicted a porewater concentration to complete accuracy, the ratio between the eluate concentration and porewater concentration would be equal to one (for a $\log_{10}$ ratio of zero).

To quantitatively assess how well the LEAF methods predicted porewater concentrations at any pH or L/S, a predefined range of variability between leach test eluate and porewater concentrations was established. Concentrations in leach test eluates and porewater samples were considered "within range" if the $\log_{10}$ of the ratio was within half an order of magnitude of zero (that is, a $\log_{10}$ ratio between -0.5 and 0.5, or approximately a threefold difference in concentrations between the leach test and median porewater results). Note that this criterion was applied to all pH and L/S eluates from Methods 1313 and 1316, respectively, and therefore provides insight on whether the leach test was comparable to field porewater concentrations at any point in the tested pH or L/S range. This criterion provided a broad measure of leach test performance relative to porewater concentrations.

However, being "within range" is not necessarily a reasonable approximation of field conditions. For example, a plus or minus threefold difference (half an order of magnitude) for a porewater constituent with a concentration of 1,000 mg/L would mean that the leach test eluate was either within or outside a range between about 320 mg/L and 3,100 mg/L. Therefore, a follow-up tabulation was performed following the approach of EPRI (2020, 2021c) using the following criteria:

- For LEAF 1313, was the natural pH (no acid or base added) eluate within 25% of the median porewater concentration?
- For LEAF 1316, were eluates at low (<1.0) or high (>1.0) L/S within 25% of the median porewater concentration?

Results and Discussion

Evaluation of LEAF Test Bias

The comparison of LEAF test results to observed porewater concentrations for all pH and L/S is presented in Table 4-1. The proportion of samples with LEAF 1313 test results within half an order of magnitude around the median porewater concentration ranged from 0% (Cr(VI)) to 100% (Hg) although the "within range" result for Hg is a reflection on detection limits because most porewater and all leach test results were lower than detection limits. The proportion of samples with LEAF 1316 test results within half an order of magnitude around the median porewater concentration spanned a range, from 0% (Cr(VI)) to 100% (Be and Hg), although the Be and Hg results were mostly non-detect.

F was the only commonly detected element with more than two-thirds of LEAF results within range for both the 1313 and 1316 tests, while Sb, Cl, Cr(VI), Fe, Mn, Se, and V had fewer than one-third of the results within range for both tests.

Table 4-1
Summary of LEAF 1313 and LEAF 1316 comparison to porewater results

Param	LEAF 1313				LEAF 1316			
	Sample Count	Samples in Range (%)	Samples Above Range (%)	Samples Below Range (%)	Sample Count	Samples in Range (%)	Samples Above Range (%)	Samples Below Range (%)
Sb	88	33	66	1.1	95	8.4	92	0
As	88	34	4.5	61	95	32	4.2	64
Ba	88	44	38	18	95	73	3.2	24
Be	88	76	24	0	95	100	0	0
B	88	19	0	81	95	38	4.2	58
Cd	88	59	31	10	95	79	9.5	12
Ca	88	45	2.3	52	95	47	3.2	49
Cl	88	11	0	89	95	26	8.4	65
Cr	88	23	77	0	95	34	66	0
Cr(VI)	78	0	100	0	85	0	100	0
Co	88	38	33	30	95	43	13	44
F	88	73	4.5	23	95	86	8.4	5.3
Fe	88	18	6.8	75	95	12	1.1	87
Pb	88	59	30	11	95	83	1.1	16
Li	88	30	0	70	95	37	1.1	62
Mn	88	24	15	61	95	13	2.1	85
Hg	88	100	0	0	95	100	0	0
Mo	88	25	8	67	95	46	25	28
Ni	49	49	41	10	55	67	22	11
^{226}Ra	29	59	17	24	30	67	10	23
^{228}Ra	29	59	10	31	30	53	0	47
Se	88	10	90	0	95	4.2	96	0
Sr	88	36	2.3	61	95	39	0	61
SO_4	88	18	0	82	95	43	14	43
Tl	88	59	36	4.5	95	62	35	3.2
V	78	18	81	1.3	85	2.4	98	0

Note: A green highlight indicates that >67% of the tests were within range, a yellow highlight indicates 33% to 66% within range, and no highlight indicates <33% within range.

The leach test to median porewater ratios are graphically illustrated in Figure 4-1. Each bar on the histogram shows the number of sample points within a given range of $\log_{10}$ median porewater ratio. If a particular leach method sample perfectly predicted porewater concentrations, the data point would fall on the x = zero line (equivalent to a ratio of 1). The half an order of magnitude range of defined variability is illustrated by the dashed lines at x = -0.5 and x = 0.5. The distribution of samples outside the area between those lines indicates bias. The color of the boxes represents results from the two LEAF tests (because the total number of samples differed between leach test methods, the absolute height of the bars will be different). Figures for selected parameters are presented in Figure 4-1 to illustrate a range of observed outcomes. Similar figures for all parameters are provided in Appendix D.

Sb provides an example where both LEAF 1313 and LEAF 1316 results are biased high (more of the ratios fall to the right of 0.5 than to the left of -0.5 in Figure 4-1a). Most of the LEAF 1316 results for Sb fall outside the half order of magnitude criterion.

Ba is an example in which LEAF 1313 is biased high and LEAF 1316 is biased low (Figure 4-1b). For both tests, the distribution of data is centered close to zero and most samples have a $\log_{10}$ ratio between -0.5 and 0.5, but there are substantially more ratio results to one side of the range compared to the other side.

The distribution for Mo LEAF 1316 data is centered close to zero (Figure 4-1c), with a similar number of ratios on either side of the range, indicating no bias. LEAF 1313 results are mostly to the left of the range, indicating a bias low in the 1313 testing.

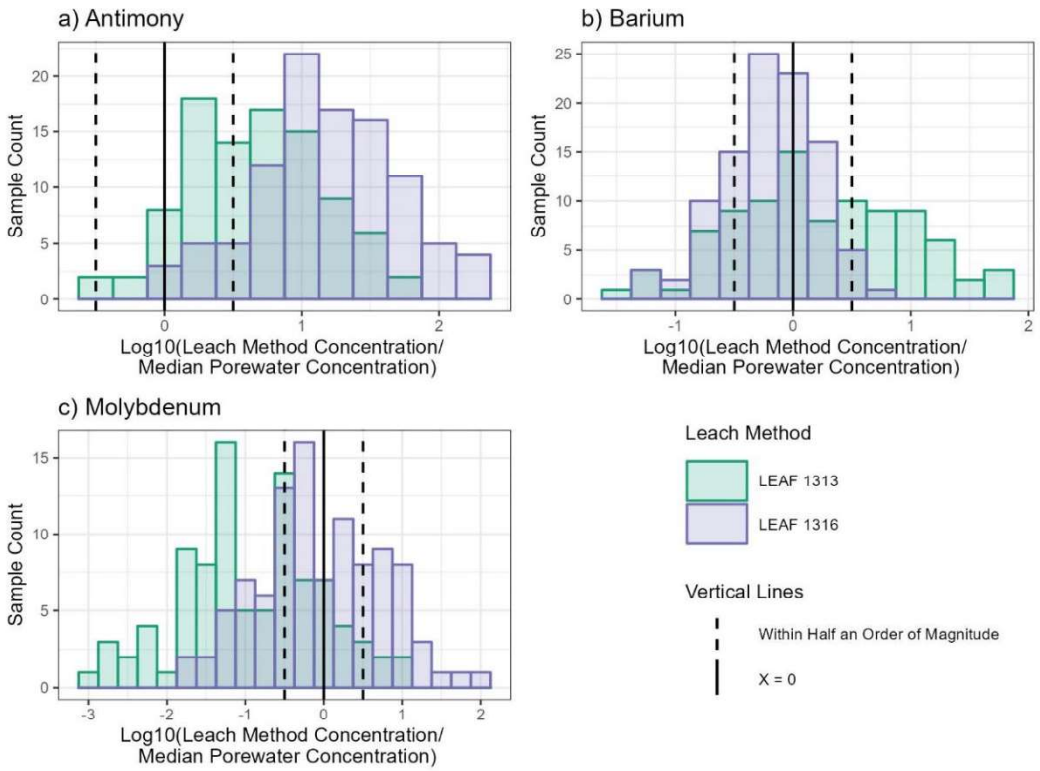

Figure 4-1
Histograms comparing the concentrations predicted by the LEAF 1313 and LEAF 1316 to the median observed porewater concentrations

Sample bias is summarized by element in Table 4-2. A test was considered to impart a bias toward higher concentration (overpredict porewater concentrations) if more than 50% of the samples were above range **or** if at least 20% of the results were above range and there were more than twice as many results above range compared to results below range. Bias low (test underpredicts porewater concentration) was assigned if more than 50% of the samples were below range **or** if at least 20% of the results were below range and there were more than twice as many results below range compared to results above range. The results of this comparison show:

- Elements often controlled by available content—such as B, Ca, Cl, Li, Sr, and SO_4—tend to be underpredicted (bias low) by the leach tests.
- As, Fe, and Mn were also underpredicted, even though they tend to be solubility controlled, because the LEAF testing was performed under oxic conditions when the solubility of these elements is low.
- Conversely, Se and Cr, which are most soluble under oxic conditions, tended to be overpredicted by the LEAF testing performed under oxic conditions.
- Sb, Tl, and V tend to be overpredicted (bias high) by the leach tests while other elements may be overpredicted or underpredicted depending on test-specific and site-specific factors.
- No bias was detected for Hg because most porewater and all the LEAF test results were non-detect.

Table 4-2
Summary of LEAF test bias compared to porewater concentrations

	Bias Low	No Bias	Bias High
LEAF 1313	As, B, Ca, Cl, F, Fe, Li, Mn, Mo, ^{228}Ra, Sr, SO_4	Co, Hg, ^{226}Ra	Sb, Ba, Be, Cd, Cr, Cr(VI), Pb, Ni, Se, Tl, V
LEAF 1316	As, B, Ba, Ca, Cl, Co, Fe, Li, Mn, ^{226}Ra, ^{228}Ra, Sr, SO_4	Be, Cd, F, Pb, Hg, Mo, Ni	Sb, Cr, Cr(VI), Se, Tl, V

Direct Comparison of LEAF Eluate Concentrations to Porewater Concentrations

Figures 4-2 and 4-3 illustrate how leach test concentration varied under the range of pH and L/S conditions imposed by the LEAF 1313 and LEAF 1316 leach tests, respectively. The $\log_{10}$ ratios of leach test sample to median porewater concentrations (y axis) are plotted against the measured sample pH (Figure 4-2) or against the L/S ratio (Figure 4-3). As shown in Figure 4-1, the zero line and predefined range of $\log_{10}$ ratios (-0.5 to 0.5) are shown. In addition, shaded areas represent the order of magnitude and 25% criteria used in EPRI (2020 and 2021c). The same three analytes discussed previously are shown in Figures 4-2 and 4-3 to illustrate a range of potential outcomes. These same figures for all analytes are presented in Appendix E (LEAF 1313, pH dependent) and Appendix F (LEAF 1316, L/S dependent).

Figure 4-1a indicates a tendency for Sb to be overpredicted by LEAF 1313. Figure 4-2a shows this to be the case across the pH range, with some underpredictions at the lowest pH tested. Figure 4-3a shows that porewater Sb tended to be overpredicted at all L/S, especially at low L/S.

Figure 4-1b indicates that Ba was overpredicted by LEAF 1313 and underpredicted by LEAF 1316. Figure 4-2b shows that the 1313 tests for Ba tended to be biased high at low pH and biased

low at high pH. Figure 4-3b shows that Ba can be underpredicted at any L/S and can also be overpredicted at higher L/S.

Figure 4-2c shows that Mo, while biased low across the LEAF 1313 pH range, had more results within range at pH >7.0 SU than at lower pH. Figure 4-3c illustrates that even though the sum of results for Mo testing using Method 1316 showed no bias, the samples at low L/S were biased high, and the samples at high L/S were biased low.

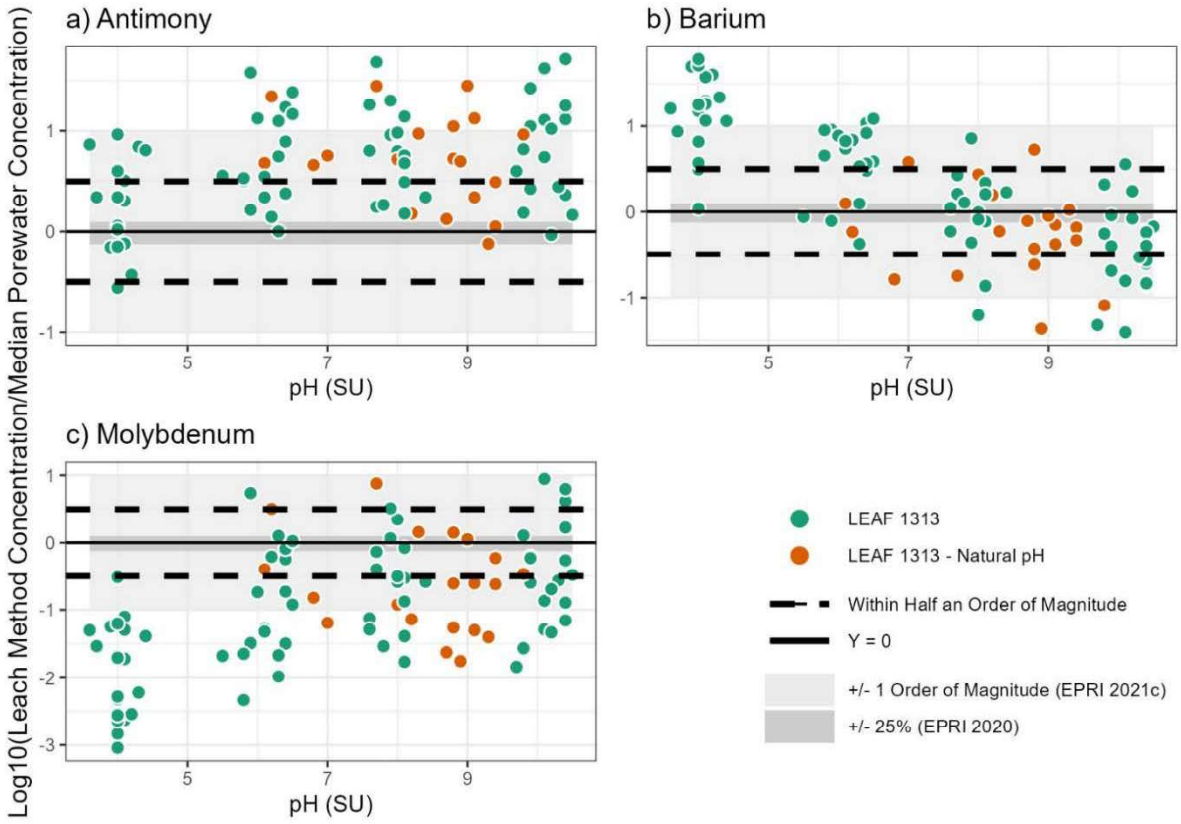

Figure 4-2
Comparison of LEAF 1313 results (normalized to median porewater concentration) across the range of pH levels tested

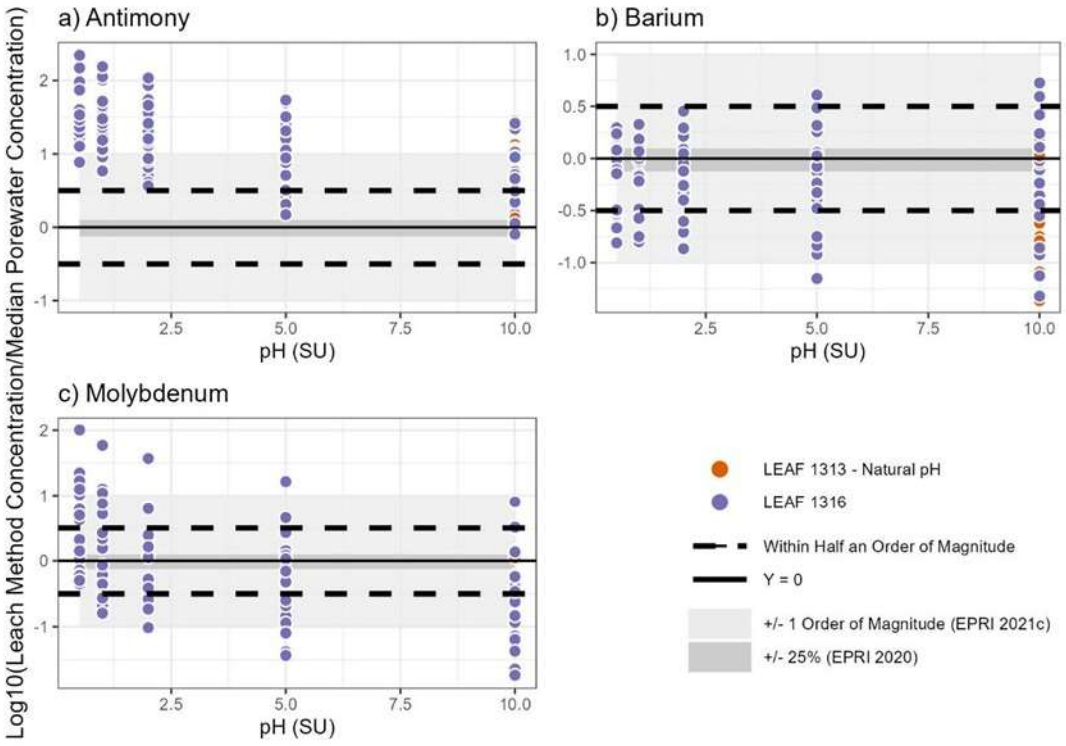

Figure 4-3
Comparison of LEAF 1316 results (normalized to median porewater concentration) across the range of L/S levels tested

Results from the LEAF 1313 test measured at natural porewater pH are included for comparison.

Focusing on natural pH results, the LEAF 1313 tests usually yielded eluate concentrations at natural pH that were higher (>25%) or lower (<25%) than the median porewater concentrations from their paired PMPs (Table 4-3). Taking this comparison a step further, examination of the plots in Appendix E indicates that all LEAF 1313 eluates (natural pH or not) at pH between 6 and 10 were more likely to be outside than inside the ±25% range.[7] The only exception to this observation is for lead, because it was often not detected and the detection limits for the porewater analysis and LEAF 1313 analysis were similar. Similarly, the 1316 eluate concentrations were usually not within ±25% of their paired porewater concentrations. Lead was most likely to yield a concentration within the ±25% criteria but only because the MDLs used for the LEAF 1316 analysis and porewater analyses were similar for this element, which was usually not detected in either porewater or eluates. These results confirm the observations from EPRI 2020 and 2021c that LEAF tests do not reliably predict porewater concentrations observed in the field.

[7] The median porewater concentrations for the ash basins were mostly between 6 and 10 (see pH plot in Appendix C), and the natural pH range for all PMPs was between 6 and 10.

Table 4-3
Tabulation of LEAF 1313 and 1316 eluate concentrations at natural pH and low or high L/S

Parameter	1313 Natural pH Eluates Within ±25%	1313 Natural pH Eluates Outside ±25%	1316 Eluates at L/S <1 Within ±25%	1316 Eluates at L/S >=1 Within ±25%	1316 Eluates Outside ±25%

Notes:

[1] Low detection frequency (<=50%) in porewater

[2] Low detection frequency (<=50%) in LEAF 1313 eluate at natural pH

[3] Low detection frequency (<=50%) in LEAF 1316 eluate at L/S = 1

5
ADDITIONAL DATA EXPLORATION

This report has discussed porewater composition on a parameter-by-parameter basis. Advanced statistical methods could be used in the future to help characterize entire porewater signatures. Multivariate statistical methods can evaluate the relationships between more than two variables simultaneously, allowing for easier interpretation of entire porewater signatures. Potentially applicable multivariate statistical methods include principal component analysis (PCA), cluster analysis, and linear discriminant analysis (the use of which is discussed in detail in EPRI, 2022).

PCA is a common dimensionality reduction method (Abdi and Williams, 2010; Shlens, 2014). The principal components calculated are essential new "variables," which are linear combinations of the original data that separate the data points and reduce redundancy in the data. In EPRI 2022, PCA was used to distinguish CCP porewater from coal pile runoff water (a potential alternative source of downgradient exceedances). Similar multivariate analyses could be used to assess how parameters co-vary within and between units as well as how successful laboratory leach testing is at determining entire porewater signatures.

B
TOTAL VERSUS DISSOLVED CONCENTRATION COMPARISON

The figures in this appendix (Figures B-1 through B-26) compare total vs. dissolved concentrations in filtered and unfiltered sample pairs when a concentration is detected in one or both samples. For clarity, samples where concentrations are below detection limits in both samples are not shown. The statistics on the graphs are for sample pairs where a concentration is detected in one or both samples and will therefore differ from the statistics shown in Table 3-2.

C
POREWATER VARIABILITY

The figures in this appendix illustrate inter- and intra-unit variability using boxplots. Intra-unit variability was based on the ratio of the 75th to 25th percentile (as illustrated by each individual box; a longer box indicates greater intra-unit variability than a shorter box). Inter-unit variability was determined based on the difference between median concentrations (horizontal line within each box) for each parameter across all sites.

D
HISTOGRAM COMPARISON OF LEAF 1313 AND LEAF 1316 LEACH TEST METHODS

Figures D-1 through D-26 use histograms to compare results of the LEAF 1313 and LEAF 1316 leach test methods. The position of the distribution indicates LEAF test bias. A distribution centered within the vertical dashed lines with a similar sample count to either side indicates little bias, while a distribution that extends more to the left or more to the right of the dashed lines indicates that the leach test results were biased low or biased high, respectively.

E
PLOTS SHOWING NORMALIZED LEAF 1313 TO POREWATER RESULTS ACROSS THE RANGE OF pH LEVELS TESTED

Figures E-1 through E-26 show normalized LEAF 1313 test results, where the results were normalized by dividing by the median porewater concentration (because results are displayed as $\log_{10}$, a value of zero indicates exact agreement). The ability of the 1313 test to reproduce porewater concentrations was evaluated based on how many results at natural pH plotted within the dark-shaded ±25% range.

F

PLOTS SHOWING NORMALIZED LEAF 1316 TO POREWATER RESULTS ACROSS THE RANGE OF L/S VALUES TESTED

Figures F-1 through F-26 show normalized LEAF 1316 test results (and 1313 at natural pH) as a function of L/S ratio. The results were normalized by dividing by the median porewater concentration (because results are displayed as $\log_{10}$, a value of zero indicates exact agreement). The ability of the 1316 test to reproduce porewater concentrations at any given L/S was evaluated based on how many results plotted within the dark-shaded ±25% range.

Export Control Restrictions

Access to and use of this EPRI product is granted with the specific understanding and requirement that responsibility for ensuring full compliance with all applicable U.S. and foreign export laws and regulations is being undertaken by you and your company. This includes an obligation to ensure that any individual receiving access hereunder who is not a U.S. citizen or U.S. permanent resident is permitted access under applicable U.S. and foreign export laws and regulations.

In the event you are uncertain whether you or your company may lawfully obtain access to this EPRI product, you acknowledge that it is your obligation to consult with your company's legal counsel to determine whether this access is lawful. Although EPRI may make available on a case by case basis an informal assessment of the applicable U.S. export classification for specific EPRI products, you and your company acknowledge that this assessment is solely for informational purposes and not for reliance purposes.

Your obligations regarding U.S. export control requirements apply during and after you and your company's engagement with EPRI. To be clear, the obligations continue after your retirement or other departure from your company, and include any knowledge retained after gaining access to EPRI products.

You and your company understand and acknowledge your obligations to make a prompt report to EPRI and the appropriate authorities regarding any access to or use of this EPRI product hereunder that may be in violation of applicable U.S. or foreign export laws or regulations.

About EPRI

Founded in 1972, EPRI is the world's preeminent independent, nonprofit energy research and development organization, with offices around the world. EPRI's trusted experts collaborate with more than 450 companies in 45 countries, driving innovation to ensure the public has clean, safe, reliable, affordable, and equitable access to electricity across the globe. Together, we are shaping the future of energy.

Contents

List of Contributors *XVII*
Mercury R&D Book Foreword *XXI*
Preface *XXIII*
List of Abbreviations *XXVII*

Part I: Mercury in the Environment: Origin, Fate, and Regulation *1*

1 **Mercury in the Environment** *3*
Leonard Levin
1.1 Introduction *3*
1.2 Mercury as a Chemical Element *4*
1.2.1 Physical and Chemical Properties of the Forms of Mercury *6*
1.2.2 Associations with Minerals and Fuels *6*
1.3 Direct Uses of Mercury *6*
1.4 Atmospheric Transport and Deposition *7*
1.5 Atmospheric Reactions and Lifetime *8*
1.6 Mercury Biogeochemical Cycling *8*
References *10*

2 **Mercury and Halogens in Coal** *13*
Allan Kolker and Jeffrey C. Quick
2.1 Introduction *13*
2.1.1 Mode of Occurrence of Mercury (Hg) in Coal *13*
2.1.2 Effectiveness of Pre-Combustion Mercury Removal *14*
2.1.3 Methods for Mercury Determination *15*
2.2 Mercury in U.S. Coals *16*
2.2.1 U.S. Coal Databases *16*
2.2.1.1 USGS COALQUAL Database *16*
2.2.1.2 1999 EPA ICR *19*
2.2.1.3 2010 EPA ICR *19*
2.2.2 Comparison of U.S. Coal Databases *20*
2.3 Mercury in International Coals *22*
2.3.1 Review of Mercury in Coal in the Largest Coal Producers *22*

2.3.1.1 China *23*
2.3.1.2 India *24*
2.3.1.3 Australia *26*
2.3.1.4 South Africa *26*
2.3.1.5 Russian Federation *27*
2.3.1.6 Indonesia *29*
2.4 Halogens in Coal *29*
2.4.1 Introduction *29*
2.4.1.1 Chlorine (Cl) *30*
2.4.1.2 Bromine (Br) *32*
2.4.1.3 Iodine (I) *35*
2.4.1.4 Fluorine (F) *35*
2.5 Summary *36*
Acknowledgments *37*
References *37*

3 Regulations *45*
Nick Hutson
3.1 U.S. Regulations *45*
3.1.1 Background *45*
3.1.2 Electric Generating Units (EGUs) *46*
3.1.3 Mercury and Air Toxics Standards ("MATS") – Existing Sources *47*
3.1.4 Mercury and Air Toxics Standards ("MATS") – New Sources *49*
References *50*

4 International Legislation and Trends *51*
Lesley L. Sloss
4.1 Introduction *51*
4.2 International Legislation *52*
4.2.1 UNEP International Legally Binding Instrument on Mercury ("Minamata Convention") *53*
4.2.2 European Union (EU) *53*
4.3 Regional and National Legislation *59*
4.3.1 Europe *59*
4.3.1.1 Germany *59*
4.3.1.2 Netherlands *59*
4.3.2 Asia *60*
4.3.2.1 China *60*
4.3.2.2 Japan *62*
4.3.2.3 Other Asian Countries *63*
4.3.3 Other Countries *64*
4.3.3.1 Australia *64*
4.3.3.2 Canada *65*
4.3.3.3 Russia *65*
4.3.3.4 South Africa *65*

4.4 Summary *65*
References *66*

Part II: Mercury Measurement in Coal Gas *69*

5 Continuous Mercury Monitors for Fossil Fuel-Fired Utilities *71*
Dennis L. Laudal
5.1 Introduction *71*
5.2 Components of a CMM *73*
5.2.1 Mercury Analyzer *73*
5.2.1.1 Cold-Vapor Atomic Absorption Spectrometry *73*
5.2.1.2 Cold-Vapor Atomic Fluorescence Spectrometry *74*
5.2.1.3 Other Analytical Methods *75*
5.2.2 Pretreatment/Conversion Systems and Probe *75*
5.2.2.1 Sampling Probe *76*
5.2.2.2 Pretreatment and Mercury Conversion *77*
5.2.3 CMM Calibration System *79*
5.3 Installation and Verification Requirements *82*
5.3.1 Installation *82*
5.3.2 CMM Verification *82*
5.3.2.1 Measurement Error *83*
5.3.2.2 Seven-Day Calibration Drift *83*
5.3.2.3 Relative Accuracy Test Audit *83*
5.4 Major CMM Tests *84*
5.5 CMM Vendors *87*
References *88*

6 Batch Methods for Mercury Monitoring *91*
Constance Senior
6.1 Introduction *91*
6.2 Wet Chemistry Batch Methods *91*
6.2.1 Early EPA Total Hg Methods *91*
6.2.2 Development of Wet Chemistry Methods to Speciate Hg *93*
6.2.3 Method Application and Data Quality Considerations *94*
6.3 Dry Batch Methods *95*
6.3.1 Sorbent Trap Method History *95*
6.3.2 Method Overview *97*
6.3.3 Total Hg Measurements *97*
6.3.3.1 PS-12B *97*
6.3.3.2 Method 30B *98*
6.3.4 Speciation Measurements *98*
6.3.5 Sampling Protocol *99*
6.3.5.1 Procedure and Apparatus *99*
6.3.6 Trap Analysis *100*
6.3.7 Relative Accuracy and Quality Assurance/Quality Control *100*

6.4 Recommendations *105*
6.4.1 Particulate Matter *105*
6.4.2 Total Versus Speciated Mercury *105*
6.4.3 Expected Mercury Concentration in the Flue Gas *105*
6.4.4 Need for Real-Time Data *106*
6.4.5 Complexity of Installation and Operation *106*
References *106*

Part III: Mercury Chemistry in Coal Utilization Systems and Air Pollution Control Devices *109*

7 Mercury Behavior in Coal Combustion Systems *111*
Constance Senior
7.1 Introduction *111*
7.2 Coal Combustion Boilers *112*
7.3 Mercury Chemistry in Combustion Systems *113*
7.4 Air Pollution Control Devices on Utility and Industrial Boilers *117*
7.4.1 PM Control *118*
7.4.2 NO_x Control *119*
7.4.3 SO_2 Control *119*
7.4.4 Boiler Populations in the United States *120*
7.5 Mercury Behavior in Coal-Fired Boilers *121*
7.5.1 Data Sources *121*
7.5.2 Mercury Behavior in APCDs *123*
7.6 Summary *129*
References *130*

8 Gasification Systems *133*
Nicholas Lentz
8.1 Principles of Coal Gasification *133*
8.2 Gasification Technologies Overview and Gasifier Descriptions *134*
8.3 Gasification Applications and Downstream Gas Cleanup and Processing *135*
8.4 Mercury Transformations and Fate *135*
8.5 Hg Measurement in a Reducing Environment *137*
8.6 Hg Control Technologies for Gasification *138*
8.7 Hg and the MATS Rule for Gasifiers *139*
References *140*

9 Mercury Emissions Control for the Cement Manufacturing Industry *141*
Robert Schreiber Jr., Shameem Hasan, Carrie Yonley, and Charles D. Kellett
9.1 Introduction *141*
9.2 Cement Manufacturing Process Description *141*
9.2.1 Wet Process Kiln *144*

9.2.2 Dry Process Kiln *145*
9.3 State of Knowledge on the Source and Behavior of Mercury in the Cement Kiln System *147*
9.4 Mercury Emissions Control Solutions in the Cement Industry *153*
9.4.1 Activated Carbon Injection (ACI) *156*
9.4.2 Wet Scrubbing *157*
9.4.3 Selective Catalytic Reduction (SCR) and Wet Scrubbing *158*
9.5 Conclusions *159*
References *160*

Part IV: Mercury Research Programs in the United States *163*

10 DOE's Mercury Control Technology Research, Development, and Demonstration Program *165*
Thomas J. Feeley III, Andrew P. Jones, James T. Murphy, Ronald K. Munson, and Jared P. Ciferno
10.1 Introduction *165*
10.2 Background *165*
10.2.1 NETL's Hg Control Technology R& D *166*
10.2.2 Mercury Speciation *167*
10.2.3 Mercury Control Technologies *168*
10.2.4 Results from Field Testing Program *169*
10.2.5 Oxidation Enhancements *169*
10.2.6 Chemical Additives *170*
10.2.7 Catalysts *170*
10.2.8 Activated Carbon Injection *171*
10.2.8.1 Untreated PAC *171*
10.2.8.2 Chemically Treated PAC *173*
10.2.8.3 Conventional PAC with Chemical Additives *175*
10.2.8.4 ACI Upstream of a Hot-Side ESP *176*
10.2.9 Remaining Technical Issues *176*
10.2.9.1 Impacts on Fly Ash *176*
10.2.9.2 Sulfur Trioxide Interference *178*
10.2.10 NETL In-House Development of Novel Control Technologies *179*
10.2.11 Hg Control Technology Commercial Demonstrations *180*
10.2.12 Mercury Control Cost Estimates *180*
10.2.12.1 Economic Analyses for ACI *181*
10.2.12.2 Economic Analyses for Wet FGD Enhancement *181*
10.2.13 Coal Utilization Byproducts (CUB) R& D Program *182*
10.2.14 Determining the Fate of Hg in FGD Byproducts *183*
10.2.15 Determining the Fate of Hg in Fly Ash *184*
10.3 Summary *185*
Disclaimer *186*
References *186*

11 U.S. EPA Research Program *191*
Nick Hutson
11.1 Introduction *191*
11.2 Congressionally Mandated Studies *191*
11.3 Control Technology from Work on Municipal Waste Combustors (MWCs) *193*
11.4 Mercury Chemistry, Adsorption, and Sorbent Development *194*
11.4.1 Halogenated Activated Carbon Sorbents *196*
11.4.2 Non-Carbonaceous Sorbents *197*
11.4.3 Mercury Control in a Wet-FGD Scrubber *198*
11.4.4 Effect of SCR on Mercury Oxidation/Capture *200*
11.5 Coal Combustion Residues and By-Products *201*
11.6 EPA SBIR Program *202*
References *202*

12 The Electric Power Research Institute's Program to Control Mercury Emissions from Coal-Fired Power Plants *205*
Ramsay Chang
12.1 Introduction *205*
12.2 Co-Benefits of Installed Controls *205*
12.2.1 Selective Catalytic Reduction/Flue Gas Desulfurization *205*
12.2.2 Unburned Carbon *206*
12.3 Sorbent Injection *207*
12.3.1 Units Equipped with Electrostatic Precipitators *208*
12.3.1.1 Western Coals *208*
12.3.1.2 Eastern Bituminous Coals and High-Sulfur Flue Gases *208*
12.3.2 Units Equipped with Fabric Filters or TOXECON® *209*
12.3.3 Challenges and Responses *211*
12.3.3.1 Preserving Fly Ash Sales *211*
12.3.3.2 Optimizing Electrostatic Precipitator Performance *211*
12.3.3.3 Optimizing Fabric Filter and TOXECON Performance *212*
12.4 Boiler Chemical Addition *213*
12.4.1 Combined Technologies *214*
12.4.2 Challenges and Responses *215*
12.4.2.1 Wet Flue Gas Desulfurization Chemistry and Mercury Partitioning *216*
12.4.2.2 Corrosion along Flue Gas Path and in the wFGD *216*
12.4.2.3 Preserving Fly Ash Sales *217*
12.4.2.4 Selenium Partitioning in Wet Flue Gas Desulfurization Systems *217*
12.4.2.5 Bromide Leaching from Fly Ash *217*
12.5 Novel Concepts for Mercury Control *218*
12.5.1 TOXECON II® *218*
12.5.2 Gore® Carbon Polymer Composite Modules *218*
12.5.3 Sorbent Activation Process *220*

12.6 Integration of Controls for Mercury with Controls for Other Air Pollutants *221*
12.7 Summary *222*
References *222*

Part V: Mercury Control Processes *225*

13 Mercury Control Using Combustion Modification *227*
Thomas K. Gale
13.1 Mercury Speciation in Coal-Fired Power Plants without Added Catalysts *227*
13.1.1 Mercury is all Liberated and Isolated in the Furnace *227*
13.1.2 Chlorine Speciation in Coal-Fired Power Plants *227*
13.1.3 Mechanisms Governing Mercury Speciation *228*
13.2 Role of Unburned Carbon in Mercury Oxidation and Adsorption *229*
13.2.1 UBC is the Only Catalyst with Enough Activity in Coal-Fired Power Plants *229*
13.2.2 UBC can Remove Hg or Oxidize Hg, Depending on the UBC Concentration *230*
13.2.3 Nature of Carbon Type Depends on Parent Coal and Combustion Efficiency *231*
13.2.4 Concentration of UBC Needed to Oxidize or Remove Mercury from Flue Gas *232*
13.3 Synergistic Relationship between UBC and Calcium in Flyash *233*
13.3.1 Calcium Enhances the Retention of Mercury on Carbon *233*
13.3.2 Calcium/Carbon Synergism is Limited to a Range of Conditions *234*
13.4 Potential Combustion Modification Strategies to Mitigate Mercury Emissions *236*
13.5 Effects of Combustion Modifications on Mercury Oxidation across SCR Catalysts *238*
13.5.1 Inhibition of Mercury Oxidation can Occur in Low-Chlorine Flue Gas *238*
References *238*

14 Fuel and Flue-Gas Additives *241*
John Meier, Bruce Keiser, and Brian S. Higgins
14.1 Background *241*
14.1.1 Bromine-Salt Mercury Oxidation *242*
14.1.2 Fuel Additive Injection Equipment *242*
14.1.3 Case Study Results *243*
14.1.3.1 Case Studies where Halogen-containing Fuel Additives are Advantageous *244*

14.1.4 Case Studies where Conditions are Disadvantageous to Fuel Additive *248*
14.1.4.1 Units Burning High Chlorine Fuel with an SCR *249*
14.1.4.2 Subbituminous Fired Units with Flue Gas Conditioning (SO_3 Injection) *249*
14.1.4.3 Units without Acid Gas Scrubbing and a Fabric Filter (FF) *250*
14.2 Summary *250*
References *250*

15 Catalysts for the Oxidation of Mercury *253*
April Freeman Sibley
15.1 Introduction *253*
15.1.1 Process Overview *253*
15.2 Hg Oxidation and Affecting Parameters *254*
15.2.1 Hg^0 Oxidation Reaction Mechanism *255*
15.2.2 Homogeneous Oxidation of Mercury *255*
15.2.3 Heterogeneous Oxidation of Mercury over SCR Catalysts *255*
15.2.4 SCR Operation-Hg^0 Reaction Effects *257*
15.2.5 Hg^0 Oxidation and SO_2/SO_3 Conversion *258*
15.3 Conclusions and Future Research *259*
References *260*

16 Mercury Capture in Wet Flue Gas Desulfurization Systems *261*
Gary Blythe
16.1 Introduction *261*
16.2 Fate of Net Mercury Removed by Wet FGD Systems *263*
16.2.1 Phase Partitioning *263*
16.2.2 Mercury in FGD By-product Streams *264*
16.3 Mercury Reemissions *267*
16.3.1 Definition and Reporting Conventions *267*
16.3.2 Reemission Chemistry *269*
16.3.3 Reemission Additives *271*
16.4 Effects of Flue Gas Mercury Oxidation Technologies on FGD Capture of Mercury *272*
References *274*

17 Introduction to Carbon Sorbents for Pollution Control *277*
Joe Wong
17.1 Carbon Materials *277*
17.2 Carbon Activation *277*
17.3 Carbon Particle Shapes and Forms *280*
17.3.1 Powdered Activated Carbon (PAC) *280*
17.3.2 Granular Activated Carbon (GAC) *281*
17.3.3 Shaped Activated Carbon *282*
17.3.4 Other Activated Carbon Forms *282*

17.4 Activated Carbon Applications *282*
17.5 Activated Carbon Properties in Emission Systems *283*
17.5.1 Activated Carbon Surface *285*
17.5.2 Activated Carbon Pores *286*
17.5.3 Activated Carbon Particles *289*
17.6 Summary *291*
References *291*

18 Activated Carbon Injection *293*
Sharon M. Sjostrom
18.1 Introduction *293*
18.2 The Activated Carbon Injection System *294*
18.2.1 Powdered Activated Carbon Storage *294*
18.2.2 Process Equipment *295*
18.2.2.1 Metering *295*
18.2.2.2 Conveying *295*
18.2.3 PAC Distribution *296*
18.3 Factors Influencing the Effectiveness of Activated Carbon *296*
18.3.1 Site-Specific Factors *296*
18.3.1.1 Flue Gas Characteristics: Halogens and SO_3 *297*
18.3.1.2 TOXECON™ *303*
18.3.2 PAC-Specific Factors *303*
18.3.3 ACI System Design-Specific Factors *304*
18.3.3.1 Injection Location *304*
18.3.3.2 Distribution *304*
18.4 Balance-of-Plant Impacts *305*
18.4.1 Coal Combustion By-Products *305*
18.4.1.1 Autoignition of PAC in Ash Hoppers *306*
18.4.1.2 Impacts on Particulate Emissions *306*
18.4.1.3 Corrosion Issues *307*
18.5 Future Considerations *307*
References *307*

19 Halogenated Carbon Sorbents *311*
Robert Nebergall
19.1 Introduction *311*
19.2 Application of Activated Carbon for Mercury Control *311*
19.3 Development of Halogenated Activated Carbon *313*
19.3.1 Motivation *313*
19.3.2 Manufacture *315*
19.3.3 Performance *316*
19.3.4 Balance-of-Plant Impacts *319*

20 Concrete-Compatible Activated Carbon *323*
S. Behrooz Ghorishi
20.1 Introduction *323*
20.2 Concrete-Compatibility Metrics *324*
20.2.1 The New and Innovative Concrete-Friendly™ Metrics; the Acid Blue Index *326*
20.3 Production of Concrete-Compatible Products Including C-PAC™ *329*
20.4 C-PAC™ Specification *331*
20.4.1 Commercial Application of C-PAC™ *331*
20.4.2 Full-Scale C-PAC™ Trials at Midwest Generation's Crawford Station *332*
20.4.3 Full-Scale C-PAC™ Trials the PPL Montana Corette Station *333*
20.4.4 Cement Kiln Mercury Emission Control Using C-PAC™ *334*
20.5 Concrete Compatibility Test – Field Fly Ash/C-PAC™ Mixture *335*
20.5.1 Air Content of Fresh Concrete *336*
20.5.2 Unconfined Compressive Strength (UCS) *336*
20.5.3 Stability of Mercury in Fly Ash and Concrete *337*
References *337*

21 Novel Capture Technologies: Non-carbon Sorbents and Photochemical Oxidations *339*
Karen J. Uffalussy and Evan J. Granite
21.1 Introduction *339*
21.2 Non-carbon Sorbents *340*
21.2.1 Amended Silicates, Novinda *340*
21.2.1.1 Background and Motivations *340*
21.2.1.2 How Does the Amended Silicates Sorbent Work? *341*
21.2.1.3 Demonstrations *342*
21.2.1.4 Conclusions *344*
21.2.2 MinPlus CDEM Group BV *345*
21.2.2.1 Background and Motivations *345*
21.2.2.2 How Does the MinPlus Sorbent Work? *345*
21.2.2.3 Demonstrations of Sorbent *347*
21.2.2.4 Conclusions *348*
21.2.3 Pahlman Process – Enviroscrub *348*
21.2.3.1 Background and Motivations *348*
21.2.3.2 How Does the Process and Sorbent Work? *349*
21.2.3.3 Demonstrations *349*
21.2.3.4 Conclusions *350*
21.3 Photochemical Removal of Mercury from Flue Gas *350*
21.3.1 Sensitized Oxidation of Mercury: GP-254 Process *350*

Mercury R&D Book Foreword

This book is very timely and important, because as I write this foreword, the U.S. Environmental Protection Agency (EPA) is finalizing the first mercury emission limitations on coal-fired power plants, known as the *Mercury and Air Toxics Standards* (*MATS*) rule. This regulation will require significant reductions of the amount of mercury (and other chemicals) contained in the coal fuel before the flue gas is released into the atmosphere.

The information in this volume has mostly been developed over the past decade, where I was engaged as a front line research manager for one of the largest power companies in the United States, Southern Company, which has many coal-fired power plants in its fleet. I have testified before the U.S. Senate on mercury chemistry and behavior in coal-fired boilers (*http://epw.senate.gov/108th/Monroe_060503.htm*), and have been in a leadership position for the utility industry in several organizations, namely, the Electric Power Research Institute (EPRI), the Coal Utilization Research Council (CURC), and the Utility Air Regulatory Group (UARG). I was the project manager for one of the first full-scale power plant tests of dedicated mercury control, at Alabama Power's Plant Gaston – which won an *R&D Magazine* "R&D 100" award in 2003. The Gaston project involved many of the authors included in this volume, especially Tom Feeley, Ramsay Chang, and Sharon Sjostrom. This is a subject that I know well.

In addition, several authors and I have collaborated on other related mercury studies. One of the most intriguing was the innovative research of the fate of mercury in coal power plant plumes, using first a fixed wing airplane and then an airship for plume sampling. This effort was led by Leonard Levin of EPRI, and included Dennis Laudal (University of North Dakota) and Jeff Ryan (U.S. EPA). Another cooperative effort through EPRI has been the computer modeling of mercury in power plants in two different efforts, led by Constance Senior and Steve Niksa.

The utility industry was taken by surprise with the announcement by the outgoing Clinton administration that it would be subject to a Maximum Achievable Control Technology (MACT) rule for mercury on 14 December 2000. That action kicked the industry into a frantic search for any data or information that could help us develop reliable control technology choices. Notably, EPRI, through the efforts of Ramsay Chang, and the U.S. Department of Energy (DOE)'s National

Energy Technology Laboratory (NETL), had already started working on mercury chemistry and control for coal-fired power plants. The subsequent efforts have largely been successful as an example of a public – private R&D partnership; where the utility industry and the suppliers of technology and materials to the industry worked with the DOE NETL to quickly advance the state of knowledge.

As the R&D progressed, an informal steering group of utility researchers, vendors of hardware and materials, and the U.S. DOE NETL was able to leverage the NETL funding to explore different options for controlling mercury from almost all power plant and coal-type combinations. In the early years of R&D, we found that we knew less and less about mercury chemistry with every new test and discovery, as contradictory results were more the rule.

The editors have assembled an experienced group of authors to make this volume, a "Who's Who's" of mercury research from the United States over the past decade. I feel lucky to have worked with virtually every one of the assembled group, and call most of them close friends. There is no better group of technical professionals to guide you in understanding the issues of mercury in coal-derived gas streams.

The volume is arranged in a logical sequence, beginning with the fate of mercury in the environment, written by Leonard Levin of EPRI. The applicable regulations, both for the United States and the international context, follow along with descriptions of trace elements in coal and the means to measure mercury in gas streams. The heart of the work is presented in the following sections on mercury chemistry, research programs, and the different technology systems that can be used and adapted for mercury control. The important topic of the stability of mercury in the solid coal combustion residues is also addressed next. Finally, the state-of-the-art in mercury modeling, both at the fundamental and process levels, is presented.

This is the manuscript that I – and the whole industry – needed back in 2000, as we contemplated what we would have do to reduce mercury emissions to meet upcoming regulations. It will serve as both a reference for those already engaged in the research and control efforts, and as an invaluable introduction for those just now becoming interested in the subject. I highly recommend it to the technical reader.

Preface

This book has its genesis in a Department of Energy (DOE) Topical Report on "Sorbents for Mercury Removal from Flue Gas" that Henry Pennline asked me to write in 1996. As a new post-doc hired to study sorbents for the capture of mercury, Henry suggested that a thorough literature review and survey would be an excellent way to start. As the topical report progressed and was nearly complete in 1997, I suggested to Henry that we write a book about mercury in flue gas. Henry shot this idea down at the time, correctly stating that we had much more to learn. Henry Pennline has turned out to be the best supervisor, researcher, colleague, and friend I could ever have. He was a little skeptical of my abilities at first, having observed my unusual photographic memory for foods; my suit and tie attire in the laboratory (unusual at DOE); and my dropping a large $25 quartz tube for the micro-balance on my first day on the job. I hope I end up doing something good in my research career to justify Henry's faith in me.

Mercury is a semi-noble metal, with both a fascinating chemistry and numerous applications throughout human history. Coal-derived flue gas and coal-derived syngas are both complex stews containing numerous species and exist over a wide temperature range at pulverized combustion and integrated gasification combined cycle (IGCC) plants, respectively. Having completed a MS thesis on coal gasification, I already knew going into the DOE that one could happily study coal flue gas and syngas for many lifetimes. Being introduced to mercury at DOE, I quickly found a terrific subject, with many wonderful colleagues.

In 1998 I met Dr Constance Senior at DOE in Pittsburgh. Constance was leading a large DOE-funded study on the behavior of the trace elements in coal-fired power plants. She impressed me immediately as a tenacious leader and terrific researcher. Constance exhibited extraordinary leadership – her efforts in corralling a large and diverse group of researchers from industry, academia, and the government resulted in a nearly 800-page report for DOE; a special issue of Fuel Processing Technology on the trace elements in coal-fired power plants in 2000; and a great expansion of our understanding of mercury in flue gas. I had the pleasure of meeting Constance again at the Workshop on Source Emission and Ambient Air Monitoring in Minneapolis in 1999. Despite the fact that I was an unknown post-doc at DOE, she introduced me to many of the researchers at dinner (a large pot of minestrone soup and a gigantic pizza that covered the

entire table) in the Mall of America. I learned a lesson that day from Constance; always be nice to your colleagues. Hopefully I have done this. Dr Senior made Herculean efforts to help this book get completed; she is one-in-a-million.

Our work at DOE has allowed us to meet many wonderful colleagues at venues such as the Annual Mercury Control Technology Meetings that were held in Pittsburgh; the AIChE and ACS National Meetings; the Air Quality Conferences, and the Mega Symposiums. At the joint ACS-AIChE National Meeting held in the spring of 2008 in New Orleans, I recruited Tom Feeley, Ramsay Chang, and Constance Senior to be my keynote speakers on mercury. They did an outstanding job, highlighting a program that had 29 speakers on the various aspects of mercury in coal-derived gases. The idea for the book on mercury, having never left my mind, was revived. In 2009 I came up with a draft outline for this book, and happily in 2010, Dr Julia Stuthe from John Wiley recruited me to organize a book on mercury in coal-derived gases. Having already planned a book, I bent her ears with a 40-page PowerPoint presentation, abstract, and outline over a burrito and spicy chicken tortilla soup dinner in San Antonio during the 2010 AIChE National Meeting. Julia – forgive me. Dr Stuthe has recently left John Wiley, and I wish her great success. Lesley Belfit from John Wiley has done an outstanding job in helping us complete this book.

Coal contains a trace level of mercury of approximately 0.1 ppm. Mercury is a neurotoxin, and can travel long distances once emitted through the stacks of coal-burning power plants. Approximately 30–40% of the electricity in the United States is generated through the combustion of coal. Coal is an abundant resource in the United States – the country has a supply for at least 200 years. The challenge is to utilize the abundant domestic coal for energy independence in environmentally friendly ways.

With the US EPA issuing a national regulation on 21 December, 2011, requiring 91% removal of mercury, and many states already with their own regulations, the need exists for low-cost mercury removal techniques that can be applied to coal-burning power plants. The injection of powdered activated carbon into the ductwork upstream of the particulate control device is the most developed technology for mercury capture. Alternative techniques for mercury capture will also play a role in the near future because of the numerous configurations of air pollution control devices present within the power plants, as well as the many different coals being burned. These methods employ sorbents, catalysts, scrubber liquors, flue gas or coal additives, combustion modification, flue gas cooling, barrier discharges, and ultraviolet radiation for the removal of mercury from flue gas streams. The DOE Mercury Program has been a huge success, spurring development, demonstration, and commercialization of many technologies for the capture of mercury.

The future research needs for mercury control include improved sorbent-flue gas contact, development of poison-resistant sorbents and catalysts, new scrubber additives for retention of mercury within wet flue gas desulfurization

(WFGD) systems, concrete-friendly activated carbons, new continuous measurement methods, by-products research, and development of an ASTM standard laboratory test for sorbent activity for mercury capture.

This book aims to cover the technologies for mercury capture and measurement from coal-derived flue gas. The fate of mercury in the environment, a great motivation for the regulations, research, development, and commercialization of capture and measurement methods, is covered in Chapter 1. The trace elements in coal are detailed in Chapter 2. In addition, the regulatory issues, both in the United States and internationally, are discussed in Chapters 3 and 4. Methods for the detection of mercury in flue gas are covered in Chapters 5 and 6. Later chapters discuss the many methods for mercury control, the various research programs, activated carbon technologies, the cement industry, gasification, mercury carbon surface chemistry, and modeling.

I thank Constance and Henry for their outstanding efforts in making this book become a reality. Constance and Henry took my crude initial outline for the book and greatly improved it. Tom Feeley deserves many thanks for the great success of the DOE Mercury Program, and for supporting our in-house research on flue gas. Gary Stiegel and Jenny Tennant from DOE have been terrific in supporting our efforts in understanding the trace elements in gasification systems. Our authors and colleagues Constance Senior, Henry Pennline, Larry Monroe, Leonard Levin, Allan Kolker, Jeff Quick, Leslie Sloss, Nick Hutson, Denny Laudal, Carrie Yonley, Tom Feeley, Ramsay Chang, Tom Gale, Brian Higgins, April Sibley, Gary Blythe, Joe Wong, Nick Lentz, Sharon Sjostrom, Rob Nebergall, Behrooz Ghorshi, Ed Olson, Karen Uffalussy, Jennifer Wilcox, and Steve Niksa did an outstanding job. They are the leading figures in the mercury capture research, development, demonstration-commercialization communities; and are also terrific colleagues and friends. Some of our authors have been working on the mercury issue for over 20 years.

Finally, I thank Phil and Rita Granite, for interest in mercury, suggestions over the years for techniques for mercury control, and for being terrific parents. The same thanks also go to my brother Larry Granite at Environmental Protection Agency (EPA). Linda Granite has humored me, feigning interest in mercury while we were dating (I bent her ears with papers on sorbents and photochemical removal of mercury on our first date – a steak dinner; despite this she went out with me again!), and has been an angel through the years as my mind is sometimes elsewhere on the topic of mercury. Linda and our daughters Ana and Marissa Granite always provide inspiration.

1
Mercury in the Environment

Leonard Levin

1.1
Introduction

Mercury is a naturally occurring chemical element found ubiquitously throughout both the natural and human environments. Mercury occurs throughout the earth's crust and is most commonly found in its geological occurrence as the mineral cinnabar (mercuric sulfide, HgS_2). Elemental mercury, the uncombined form, occurs at room temperature and sea level pressure as a liquid, the only chemical element so occurring. Due to its relatively high vapor pressure, liquid mercury will evaporate readily into the atmosphere.

Elemental mercury can be oxidized to the mercurous (Hg^{1+}) or mercuric (Hg^{2+}) inorganic form in the presence of hydroxyl radicals, ozone, or a number of other oxidizing agents. The more commonly occurring mercuric form readily recombines into either water-soluble forms, such as with halogens (e.g., $HgCl_2$), or insoluble salts (HgS_2).

Surface exposure of geological mercury minerals or elemental mercury concentrations led to the presence of both elemental and inorganic mercury in the global atmosphere, even prior to its enhanced release due to human activity after the onset of the Industrial Revolution (mid-eighteenth century). Indeed, this ubiquity of mercury, and its uptake by fauna via leaf stomata and root systems, leads to its association with fossil fuels such as oil and coal. These fuels derive from burial and metamorphosis of plant matter under anoxic conditions via stages starting with peat formation. Core sampling of peat formations in Arctic Canada by Givelet *et al.* [1] has shown transitory excursions of mercury deposition dating from before 1700 CE attributed to wildfires set by First Nations for land clearing.

One feature of interest to investigators is the relative increase in abundance of mercury in the environment from the pre-Columbian era to the present day, due to human mobilization of the substance. This mobilization has occurred in several ways, but primarily through either direct use of mercury in products or via combustion-related emissions of fuel-associated mercury. The use of elemental mercury in medical and consumer products has occurred over hundreds of years, in such instances as the forming of pelts and felts into chapeaux and

Mercury Control: for Coal-Derived Gas Streams, First Edition.

its use in electric switches. Fuel-associated mercury continues to be released globally in the production of power, space and process heat, process steam, and other uses.

This relative increase in global mercury cycling in the modern era can be determined by comparing mercury concentrations at both deep and shallow depths in cores of glacial ice or lake sediments, or by comparing global source inventories of mercury. In the case of inventory comparisons, the modern: preindustrial ratios are derived from separately calculating emission rates from undisturbed natural background sources (exposed mercuriferous deposits, surface, and undersea volcanism) with the total of those sources and human sources (atmospheric evasion from inactive mining sites, mineral recovery sites, point and area fuel combustion sources, and waste sites).

Each such method has both advantages and disadvantages. Core samples can represent localized conditions (e.g., lensing of lake sediments), while global inventories are subject to large uncertainties due to spatial scaling of local measurements, inaccurate extrapolation to unmeasured sources, and so on. Generally, results indicate that, globally, there is roughly three to four times as much mercury cycling through the biogeochemical and human environment currently as there was in pre-Columbian times (see Figure 1.1) [2]. This modern: preindustrial ratio, however, is a global average. There are many individual experimental samples in ice cores, peat bogs, lake-bottom sediments, and other environments globally exhibiting much higher ratios. For example, Schuster *et al.* [3] found a 20-fold enhancement ratio in ice core data from the Lower Fremont Glacier, Wind River Mountains, Wyoming, USA.

The atmospheric lifetime of vapor-phase elemental mercury is believed to be roughly 7–12 months, in bulk, although the mean lifetime of reactive oxidized mercury is more likely measured in days to weeks. Atmospheric oxidized mercury may undergo chemical reduction to the insoluble gaseous elemental form, or may be removed from the atmosphere by solution in precipitation or by dry deposition to the earth's surface.

Mercury concentrations in the planetary boundary layer appear to react to changes in global input within months to years (see, for example, [5]). There is a much longer period for aquatic systems to fully react to changes in mercury input via deposition and runoff, but this is somewhat dependent on the trophic depth of the ecosystem involved. Large piscivorous fish represent multiyear mercury reservoirs whose body burden of mercury (primarily as methylmercury) acts as multiyear transfers of an integrated record of mercury exposure from their feeding patterns.

1.2
Mercury as a Chemical Element

Mercury is a chemical element (atomic number 80, isotope-weighted atomic mass 200.59 amu) known as a *distinct substance* since the earliest days of civilization.

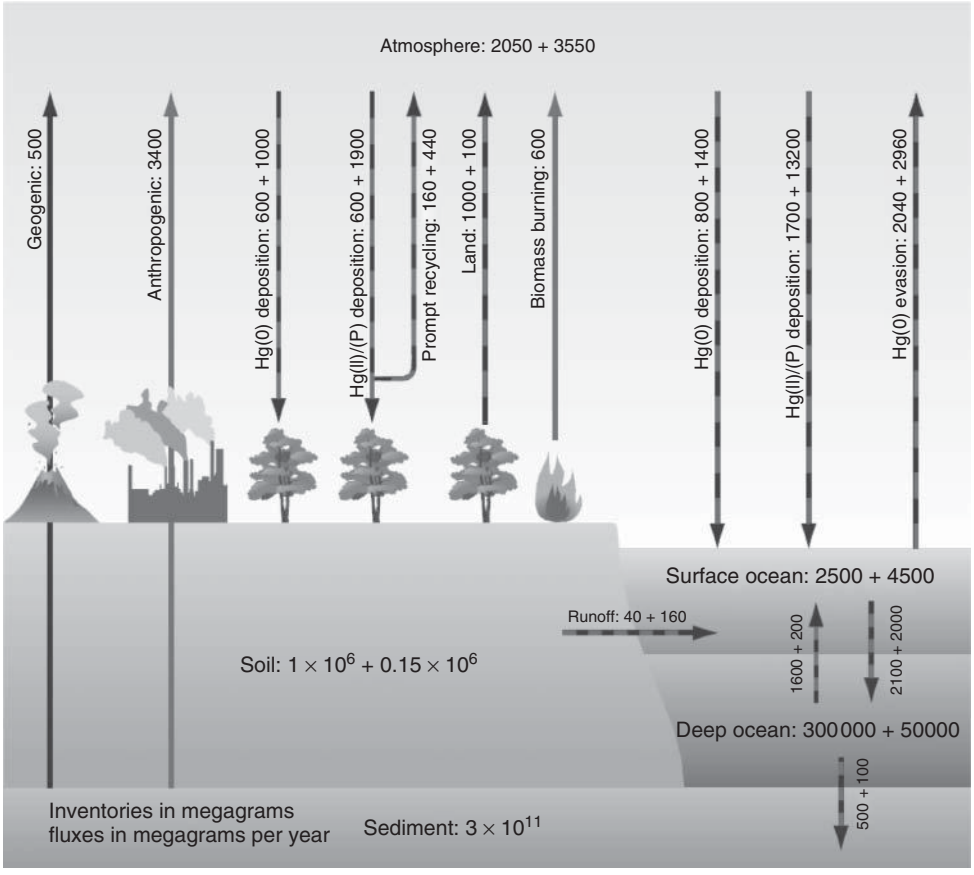

Figure 1.1 Global biogeochemical cycle for mercury. Natural (preindustrial) fluxes (megagrams (Mg) per year) and inventories, in megagrams, are noted in black. Anthropogenic contributions are in gray. Natural fluxes augmented by anthropogenic activities are noted by gray-and-black dashed lines. (Modified from Selin *et al.* [4].) A mean enrichment factor of 3 between the preindustrial and present-day mercury deposition, based on remote sediment cores, is used as a constraint. (Figure from Selin [2] © 2009 by Annual Review.)

The Greek word for mercury, Υδραργυρος, means "water + silver." This was adapted into the Latin hydrargyros, for "water – silver." Both terms refer to the morphology of pure elemental mercury at room temperature, a silvery liquid, and the only chemical element occurring in pure form as a liquid at ambient temperatures.

The abundance of naturally occurring stable isotopes of mercury is shown in Table 1.1 [6]. In addition, several unstable isotopes of mercury are known. One of these, 203Hg, is commonly used as a spiked tracer in, for example, experiments on mercury methylation in aquatic systems [7].

Table 1.1 Background natural abundance of stable mercury isotopes.

Isotope	^{198}Hg	^{199}Hg	^{200}Hg	^{201}Hg	^{202}Hg	^{204}Hg
Abundance (%)	10	17	23	13	30	7

1.2.1 Physical and Chemical Properties of the Forms of Mercury

A key variable of mercury and its chemically combined forms is its vapor pressure. The vapor pressure is of interest because one form of transference of mercury from the earth's surface to the overlying atmosphere is evasion, or net positive flux into the atmosphere [8].

1.2.2 Associations with Minerals and Fuels

Mercury is typically found in association with fossil fuels: coal, petroleum, and natural gas. Mercury associated with coal deposits ranges globally from 0.02 to 1.0 ppmw [9]. This range is similar to that found for the occurrence of mercury in background topsoil samples (<0.01 – 4.6 ppmw, [10]). Mercury association with coal is thought to be via diagenesis in coalbeds [11, 12]: during metamorphic processes, inclusions of pyritic minerals into coalbed fracture zones have brought with them mercury inclusions. This is in opposition to the obvious association of naturally occurring atmospheric mercury in surface vegetation later incorporated into sedimentary precursors to coalbed seams. The pyritic association of mercury in coal is primarily evident in bituminous and anthracite seams, while subbituminous and lignite coals tend to have mercury associated with organic constituents, perhaps the remnant of mercury ligands in surface vegetal deposits. The pyrite association is borne out by concentration enrichments of ~×100 in analyses of pyrites from coal versus the concentrations in whole coal samples.

1.3 Direct Uses of Mercury

Mercury in medical treatment: Mercury in various chemical forms has long served as an artisanal medical treatment. Although liquid mercury is still used in scattered applications in the United States, it was more widely used in the early twentieth century for treatment of venereal disease; one documented example is the syphilis treatment of Karen Blixen ("Isaac Dinesen," *Out of Africa*) in Kenya by prescription of mercury pills [13]. Chinese herbal balls, with recommended doses of two balls swallowed per day, have been found to have mercuric sulfide added to

Table 1.2 Total mercury sold in pumps in the United States (pounds).

2001 Total mercury	2004 Total mercury	2007 Total mercury
12 745 (6.4 ton)	13 911 (7.0 ton)	10 383 (5.2 ton)[a)]

a) *http://www.newmoa.org/prevention/mercury/imerc/factsheets/pumps.cfm#4*
Source: NEWMOA [19].

their composition [14]. The daily dose of mercury can amount to 1200 mg. For a 70 kg consumer, this dose is equivalent to nearly 200 000 times the Environmental Protection Agency (EPA) mercury Reference Dose of 0.1 $\mu g\,kg^{-1}\,day^{-1}$. More common uses of mercury have been in medical devices such as thermometers and sphygmomanometers; in the latter case, replacement of these devices where mercury is employed by aneroid or digital versions has produced problematic intercomparisons of readings [15].

Mercury in products: Mercury, particularly elemental mercury in liquid form, has often been directly used in consumer and industrial products and processes. In the United States, this was particularly the case for its use in batteries and switches [16]. Another common use was as a conductor in quiet mercury switches, which were commonly used in natural gas and petroleum distribution lines [17]. These uses have dropped significantly in recent years (Table 1.2). One of the last remaining large consumer uses for mercury is in fluorescent lamps, including compact fluorescent lamps (CFLs), each of which typically contains several milligrams of mercury [18].

1.4 Atmospheric Transport and Deposition

The concentration of mercury in ambient air is on the order of 1 – 5 ppt. Most of this occurs as gaseous elemental mercury (GEM), especially above the atmospheric boundary layer, although trace levels of the divalent form and even methylmercury have been measured [20]. A recurring public fallacy is that, as mercury is classified as a "heavy metal," [21, 22], the substance "falls out of the sky" quickly upon being emitted to the atmosphere. Because the mercury from heated elevated sources disperses in the atmosphere, gravitational settling at the atomic or molecular level does not play a role in mercury dynamics – except for particulate-bound mercury (Hgp, primarily HgII bound to crustal and combustion particles), where particle deposition velocities do play a role. The high vapor pressure of elemental mercury serves to disperse it widely so that atmospheric turbulence keeps GEM in the atmosphere for a lifetime of 7 – 16 months (e-folding time). This long lifetime in the free troposphere classifies mercury, particularly elemental mercury, as a global pollutant [23].

1.5 Atmospheric Reactions and Lifetime

Mercury released to the atmosphere from natural sources, such as volcanoes or mercuriferous crustal deposits, is generally in the form of elemental mercury (Hg^0), commonly termed *gaseous elemental mercury* in its atmospheric occurrence. Anthropogenic emissions are, in general, a mix of GEM and divalent mercury (Hg^{II}), referred to as *reactive gaseous mercury* or *RGM* in its atmospheric occurrence. The lifetime of mercury species in the atmosphere is bounded by the reaction and removal rates of the two primary species, GEM and RGM. The oxidation of GEM to RGM by ozone, O_3, has been studied by many investigators. An important removal mechanism for RGM is due to its relatively high solubility in precipitable water. Calvert and Lindberg [24] concluded that the single-stage reaction $Hg + O_3 \rightarrow HgO + O_2$ was less likely to occur than an intermediary unstable molecule HgO_3, decaying to OHgOO, and then decomposing into $HgO + O_2$. Further removal reactions have been investigated; one such process, the oxidation of Hg^0 by hydroxyl radical, OH, was found by Goodsite *et al.* [25] to be a relatively unimportant step.

The atmospheric lifetime (average residence time) of GEM is normally assumed to be 7–15 months. Work by Selin *et al.* [4] tried to refine these numbers into the contributing factors: removal by dry deposition; oxidation to RGM by homogeneous- and heterogeneous-phase reactions in the atmosphere; additions by reduction reactions of RGM in the upper troposphere/lower stratosphere (UTLS); and evasion of GEM from surface reservoirs. Each of these processes is still poorly understood, particularly the subsidence and transport of UTLS mercury forms. The reservoir of RGM just above the tropopause plays an important role in nighttime subsidence peaks of RGM in the lower troposphere [26] and in Arctic mercury depletion events (AMDEs) [27].

1.6 Mercury Biogeochemical Cycling

Once deposited to the earth's surface, mercury may undergo a complex series of reactions that may result in one or more steps in its biogeochemical cycling: being re-evaded to the atmosphere, bound to organic compounds in the terrestrial understory; dissolved in seawater and removed by binding to marine "snow" [28].

One important study of mercury dynamics in an aquatic watershed was the Mercury Experiment to Assess Atmospheric Loading in Canada and the United States (METAALICUS) experiment [29]. During the METAALICUS experiment, solutions of mercuric chloride, each "tagged" with elevated concentrations of a different naturally occurring stable isotope of mercury, were deposited in segments of a test watershed in Ontario, Canada. This isotope spiking allowed tracing of the rate and partitioning of mercury introduced into each watershed compartment to be traced over both time and space. The isotope spikes were introduced into the

upland and wetland compartments as simulated precipitation: using fixed-wing aircraft, solutions of isotope-spiked $HgNO_3$ were distributed over each compartment just prior to or during periods of rainfall in the area. The wetland and upland spikes were added yearly for 3 years. The waterbody spike was applied by a small boat cruising a crisscross pattern on the lake itself; the water surface applications occurred every 2 weeks during the open-water seasons.

METAALICUS results from the first 3 years of the study showed that mercury movement from the application compartments (surfaces of wetlands, uplands, and waterbody) to sequestration in soils and sediments, respectively, was still underway at the end of the application period. Upland spike mercury was, by that time, preferentially found (areal mass distribution) in the underlying soil, but still progressing from the surface vegetation exposed to the original spike application. Wetland spike mercury exhibited the opposite distribution: that addition was still predominantly in the lowlands vegetation than in the underlying peat. Overall, there was a 2–5% increase in peat, soil, and sediment mercury concentrations from the 3 years' additions.

Lake water column mercury showed an overall 53% increase in concentration due to the introduction of the lake spike itself, while the upper layer of lake-bottom sediments revealed a 5% concentration increase. Since Lake 658 communicates with an adjacent shield lake via a narrow weird outflow, a 5% portion of the spike was itself lost through the outflow. The researchers estimated that 25–30% of the wetland and upland spikes, and 45% of the lake spike, were lost to the atmosphere via evasion over the 3-year period.

The METAALICUS findings are significant in several regards. As the only whole-ecosystem mercury study to date, the experiment demonstrates once more the relatively slow response of lake bodies to changes in atmospheric deposition. The authors conclude that lakes receiving all of their new mercury via deposition, such as perched seepage lakes, might respond to step changes in deposition (such as were simulated by the spike additions) over about a decade; that is, a proportional change in water column mercury to the deposition step would require that period of time to be reached. For drainage lakes, a longer adjustment period can be expected.

Additionally, the findings concerning evasion losses are a critical experimental check on assumptions used in mercury modeling. Generally, regional and global models of mercury assume a prompt re-emission of 50% of deposited mercury (see, e.g., [30]). This re-emitted or evaded mercury is the primary contributor to what is generally termed the *grasshopper effect* [31]: successive deposition and re-emission of mercury from lower to higher latitudes (down-gradient transport), leading to a successive and relatively high build-up rate of mercury (and other pollutants) in high temperate and boreal regions. The experiment at Lake 658 reveals that this effect is probably dominated by evasion from oceans and water bodies rather than terrestrial environments, and so is limited by the sum of deposition to and native mercury emissions from those marine and aquatic environments.

2
Mercury and Halogens in Coal

Allan Kolker and Jeffrey C. Quick

2.1
Introduction

2.1.1
Mode of Occurrence of Mercury (Hg) in Coal

In bituminous coals, the iron disulfide, pyrite and its FeS_2 polymorph, marcasite, typically host the greatest fraction of Hg present [1–8], with lesser fractions of Hg associated with organic matter and with non-FeS_2 mineral hosts. Evidence for the occurrence of Hg and other trace metals in Fe disulfides in coal is reviewed by Kolker [9], including crystal chemistry and controls on element substitution in Fe disulfides and available data on Hg concentrations from direct determinations by microanalysis. In cases where individual Fe disulfide grains in coal have been analyzed, Hg contents are in the tens to hundreds of times those in the whole coal. But assuming that pyrite-rich coals are necessarily Hg-rich coals is an oversimplification. A good example to the contrary is the U.S. bituminous Illinois #6 coal. This commercially important coal has relatively high contents of total and pyritic sulfur widely attributed to marine influence, but low to moderate Hg (and As) contents [10–12], as the extent of substitution in Illinois #6 pyrite by impurities is relatively small [7, 12–14].

In low-rank coals, including lignite and subbituminous coals, Hg and S contents are generally lower overall than in bituminous coals, and the proportion of Hg occurring in association with organic material is greater [2, 15]. From the standpoint of Hg capture, compared to bituminous coals, the lower overall Hg content of low-rank coals is offset by the tendency of these coals to also have lower halogen contents, and, because of their lower calorific value, the requirement that greater amounts of low-rank coal are needed to achieve an equivalent energy output.

As shown elsewhere in this volume, the form of Hg in feed coal does not impact Hg speciation at boiler temperatures. In the furnace, Hg is present in the elemental form but it can combine to form compounds as the flue gas cools. Knowledge of the mode of occurrence of Hg in coal has important implications for the extent to

Mercury Control: for Coal-Derived Gas Streams, First Edition.

which pre-combustion Hg control might be possible (following section), whereas the halogen species present influence post-combustion Hg capture.

2.1.2 Effectiveness of Pre-Combustion Mercury Removal

Three approaches, coal preparation, selective mining, and upgrading low-rank coals by drying, offer the potential to reduce Hg input to the boiler. A detailed review of each is beyond the scope this chapter, but some of the major factors influencing the effectiveness of pre-combustion removal are highlighted in this section.

For coal preparation, the major factors influencing its effectiveness in Hg reduction are the mode of occurrence of Hg in coal, its particle size, and the approach taken in preparation. For bituminous coals having pyrite as the primary mineralogic host of Hg, preparation by density separation, such as in a heavy media cyclone, is more likely to be effective than methods that depend on differences in surface characteristics, such as froth flotation, because coal and pyrite have similar surface characteristics [16, 17]. Grain size is especially important in multistage preparation circuits because gravity concentration is the dominant cleaning method for coarse and intermediate size fractions of coal, whereas flotation is the dominant method for cleaning fine size fractions [18]. Where pyrite occurs primarily as framboids, their fine grain size (typically 10 μm) and presence of interstitial voids filled with non-pyrite material may make them especially difficult to remove by coal preparation. Low-rank coals having a greater fraction of organically bound Hg than bituminous coals are also less likely to be responsive to coal preparation for Hg reduction. Recent studies by Wang *et al.* [19, 20] show significant degrees of removal of Hg and/or associated elements in large-scale preparation plants processing Chinese coals. Huggins *et al.* [14] determined element concentrations, and modes of occurrence by spectroscopic methods, for a range of major and trace elements in fractions of an Illinois #6 coal produced by physical separation at a preparation plant. For Hg, results show a 25% reduction on a weight concentration basis for the cleaned product relative to the feed coal, with corresponding enrichment in the reject fractions. These investigations follow from previous work showing the effectiveness of coal preparation in reducing air toxics as a co-benefit to reducing ash and increased calorific value (e.g., [21–24]).

Effective reduction of Hg by selective mining requires characterization and analysis of the coal beds being mined. This approach has been used to better define the spatial distribution of Hg variation in bituminous coals of the Illinois Basin in Indiana, USA [25, 26], in the Appalachian Basin of eastern Kentucky, USA [27, 28], and in subbituminous coals of western Canada [29]. Where Hg is concentrated by geologic processes, such as along fault-controlled zones of mineralization, or controlled stratigraphically, such as by incursion of marine waters, detailed characterization can be effective in delineating Hg-rich zones to avoid in mining operations.

Various thermal pretreatment processes have been proposed or are in place for low-rank coals, for the purpose of enhancing power plant performance [30–32]. Thermal pretreatment can have the co-benefit of Hg reduction, as reported by Merriam [33] for a Powder River Basin subbituminous coal and subsequently, by Guffey and Bland [34], for a Powder River Basin coal, and a North Dakota lignite. These studies show Hg removals in the 70–80% range with heating of both coals to temperatures ranging from 150 to 290 °C. Mercury driven from these coals primarily enters the gas stream of the process.

2.1.3 Methods for Mercury Determination

Sub-parts per million levels of Hg in coal require methods with adequate sensitivity, but generally do not require the most sensitive methods used for low-level determinations of Hg in the environment ([35], this volume). The two methods most widely employed for analysis of Hg in coal are cold vapor atomic absorption spectrometry (CVAA; [36, 37]), and thermal decomposition, amalgamation, and atomic absorption spectrophotometry, otherwise known as direct mercury analysis (DMA; [38]). Mercury concentrations normally encountered in coal are well within the working range of either method. DMA has gained acceptance in recent years because sample digestion, required in CVAA analysis, is not necessary. In U.S. Geological Survey (USGS) databases discussed in this chapter, Hg data obtained before about 2005, including coal quality (COALQUAL) [11] were obtained by CVAA. Results for international coals in the World Coal Quality Inventory (WoCQI, [39]) include data obtained by both methods, depending on the date of sample acquisition.

Other methods that have been used to determine Hg in coal include instrumental neutron activation analysis (INAA; [10, 40]) and cold vapor atomic fluorescence spectrometry (CVAFS; [41]). INAA can be used directly on small samples, but requires sample irradiation by neutrons at a reactor facility and subsequent counting of gamma rays emitted at the energies of radionuclides present [40]. CVAFS offers better detection limits than either CVAA or DMA, with the potential to obtain higher precision total Hg results than by the other two methods. However, CVAFS has not been widely employed because low-level determinations in the parts per billion range are generally not required for coal. Furthermore, because total mercury contents are controlled to a large degree by Fe disulfide minerals, sample heterogeneity, especially in pyrite content, can result in total Hg variations for different sample splits that are larger than analytical uncertainties by CVAFS. Other methods for Hg analysis of coal have been used in specific applications. For example, multicollector inductively coupled plasma mass spectrometry (ICP-MS) methods with cold vapor Hg generation have been used in recent studies to determine variations in the natural Hg isotopic composition of coal [42, 12]. Synchrotron-based determinations of element speciation by X-ray absorption fine structure (XAFS), which have been very useful for As in coal, have limited applicability for Hg as only the most unusually Hg-rich coals

have sufficient Hg to apply this method (F.E. Huggins, personal communication, 2012) [43].

2.2 Mercury in U.S. Coals

2.2.1 U.S. Coal Databases

Three large databases, described here, and several smaller ones, provide detailed information on the Hg contents of U.S. coals. These are (i) the 1999 U.S. Environmental Protection Agency (EPA) Information Collection Request (ICR) database [44], (ii) the 2010 EPA Utility MACT ICR (MACT, maximum achievable control technology) [45, 46], and (iii) an extensive USGS database known as COALQUAL [11]. Each database provides coverage for a wide range of U.S. commercial coals, but with somewhat different emphases. The two EPA databases emphasize Hg contents of coals delivered to U.S. utility power stations, whereas the COALQUAL database reflects the composition of coal in the ground. As noted by Quick *et al.* [47], in a comparison of the COALQUAL and 1999 ICR data, sample frequency in these databases is not production weighted and therefore, mean values for each database are not accurate indicators of the Hg content of either in-ground or delivered U.S. coal. The databases nonetheless provide useful comparisons with international coal sample databases in which large numbers of samples are compiled and averaged.

2.2.1.1 USGS COALQUAL Database

The USGS COALQUAL database consists almost entirely of results for coal samples collected or calculated to represent the entire thickness of a coal bed in the ground [48, 11]. The COALQUAL data include analytical results for 7432 coal samples collected from 399 counties in 33 U.S. states. Up to 136 data fields listing the sample type, location, and assay results are included for each sample record. Nearly all records have complete proximate and ultimate assays as well as major, minor, and trace-element values. Excluding weathered coal and samples from non-producing counties, COALQUAL contains records for 4566 samples originating from 170 of the 198 counties that produced coal during 2009 (see comparison of databases). Most of the samples were collected as whole-bed or bench samples from working mines. These samples give an arithmetic mean of 0.17 ppm Hg ([48]; Table 2.1), almost twice the mean Hg content in the 1999 EPA ICR for coals delivered to utilities (following section). The difference in mean Hg contents between the USGS and EPA databases is a consequence of (i) COALQUAL data include the portion of Hg that is removed by coal preparation and (ii) compared to current U.S. coal production, in which the Power River Basin is the largest single producer, COALQUAL is weighted heavily toward eastern U.S. bituminous coals, with nearly 60% of its samples from the Appalachian Basin.

Bold values — Averages of multiple analyses

COALQUAL: Compiled data exclude weathered coal as well as samples from counties that did not produce coal during 2009. Non-detects are reported in COALQUAL as 0.7 times a detection limit, but the actual detection limit and affected records are not identified. Instead, the percent of affected records for each element (called *qualified* data within COALQUAL) is noted in text that accompanies the data. We used this percent value to identify the apparent detection limit from the corresponding percentile distributions.

1999 ICR: Compiled data exclude non-coal fuels but include waste coal. We estimated the apparent detection limit as the median value of all values reported with a < symbol.

2010 ICR: Compiled data exclude duplicate records and non-coal fuels, but include waste coal. Values annotated with a < symbol were multiplied by 0.5 and included in the compilation. We estimated the apparent detection limit as the median value of results reported with a < symbol. The 2010 ICR part 2 data collection did not identify the Cl and F values that were below detection limits.

Whereas the EPA ICR databases are more representative of current U.S. steam coal production, COALQUAL is nonetheless useful as a reference in comparing U.S. and international coal samples, especially for the in-ground state.

2.2.1.2 1999 EPA ICR

The 1999 ICR coal quality data [44] Originated from an ICR issued by the EPA to inform its Section 112 rulemaking to regulate Hg emissions from electric utility steam generating units. The EPA required units of 25 MW or more to report coal origin, as well as dry-basis tonnages, ash, S, and heating value for every solid fuel shipment received during 1999, and to periodically report fuel Hg and Cl content. This systematic data collection effort produced analyses for 152 476 samples, which are available in four quarterly EXCEL files on an EPA website [44]. Excluding non-coal fuels and records without Hg or Cl values, the 1999 ICR includes results for 37 916 coal samples. Limitations of these data include erroneously low Hg values for most Gulf Coast coal, coal shipments of unknown origin (14% of records), inconsistent reporting bases (8%), and duplicate or nominal data (4%; [49]). Nonetheless, the 1999 ICR data were systematically collected and include coal from most coal-producing counties. Estimates based on the 1999 ICR coal analyses and corresponding emissions testing showed that coal burned in U.S. utility boilers during 1999 contained 75 ton of Hg, of which 48 ton (64%) was emitted to the atmosphere [50].

2.2.1.3 2010 EPA ICR

The 2010 ICR coal quality data originate from an ICR issued by the EPA in 2009 to inform its Mercury and Air Toxics Standards (MATS) rulemaking effort. The data were made available in two ACCESS databases, designated Part II [45] and Part III [46]. Limitations of these data include inconsistent reporting units for trace and minor elements and numerous duplicate records.

The Part II data include analyses reported by U.S. electric utilities for more than 14 000 coal samples. Most of the samples were collected from coal shipments delivered to power plants during 2009 and the corresponding data records include dry-basis ash, S, Hg, and heating values. About 25% of the records also include coal Cl content, and 10% include trace-metal content. Comparison of the Part II data with 2009 EIA-923 data [51] showed that about one-third of the ash, S, and heating values are actually on a moist basis, rather than the dry basis indicated in the Part II database [52]. State origins are listed for most samples and county origins are listed for about half of the samples.

The Part III data include analyses for over 1600 coal samples reported by electric utilities that were selected for mandatory emission testing to inform the MATS rulemaking. These were feedstock samples intended to represent the coal that was burned during the emission testing. Sample collection methods were not noted, but probably included automated or manual sampling from feed belts, as well as grab samples from stockpiles. Most of the data records include analytical results for Hg, Cl, F, and trace metals, and many also include complete proximate and ultimate analyses (moisture, ash, volatile matter, fixed carbon, heating value, C,

H, N, O, and S). The Part III data include numerous coal blends with multiple or uncertain origins. Nonetheless, state origins are listed for about half of the samples and county origins are listed for about a third.

In December 2011, results from the 2010 ICR were used in developing a final rule for MATS that limits emissions of Hg, other non-Hg metal air toxics, including As, Ni, Cr, and Se, as well as acid gasses (HCl, HF; [53]). The health-based rationale for MATS, the events leading to its approval, and the process of its implementation are covered in greater detail by Hutson [54], this volume.

2.2.2 Comparison of U.S. Coal Databases

Table 2.1 compares the halogen and trace-metal content of coal samples in the COALQUAL, 1999 ICR, and 2010 ICR data. Note that the Hg content of coal shipped to utilities (ICR data sets) is lower than the Hg content of the in-ground coal resource (COALQUAL data). This difference is a result of impurities removed from commercial coal during coal washing and selective mining of higher quality coal [47], as well as the greater proportion of Appalachian Basin coals in COALQUAL [11]. Similarly, Table 2.1 shows that delivered commercial coals contain less Sb, As, Be, Pb, and Se than indicated for in-ground coal by COALQUAL.

The lower apparent detection limit for Cl in the 2010 ICR Part III data compared to the 1999 ICR is noteworthy. Because Cl promotes Hg capture, the lower apparent detection limit for Cl should improve prediction of Hg capture for units burning low-Cl coal. Also notable is the relatively large number of Hg analyses in the 2010 Part II data (13 130 records) compared to other trace metals (~1000 records). The abundance of available Hg analyses for coal shipments is likely due to mandatory reporting of coal Hg content on the U.S. Energy Information Administration Form 923 [51]. Although the Hg content of U.S. coal shipments to electric utilities has been reported to the EIA since 2008, these data have not yet been published.

Publication of Hg assays collected with the EIA-923 data should eventually provide an accurate estimate of the Hg content of coal burned at U.S. electric utilities. In the meantime, the Hg content of coal burned at U.S. power plants can be reasonably estimated. This is done by assigning a Hg content to each coal shipment in the EIA-923 data according to the shipment origin using county-average Hg contents from the 1999 ICR [49]. The same estimation can be applied to Cl in coal. The resulting estimates of the Hg and Cl contents of coal shipped to electric utilities during 2009 are compared in Figure 2.1 with Hg contents of samples listed in the COALQUAL, 1999 ICR, and 2010 ICR databases. Heating values, ash yields, and sulfur contents of these databases are also compared. Note the lower ash, S, Cl, and Hg values for the 2009 EIA-923 data, which are weighted by delivered tons, compared to the other data sets. Comparison of the ash and S distributions helps to explain this difference. Figure 2.1 shows that the 2010 ICR coal samples have more S and more ash than coal delivered to U.S. power plants during 2009. This

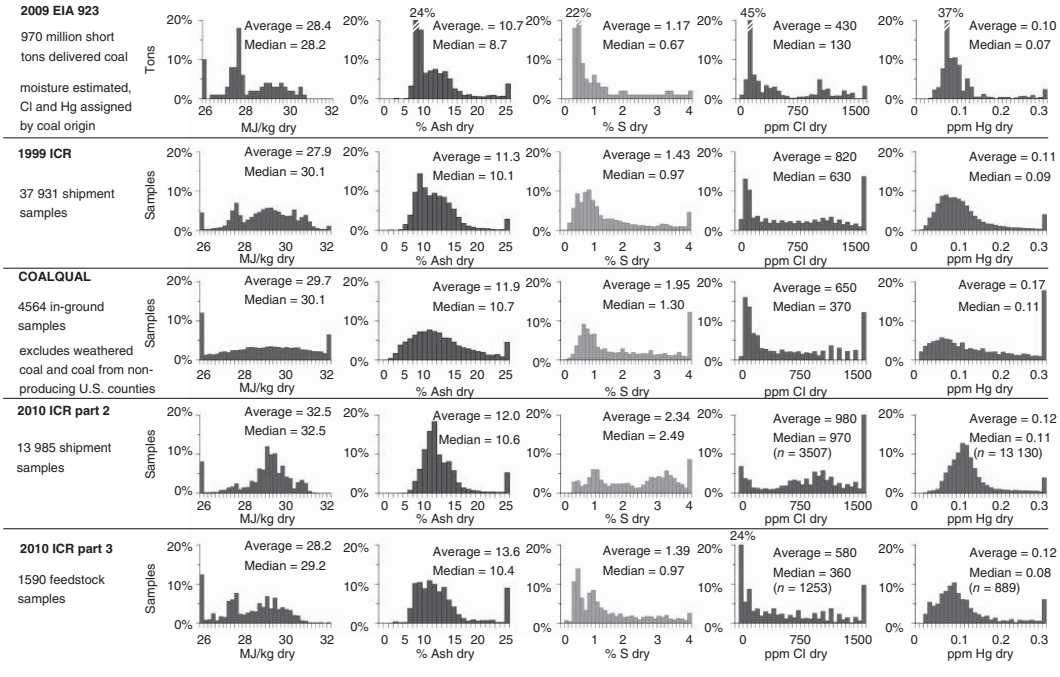

Figure 2.1 Comparison of megajoules per kilogram, ash, S, Cl, Hg distributions for shipped coal tons (EIA 923, 2009) with sample frequency distributions for in-ground (COALQUAL), shipped (1999 ICR; 2010 ICR part 2), and feedstock (2010 ICR part 3) samples. Notably, sample frequency distributions indicate higher ash, S, Cl, and Hg values than the shipped coal tons distributions shown at the top of the figure. Heat and ash values for the 2009 EIA 923 data [51] were adjusted to a dry basis using estimated moisture values, whereas Cl and Hg values were assigned to coal shipment tons by county origin based on compiled 1999 ICR data [49]. The data sets are described in the text. (Modified from Reference [47] Copyright © 2003, Springer.)

is consistent with the higher Hg content for the 2010 ICR coals, given that Hg is associated with pyritic S and is abundant in high-ash waste coal. More importantly, this comparison suggests that like COALQUAL, the 2010 ICR data are not representative of commercial U.S. coal. Consequently, the non-Hg trace-metal content of commercial U.S. coal will likely differ from the values listed in Table 2.1 and remains uncertain. Nonetheless, the 2010 ICR data are unique in that they are publicly available and include trace-element values for a wide range of commercial U.S. coals. Consequently, these data should assist efforts to understand the abundance, behavior, and fate of Hg and other trace metals in coal-derived gas streams.

2.3 Mercury in International Coals

2.3.1 Review of Mercury in Coal in the Largest Coal Producers

China, the United States, and India, listed in order of hard coal production rank, accounted for ~75% of 2010 world coal production [55]. If Australia, South Africa, the Russian Federation, and Indonesia are added, these countries accounted for more than 90% of 2010 hard coal production (Table 2.2). Of the major coal-producing countries, detailed nationwide surveys of Hg distribution are available only for the United States and China, as described below. For countries lacking comprehensive surveys of Hg distribution, brief summaries of available information are given below, together with the possible implications of these results for Hg output from coal combustion. Where applicable, results from the USGS WoCQI [39] are compared to other published results. WoCQI is a publicly available database that contains analyses of 1580 samples from 57 countries, including Hg, Cl, and other relevant coal quality determinations on a dry, whole-coal basis. For China, WoCQI contains 328 samples from 25 provinces

and autonomous regions, representing an estimated 80% of production at the time of sampling. For major coal producers India, Australia, South Africa, the Russian Federation, and Indonesia, WoCQI sampling is much less complete than for China. For India, Australia, and the Russian Federation, USGS sampling is limited to specific study areas.

2.3.1.1 China

China is both the world's largest producer and user of coal. Recent compilations confirm that Hg concentrations of coals used commercially in China are similar to those used elsewhere [56–59], with nationwide means from studies over the last 10+ years ranging from 0.10 to 0.22 ppm [59]. The most recent compilations show less variability and an overall value for Chinese commercial coal between 0.15 and 0.19 ppm is likely (Table 2.3). For example, Dai *et al.* [58] report a mean of 0.16 ppm Hg for 1666 samples, which is identical to that determined by the USGS (0.16 ppm) for 305 WoCQI samples, excluding 23 samples of prepared coal [60]. Streets *et al.* [56] used a merged dataset of USGS results and available data from the literature to determine a mean for China of 0.18–0.19 ppm. Ren *et al.* [61], as reported by Dai *et al.* [58] give a mean of 0.19 ppm for 1413 samples. A subset of 619 of the Ren *et al.* samples reported by United Nations Environment Programme (UNEP) [62], give a mean of 0.33 ppm where a large proportion (21%) of samples is from Guizhou Province. Zheng *et al.* [57] determined an arithmetic mean of 0.19 ppm for 1699 samples, but with 16% (276) of these from Guizhou Province, compared to only 5% (16 of 305) in the USGS dataset (see next section). Taken together,

the result of various compilations of Hg in Chinese coal are comparable to the in-ground mean for U.S. coals (0.17 ppm; [11]) both in concentration value and numbers of samples, but unlike COALQUAL, are probably more representative of current production.

It is apparent in coal Hg compilations for China that some provinces, especially Guizhou, and to a lesser extent Shanxi, and Inner Mongolia, have greater variability in Hg contents than others [56, 59, 62, 67]. Furthermore, province-wide means for Guizhou are strongly influenced by the proportion of Hg-enriched samples included in the data. In an analysis of USGS data for Chinese coals, Wu *et al.* [67] showed that the distribution of Hg contents in Guizhou Province coals contains a tail of values in excess of 1 ppm Hg, giving an overall mean of 0.51 ppm for 46 samples. A similar trend in Hg distribution was shown for coals in Shanxi Province. The highest Hg values in Guizhou Province are associated with mineralized coals produced in small-scale mines and used primarily for domestic purposes [68, 69]. While various studies [69, 70–73] have drawn attention to health risks associated with the latter, inclusion of mineralized coal samples from small-scale workings in database compilations to assess Hg input to the utility sector is inappropriate and has resulted in over-estimates in the past. If mineralized coals are excluded from those produced on a commercial scale, the province-wide mean for Guizhou is comparable to current estimates of the nationwide mean (Figure 2.2). Consideration of Hg in Chinese coals on a production-weighted basis could help refine the estimate for China and keep pace with rapidly evolving utilization patterns.

2.3.1.2 India

India is the world's third largest coal producer after China and the United States, and coal accounted for 69% of India's electric power generating capacity in 2010 [55, 74]. Coals in the Indian subcontinent originated in the Gondwana supercontinent encompassing all or part of peninsular India, Australia, southern Africa, South America, and Antarctica. These coals are dominantly of Permian age, in contrast to Carboniferous coals of Europe and North America. Compared to Carboniferous coals in the northern hemisphere, Gondwana coals tend to be relatively high in ash and low in sulfur, with a greater proportion as organic sulfur, except where coal beds are overlain by marine sediments [75].

Unlike China and the United States, detailed studies of elemental concentrations, especially Hg, in Indian coals are lacking. For example, a recent report by Mukherjee *et al.* [76] on Hg emissions from industrial sources assumed a mean value of 0.376 ppm Hg for Indian coal, based on the average of coals sampled at eight (of about 80) operating power stations in India, whose range in Hg contents was from 0.18 to 0.61 ppm. In a study of global Hg flow from coal utilization, Mukherjee *et al.* [77] give a range from 0.11 to 0.80 ppm for Hg in coal from India, but note a much smaller variation (0.11–0.14 ppm) in results provided by the National Thermal Power Corporation of India. Rajagopalan [78] gives a range for Hg in Indian coal from 0.26 to 0.49 ppm that was reported by Mukherjee and Zevenhoven [79]. The number of samples on which these ranges are based, and the analytical methods employed, are not clearly stated.

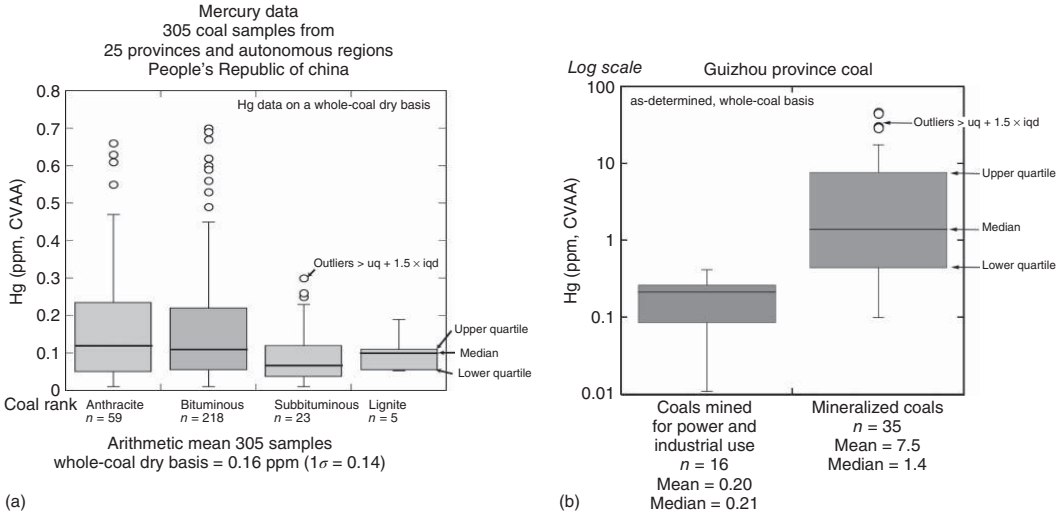

Figure 2.2 (a) Comparison of mercury content of Chinese coals by rank. (Results from Belkin *et al*. [60].) (b) Comparison of Guizhou Province, China, coals produced for power generation and industrial uses with mineralized coals. (Results from Ref. [60, 80].)

USGS sampling in India (102 samples; [39]) is limited to the Sohagpur Basin, an important Permian coal basin, together with reconnaissance sampling of younger, Tertiary coals having more limited commercial use. Together, these samples give a mean Hg value of 0.09 ppm. Additional sampling is required to determine an overall Hg content of Indian coals similar to values obtained by more comprehensive sampling in China and the United States. Coal washing is widely employed in India to reduce high-ash contents, a characteristic of some Gondwana coals. Additional characterization is needed to determine the effect of coal washing on Hg contents and to expand the information available on Hg in Indian coals.

2.3.1.3 **Australia**

Australia is the largest hard coal exporter (298 Mton in 2010) and the fourth largest producer [55]. Australia relied on coal for 77% of its 2010 power generation needs [55]. Mercury contents in Australian coals are low by international standards. In estimating Australia's atmospheric Hg emissions, Nelson [81] assumed a mean value of 0.05 ppm Hg for Australian hard coal, based on work by Dale [82] and Riley *et al.* [83], giving mean values of 0.045 and 0.040 ppm, respectively, on an as-received basis, for a suite of 100 Australian hard coals. A mean value of 0.08 ppm, on a dry basis, was assumed for Australian brown coals, as noted by Brockway *et al.* [84]. Most Australian hard coals are Permian in age, whereas brown coals are Tertiary. Mercury contents in Australian export coals are especially low, ranging from 0.01 to 0.08 ppm, with a mean of 0.02 ppm according to CSIRO [85]. Only 10 samples are included in WoCQI for Australia. Four export bituminous coals from the Bowen Basin, Queensland, have Hg contents ranging from 0.011 to 0.026 ppm on a dry, whole-coal basis [39]. One low-rank coal has a much higher Hg concentration (0.16 ppm), consistent with higher Hg values for low-rank coals suggested by Brockway *et al.* [84]. Of four bituminous coals investigated in detail in an international round robin study of methods for determining element affinities in coal [86], the Wyee (Australia) coal had the lowest pyritic S content (0.05 wt%) and the lowest Hg content (0.01 ppm; [87, 4]). As part of a more recent study of element modes of occurrence, Riley *et al.* [88] determined Hg contents by cold vapor atomic fluorescence for six Permian and Triassic Australian coals, including several blended coals. These six samples give a mean of 0.050 ppm Hg and a median of 0.022 ppm, reflecting one sample (GG) of high sulfur coal, formed under marine influence, having a Hg content of 0.16 ppm. Selective leaching studies of these six coals are consistent with pyrite as the predominant mineral association for Hg [88].

2.3.1.4 **South Africa**

South Africa is of particular interest from the standpoint of Hg emissions because it has the highest proportion of its electricity produced by coal combustion (93%; [74]), and is a major user of coal for liquid fuels. South Africa is also the world's fifth largest hard coal producer and a significant (68 Mton) coal exporter [55]. There is considerable range in coal products produced, both by natural variation in quality and by coal beneficiation, with the best quality (lowest ash, highest calorific

values) coals produced for export and higher ash coals retained for domestic use or rejected (C. van Alphen, personal communication, 2011) [89]. This variation likely contributes to a considerable range in Hg content, even for a single coal by a single producer, with export coals expected to be lowest by virtue of removal of mineral matter, including pyrite. A large portion of coal production and generation capacity has traditionally come from central coalfields within the main part of the Permian Karoo Supergroup in Mpumalanga Province, including the Witbank, Highveld, and Ermelo coals. The Witbank and Highveld coals are approaching exhaustion. The largest remaining coal reserves are in the Waterburg coalfield in Limpopo Province to the northwest; together these three coal fields constitute more than 70% of total reserves in South Africa [90].

Wagner and Hlatshwayo [91] determined a series of potentially hazardous trace elements in five Highveld coals, giving a range of 0.04–0.27 ppm Hg and a mean of 0.15 ± 0.05 ppm. These authors recognized that many of the element concentrations determined were either less than or comparable to global values for coal with the exception of Cr, which is noticeably higher. Bergh *et al.* [17] investigated the potential for trace-element reduction by beneficiation of the Witbank no. 4 coal. The no. 4 coal has a higher ash yield than the no. 2 coal, historically the most important producer in the Witbank coalfield, but whose reserves are declining. Bergh *et al.* [17] give a mean of 0.3 ppm Hg for an unspecified number of run-of-mine samples of the Witbank no. 4 coal. Extents of trace-element reduction by dense media and by froth flotation were investigated, with dense media beneficiation showing a greater reduction of pyrite-associated elements such as Hg.

Reconnaissance USGS sampling of South African coals (40 WoCQI samples, major coalfields represented; [39]), gives a mean of 0.20 ppm Hg for 11 samples of Highveld coal, comparable to findings of Wagner and Hlatshwayo [91]. But for 10 samples of Witbank coal, the mean is only 0.045 ppm, excluding one Witbank sample with 0.83 ppm Hg. The ash yield of the 10 USGS Witbank samples ranges from only 7.2% to 16.4%, suggesting these are export coals, whereas the outlier with 0.83 ppm Hg has an ash yield of 32.5% (Figure 2.3). USGS results confirm that Highveld coals are especially Cr-enriched, in agreement with Wagner and Hlatshwayo [91] and consistent with possible exposure of chromite-($Fe^{2+}Cr_2O_4$) bearing source rocks during Karoo sedimentation.

Wagner and Tlotleng [92] prepared and analyzed density fractionated mineral concentrates from four Waterburg coal samples. Results show a strong association of As with the most pyritic fractions for all four samples and a more variable mode of occurrence for Hg, which includes a pyritic association for three samples from the Grootegeluk formation. These results suggest that Waterburg coals may be amenable to reduction of As and Hg by coal preparation.

2.3.1.5 **Russian Federation**

Russia has the world's second largest coal reserves, after the United States, and currently (2010) is the sixth largest hard coal producer (248 Mton) immediately following South Africa [55]. Thermal power stations account for nearly 70% of the power generation sector in the Russian Federation, but the majority of these

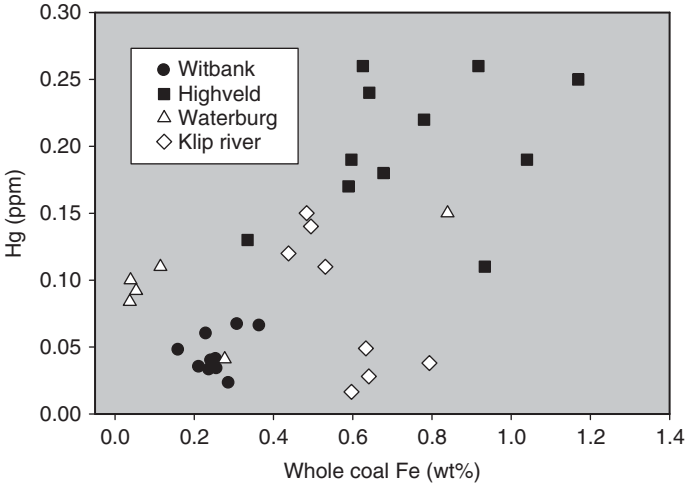

Figure 2.3 Plot showing variation in Hg content as a function of Fe content (a proxy for pyrite) for reconnaissance USGS sampling of South African coals from four coalfields. Both parameters are expressed on a dry, whole-coal basis. One Witbank sample with 1.24% Fe and 0.83 ppm Hg is omitted as well as four other WoCQI samples – two with unidentified locations and two from other coalfields (Hg in these four samples ranges from detection limit to 0.62 ppm). Low-Hg Witbank samples (lower left) are probably export coals (see text).

plants are gas-fired. Coal accounts for nearly 30% of this capacity, comprising about 20% of overall electric power generation [93, 94]. Although coal is produced in several parts of the Russian Federation and adjacent areas of Ukraine and Kazakhstan, three coal basins, the Ekibastuzsk Basin in northeastern Kazakhstan bordering Siberia, the Kuznetsk Basin in southwestern Siberia, and the Kansk-Achinsk Basin, also in Siberia, accounted for about 60% of the coal used for power generation in 2007 [95, 94]. Of these, the Kuznetsk Basin is the primary source of coal produced for export, whereas in the Kansk-Achinsk Basin, brown coals are produced, with use outside of Siberia limited to small amounts that are shipped to European Russia [94].

Mercury contents of Russian coals show some variability within and between major coal basins, but available data for areas with the greatest production are well within international standards. Mercury contents of Kuznetsk coals tend to be on the low side, with an average of 0.06 ppm given by ACAP [96] for coal produced in 40 mines, similar to that reported by Meij and te Winkel [97] about 0.05 ppm for Kuznetsk coal exported to the Netherlands. Higher Hg contents have been reported for some basins. The Donets Basin (Donbas region) of eastern Ukraine and adjacent parts of the Russian Federation has historically been an important coal-producing region, especially for metallurgical coals. These coals are known to have relatively high Hg concentrations with Hg enrichment that is controlled geologically by faulting and other structures. Kolker *et al.* [98] report a mean content of 0.68 ppm Hg for 29 samples of commercial coal collected from active mines in

the vicinity of Donetsk, Ukraine, but this is reduced to 0.43 ppm for 17 samples if 11 samples from the mining district closest to the geologic Hg source, and one outlier with 3.5 ppm Hg, are excluded. On a nationwide basis, the proportion of Hg-enriched coals used for power generation in the Russian Federation is likely to be small, as commercial coal production is dominated by three main sources, each having low to moderate Hg contents.

2.3.1.6 **Indonesia**

Indonesia is the world's largest producer of brown coal (163 Mton), the second largest hard coal exporter (162 Mton) after Australia, and the seventh largest hard coal producer (173 Mton; [55]). Indonesia's production is likely to increase as new coal fields are developed. Coal in Indonesia is present in a series of shallow, geologically young basins that are distributed across the archipelago. As a result, 85% of coal produced in Indonesia is lignite or subbituminous in rank. In a study of trace elements in coal imported to the Netherlands, Indonesian coal is at the lower end of the range of Hg concentrations in coal from 14 countries, with a mean value <0.10 ppm [97]. In an effort to better define the environment of deposition of coals in Kutai Basin, East Kalimantan, Widodo *et al.* [99] examined the distribution of pyrite in these coals and found excellent correlations between the occurrence of pyrite and total iron content, which likely extends to Hg.

Detailed geochemistry for eight samples of in-ground Indonesian coal is given by Belkin and Tewalt [100]. These are the only Indonesian samples in the USGS WoCQI database, but give a range in rank (lignite B to semi-anthracite) and geographic distribution. Most of these samples are low in S, as is typical of Indonesian coals. These eight samples give a mean Hg content of 0.10 ppm with a range of 0.02–0.19 ppm, and Cl contents ranging from <150–300 ppm, with a mean of 260 ppm.

2.4
Halogens in Coal

2.4.1
Introduction

Information on the controls and natural variation of halogens in coal is provided here as background to their impact on mercury capture in combustion systems. In general, halogen contents of coals used for power generation increase with rank, which, in the absence of localized thermal sources, corresponds to depth of burial or paleo-depth in coal-forming sedimentary basins. This is because the salinity of formation waters and the concentration of dissolved constituents such as halogens increase with depth in sedimentary basins, and halogen concentrations are influenced by exchange between formation waters and coal.

2.4.1.1 Chlorine (Cl)

Elemental Hg is a semi-noble metal, exceedingly water insoluble, and difficult to capture by adsorption on unpromoted activated carbons, or by absorption in wet scrubbers. Compounds of mercury, such as mercuric chloride, have some water solubility, and are more amenable to capture by sorbents or scrubbers. Halogens such as Cl can also facilitate the oxidation of mercury by selective catalytic reduction (SCR) catalysts located upstream of wet scrubbers. At flue gas temperatures, the Cl content of coal strongly influences Hg speciation, converting Hg^0 present at boiler temperatures to oxidized forms that can react with Cl species in the flue gas to form Hg – Cl complexes or compounds. These Hg – Cl complexes or compounds can be captured by air pollution control devices or taken up by halogen-doped sorbents ("[100], [101,102], this volume" or equivalent.). The proportion of oxidized Hg formed in combustion systems increases with increasing Cl, for coals having Cl contents between about 100 and 1000 ppm Cl [7, 104].

The range in coal Cl values shown to be effective in enhancing Hg capture is rank-dependent and corresponds to values typically found in bituminous coals [105, 106]. Yudovich and Ketris [105] compiled Cl data for coals throughout the world and their ashes. This compilation gives a median Cl concentration in hard coals (340 ± 40 ppm) that is roughly three times that for lignites (brown coals; 120 ± 20 ppm). The world value for hard coal and the mean for Chinese coal (255 ppm; [58]) are comparable. Both values are lower than the U.S. mean (614 ppm; [11, 107]) that is elevated by the predominance of eastern U.S. bituminous coals in COALQUAL.

U.S. coals show rank dependence of Cl concentration (Figure 2.4a) and considerable variation within and between U.S. coal basins [106]. In the Appalachian Basin, Bragg *et al.* [106] have shown that chlorine contents have a pronounced stratigraphic dependence with the highest mean concentrations found in the lowermost coals sampled (Table 2.4). A similar variation in Cl contents with depth has been observed in the Illinois Basin (USA), with concentrations ranging from below detection at outcrop to 0.8 wt% in the deepest part of the basin [108, 109]. Some of the highest Cl values shown in Figure 2.4a for the U.S. Interior Province correspond to deep-basin samples from the Illinois Basin. Variation in Cl contents with depth in the Illinois Basin is attributed to equilibration with groundwater whose salinity increases with depth. For 13 mines in which Cl was determined for both coal and ground water, a correlation coefficient of 0.93 was obtained for these two parameters [108]. Elsewhere, proximity to geologic structures that have acted as pathways for influx of Cl-bearing fluids can result in localized Cl enrichment. This is thought to be the case in the Southwestern reserve district of eastern Kentucky, USA, where the major coal beds present have higher mean Cl contents than their equivalents elsewhere in eastern Kentucky [28]. Whereas Cl is desirable for its capacity to enhance Hg capture, at high concentrations it can be deleterious. Chlorine contents greater than about 0.3 wt% are known to cause significant fouling and corrosion of boilers [109]. Moreover, HCl emissions from Cl in coal are regulated under the new MATS rule.

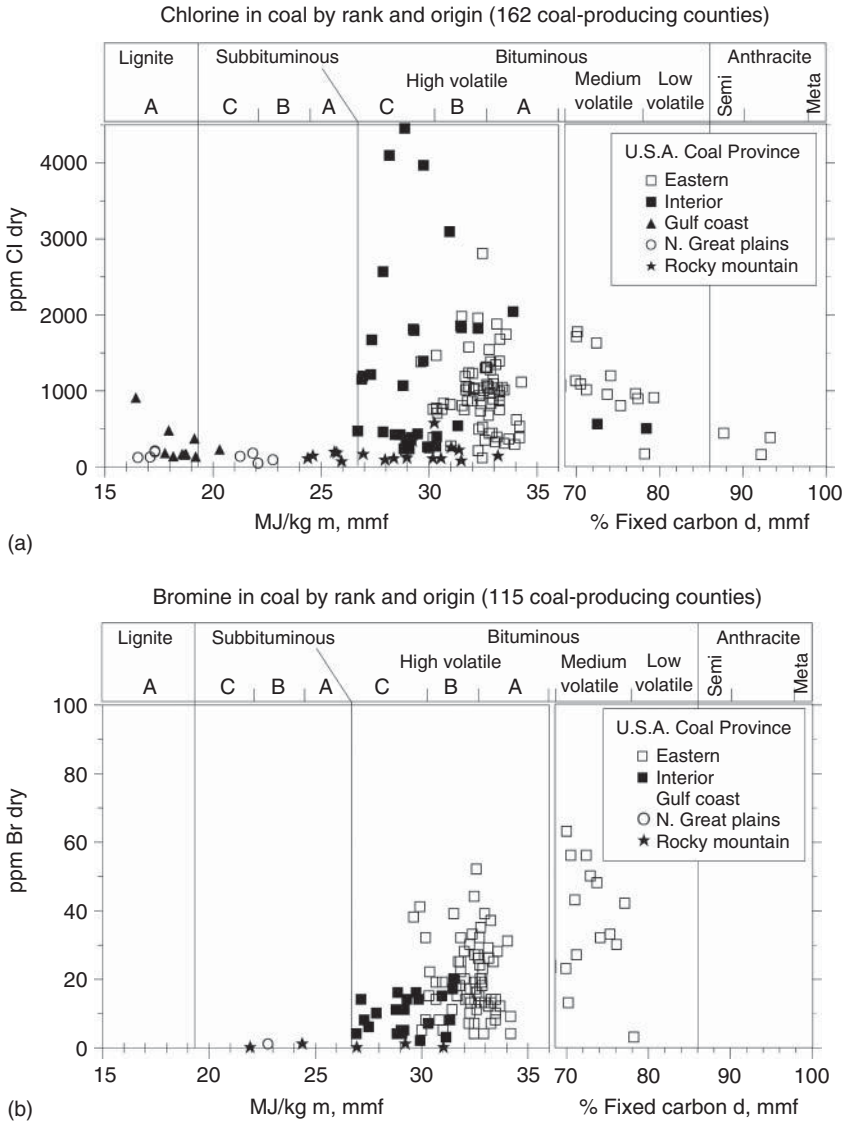

Figure 2.4 (a,b) Plots showing variation of county-average Cl and Br contents of U.S. coal with ASTM [110] coal rank and geographic origin. County-average values were calculated from at least five samples. With a few exceptions, Cl values are from the 1999 ICR, Br values are from COALQUAL, megajoules per kilogram values are mostly from year 2005 EIA-423 coal shipment assays with a few from the 1999 EIA-423 data, and fixed carbon values are mostly from COALQUAL with a few from Keystone. Additional data from the Illinois Geological Survey, which include Br and Cl values for coal from 12 counties in Illinois, were also used. The data sets have been described elsewhere [111]. Compared to Cl, relatively few data are available for Br in lower rank U.S. coal. (Modified from Reference [7] Copyright © 2006, Elsevier.)

Table 2.4 Mean chlorine content of coal by formation in the central Appalachian Basin, Pennsylvania, and West Virginia, USA.

Age	Formation	Number of samples	Mean (ppm)[a)]
Permo-Pennsylvanian	Dunkard Group	44	162
Upper Pennsylvanian	Monongahela	73	477
Upper Pennsylvanian	Conemaugh	41	828
Middle Pennsylvanian	Allegheny	709	1097
Middle Pennsylvanian	Kanawha[b)]	36	1408
Lower Pennsylvanian	New River[b)]	56	1503

Formations are listed in order of increasing age.

a) Detection limit is 100 ppm. In calculating mean, non-detects are assumed to contain 70% of the detection limit.

b) Samples from southern West Virginia; other samples are from Pennsylvania.

Source: Ref. [106].

The mode of occurrence of Cl in coal has drawn considerable attention in part because of boiler corrosion problems caused by coals with excessive Cl contents and in part because multiple forms of Cl have been suggested, which has led to considerable disagreement. Major forms recognized or suggested include inorganic Cl in mineral chlorides or other mineral matter in coal, organically bound Cl, and chloride anions present within moisture in coal [105, 112, 113]. Huggins and Huffman [112] used Cl K-edge XAFS spectroscopy to investigate the mode of occurrence of Cl in bituminous and low-rank coals and compare Cl in raw coals with that in cleaned coals, and before and after aqueous leaching treatments. These authors found that hydrated chloride species provided a much better fit to the Cl K-edge X-ray absorption near edge structure (XANES) spectra obtained for a range of U.S. and U.K. coal samples than either a series of organochlorine compounds or crystalline NaCl. They concluded that in coals with typical Cl contents, Cl is present as chloride anions associated with coal moisture and weakly bound to the surfaces of micropores in coal macerals by organic–ionic complexes [112]. A similar model was advanced for Br (following section).

2.4.1.2 **Bromine (Br)**

Compared to Cl, on a molar equivalent basis, Br is a much more effective oxidizer of Hg in power plant flue gas ([102], this volume). As a result, the native Br content in coals may be even more important than Cl in determining the extent of spontaneous Hg oxidation and self-capture in combustion systems [104, 114–117]. For coals that are low in halogens, including many low-rank coals, this has led to the suggestion that limited addition of Br would effectively enhance Hg oxidation and capture [117]. As a result, a range of Br-based commercial sorbents has been developed, particularly for use with subbituminous coal ([103], this volume).

Like Cl, the absolute concentration of Br in coal is rank-dependent (Figure 2.4b). However, the proportions of Br and Cl are relatively constant. Vosteen *et al.* [117] reviewed the native halogen content of coals in the United States, China, and several other countries, and determined that Br/Cl mass ratios of 0.01–0.04 were

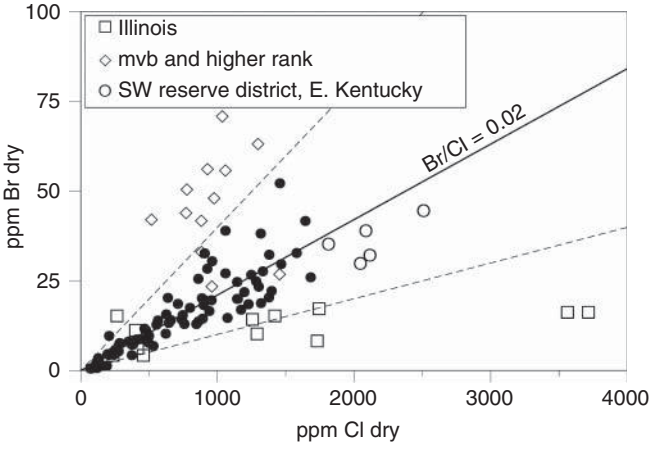

Figure 2.5 Average Cl and Br contents for coal produced in 110 U.S. counties showing that most have Br/Cl mass ratios near 0.02. Points show county-average values calculated from selected COALQUAL records where there were at least five Cl and Br analyses. Dashed lines show Br/Cl ratios of 0.04 (top) and 0.01 (bottom). Data for nonproducing counties are included in the figure but weathered coal and samples collected from outcrop have been ignored. Additional data from the Illinois Geological Survey were also used. The data sets have been described elsewhere [80, 111].

typical, even in coals having low overall halogen contents (i.e., regardless of rank). For U.S. coals, most scatter about a Br/Cl ratio of 0.02 (Figure 2.5). Exceptions include high-rank coals (above high volatile bituminous rank) and coals influenced by saline formation waters, including coal from the Southwestern reserve district in eastern Kentucky, and some Illinois coals (Figure 2.5). Using a Br/Cl ratio of 0.02 as a guide, Br concentrations near 2 ppm might be expected for a subbituminous coal with 100 ppm Cl, and 8 ppm Br for a bituminous coal having 400 ppm Cl. In some cases, for example, in selected coals from Bulgaria and parts of the Ukraine Donbas, exceptionally high Br concentrations are present, with Br contents in excess of those for Cl for some samples ([113, 117]; Figure 2.6). Inclusion of these highly Br-enriched coals in results for 34 world coal deposits [113] gives a mean Br value in excess of 100 ppm that is probably not representative. Excluding seven deposits with Br contents >50 ppm gives a mean Br/Cl ratio of 0.05 for the 27 remaining deposits, which is more in line with typical Br/Cl proportions. In a review of Cl and Br in U.K. coals, Spears [118] found that means for both elements were enriched proportionally in a representative suite of 24 samples.

Bromine/chlorine ratios are potentially of use in distinguishing the processes controlling halogen distribution in coal. In the simplest cases, this ratio is controlled by pore waters present during coal formation or by formation waters presently in equilibrium with coal. At the peat stage, halogens are enriched in peat and its pore water relative to atmospheric deposition [119, 120] and the proportion of Br to Cl is higher than that of modern seawater, which has a consistent Br/Cl ratio of 0.0035 on a weight concentration basis [121]. Typical Br/Cl ratios

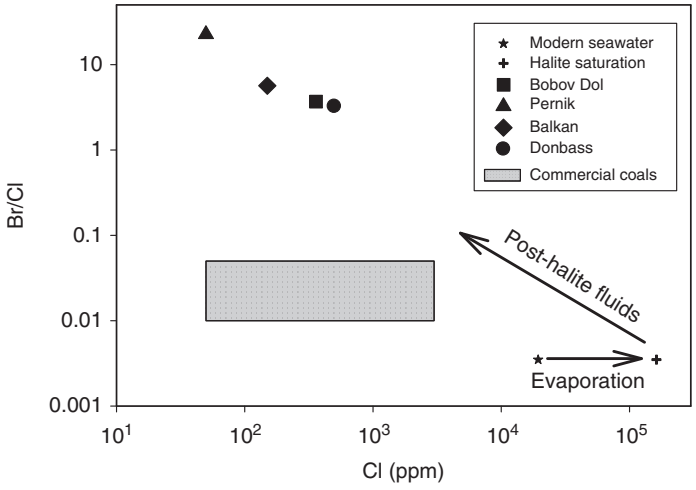

Figure 2.6 Generalized Br–Cl systematics for coals and brines, showing compositions typical of commercial coals (gray swath) and results from Vassilev *et al.* [113] for four coal deposits with extreme Br enrichment including Bobov Dol, Pernik, and Balkan, in Bulgaria, and Donbass in Ukraine. Halite precipitation enriches residual fluids in Br, thereby increasing Br/Cl. Actual trajectory is dependent on conditions present in a particular basin. Range for commercial coals assumes a Br/Cl from 0.01 to 0.05, 50 ppm Cl as a minimum and 3000 ppm as a maximum, based on boiler corrosion problems using more Cl-rich coals.

in coal are approximately 5–10 times that of seawater (Figure 2.6), reflecting either inheritance from the peat stage, exchange with formation waters, or both. As seawater evaporates and salinity increases, Br/Cl remains relatively constant until halite (NaCl) precipitates, which excludes Br. As a result, halite precipitation in saline formation waters enriches the residual fluids in Br, increasing the Br/Cl ratio ([122], expressed as lowering Cl/Br; Figure 2.6). Halite-bearing "salt coals" in a number of countries have unusually high Cl concentrations and atypical Br/Cl ratios [113, 120], which may be inherited in part from the peat stage or a consequence of halite precipitation. Conversely, halite dissolution by less saline formation waters serves to decrease Br/Cl ratios ([122], expressed as raising Cl/Br).

Like Cl, the mode of occurrence of Br in coal has been difficult to ascertain with certainty. In Cl-enriched coals containing discrete mineral chlorides such as halite (NaCl), sylvite (KCl), or other Cl-bearing minerals such as chlorapatite ($Ca(PO_4)_3$(Cl, F, OH), limited inclusion of Br may be expected. But as suggested by Huggins and Huffman [112], mineral occurrence of halogens in coal may be the exception rather than the rule. Based on more limited XAFS spectroscopy at the Br K-edge showing many features in common with the Cl data, Huggins and Huffman concluded that the dominant mode of occurrence for Br is in association with coal moisture, similar to that for Cl. Based on the similarity of Cl and Br, Spears [118] concluded that moisture-hosted Cl and Br were consistent with results for U.K.

coals showing (i) correlation between Cl in coal with that in adjacent groundwater; (ii) correlation between coal Cl content and moisture content; and (iii) brine-like water extracted from coal moisture by centrifugation.

2.4.1.3 Iodine (I)

Various studies have found I and its compounds such as potassium iodide to be effective oxidants and sorbent promoters for capture of Hg^0 in flue gas from coal combustion [104, 123–125]. On a volume-equivalent basis, Chi *et al.* [125] determined I to be even more effective than Br in promoting Hg^0 oxidation, whereas Cao *et al.* [104] found Br (as HBr) to be more effective, and both HBr and HI more effective on a per volume basis than either HCl or HF. These results follow a general trend that the heavier halogens (Br, I) are more effective oxidants than the lighter halogens (Cl, F), a surprising result given that oxidizing ability decreases in the group with increasing atomic weight.

Information on the naturally occurring I content of coals is limited. However, several recent studies have introduced methods to quantify I content, particularly in Chinese coals [126–128]. Wu *et al.* found a range in I content from 0.04 to 39.5 ppm for 305 samples of coal from throughout China, with an arithmetic mean of 2.6 ppm and a geometric mean of 1.27 ppm. Iodine content was found to be positively correlated with coal rank and with depositional environment, with anthracite having the highest values. Chinese coals deposited under the influence of marine or brackish conditions have a higher mean I content than those deposited in non-marine settings and this is likely to be applicable elsewhere, analogous to other marine-associated elements such as B [129]. Bettinelli *et al.* [130] give a range of 0.15–12.8 ppm I by ICP-MS for 158 commercial coal samples imported to Italy from China, Columbia, Poland, South Africa, the United States, and Venezuela. This study confirms that median I concentrations in the 1–3 ppm range are typical from various sources. Wang *et al.* [126] report I contents (by INAA) ranging from 2.2 to 15.7 ppm for a series of coals from Guizhou Province, China. There, the most I-enriched coals reflect post-coalification interaction with hydrothermal fluids and are not representative of values for coals used commercially. Wang *et al*. [126] (their Figure 1) and Zheng *et al.* [73] argue that domestic use of I-enriched coal in Guizhou Province limited the incidence of iodine deficiency disorders in the Province to wood-burning areas, prior to its virtual elimination by introduction of iodized salt throughout China.

2.4.1.4 Fluorine (F)

Comparison of the impact of F addition on oxidation of Hg^0 with addition of Br, I, and Cl indicates that the effect of F is similar to or less than that of Cl [104]. As a result, there has been less interest in addition of F, the lightest halogen, as a means to promote Hg capture from combustion systems. However, because its behavior is comparable to that of Cl, in coals with naturally high F contents, the sum of F and Cl may be a more important indicator of the potential for Hg self-capture than Cl itself.

Like other halogens, F concentrations in coal show considerable variation. Values in the 50–100 ppm range are typical, with similar means estimated for world coal (88 ppm; [131]), U.S. coal (98 ppm; [11, 107]), and coal in China (82 ppm; [71, 132]), although Dai *et al.* [58] later give a higher mean value for China (130 ppm). Unusually F-enriched coals (mean of 286 ppm for 29 samples) in Inner Mongolia, described by Wang *et al.* [133], are thought to be the result of introduction of Al- and F-bearing solutions to the mire during coal formation. These solutions are likely derived from an adjacent geologically ancient, deeply weathered, bauxite-bearing terrane. This history is reflected by the presence of boehmite (AlO(OH)) in these coals and a strong correlation between F concentration and the volume percentage of boehmite [133]. Elsewhere in China, high F contents are known in some stone coals (carbonaceous mudstone), and in manufactured coal briquettes that use F-rich clay as a binder. Domestic use of these materials is thought to contribute to endemic fluorosis in China [71, 73, 133], but based on the moderate F contents typical of Chinese coals, the contribution of coal itself to the fluorosis problem is considered to be secondary [71].

2.5 Summary

As discussed elsewhere in this volume, interaction of coal-derived Hg and halogens in the flue gas of combustion systems provides a fundamental mechanism for mercury capture. Variation in the concentrations of these parameters in coal is a consequence of geologic processes, and as a result, to some extent, every coal is unique. In general, low-rank coals have lower contents of both Hg and halogens than bituminous coals, and when combined with their lower energy output and higher moisture content, may offset some of the advantage of being low in Hg. At the other end of the spectrum, bituminous coals generally have higher Hg content but also have halogen concentrations in a range that promotes a greater degree of Hg self-capture. Compared to low-rank coals, bituminous coals have a greater fraction of Hg occurring within Fe disulfides, which potentially allows for pre-combustion removal of Hg to some extent. Concentrations of halogens in coal are influenced by the interaction of coal with associated fluids that may include pore water present during various stages of coal formation, formation waters present in a coal basin, or thermally or structurally driven brines. Where coals are in equilibrium with deep-basin brines, halogen contents may be especially high, and this may limit their commercial usefulness due to corrosion of boilers and emission of acid gasses. The content of Br in coal is typically only a small percentage of the Cl content, but even so, this proportion is enriched relative to that of seawater. As shown elsewhere in this volume, the capacity of Br to promote Hg oxidation is substantially greater and disproportionate to that of Cl.

Of the major coal-producing countries, database compilations sufficient to estimate Hg input to the boiler on a nationwide basis are available only for the United States and China. More detailed sampling and analysis of Hg in coal are

needed, especially for the next largest coal-producing countries such as India, South Africa, the Russian Federation, and Indonesia. In the absence of available detailed compilations, extrapolation of limited datasets to estimate Hg input to the utility sector on a nationwide basis is unlikely to be representative.

Acknowledgments

We thank the editors of this volume for inviting us to contribute a chapter on mercury in coal. The editors are acknowledged for their insightful comments on the manuscript. Additional reviews by Harvey Belkin and Susan Tewalt, on behalf of the USGS, and by David Tabet and Mike Hylland for the Utah Geological Survey, helped improve the manuscript. Harvey Belkin is acknowledged for his help in interpreting USGS mercury data for Chinese coals.

3
Regulations

Nick Hutson

3.1
U.S. Regulations

3.1.1
Background

The enactment of the Clean Air Act of 1970 (1970 CAA) resulted in a major shift in the federal government's role in air pollution control. This legislation authorized the development of comprehensive federal and state regulations to limit emissions from both stationary (industrial) and mobile sources. At this time, the National Emission Standards for Hazardous Air Pollutants (NESHAP) program was initiated to limit emissions of toxic or hazardous air pollutants (HAPs) from stationary sources. CAA Section 112 addresses emissions of HAPs, which are those pollutants which are hazardous to human health or the environment but are not specifically covered under another portion of the CAA. These pollutants are typically carcinogens, mutagens, or reproductive toxins. In 1990, the U.S. Congress, believing that the 1970 CAA and subsequent amendments had failed to provide substantial reductions of air toxic pollutants, passed the Clean Air Act Amendments of 1990 (1990 CAAA). The 1990 CAAA authorized, among other things, the incorporation of the NESHAP into a greatly expanded program for controlling toxic air pollutants.

The new law included a list of 189 toxic air pollutants (including mercury and its compounds) for which emissions must be reduced. Congress then mandated that the Environmental Protection Agency (US EPA) publish a list of source categories that emit certain levels of these pollutants within 1 year of the law's passage. For major sources (those emitting more than 10 ton of any single HAP or more than 25 ton cumulatively of all the listed HAPs), Section 112 mandates that the EPA establish emission standards that require the maximum degree of reduction in emissions of HAPs. These emission standards are commonly referred to as *maximum achievable control technology* or *MACT* standards. These standards are to be based on the best demonstrated control technology or practices within the regulated industry.

Mercury Control: for Coal-Derived Gas Streams, First Edition.
Edited by Evan J. Granite, Henry W. Pennline and Constance Senior.

Eight years after issuance of the technology-based standards, the EPA is required to review those standards to determine whether any residual risk exists for that source category and must, if necessary, revise the standards to address such risk.

3.1.2 Electric Generating Units (EGUs)

Congress established a specific structure for determining whether to regulate electric generating units (EGUs) under CAA Section 112. Specifically, Congress required the EPA to conduct a study to evaluate the remaining public health hazards that are reasonably anticipated to occur as a result of EGUs' HAP emissions after imposition of other CAA requirements. The EPA was required to report the results of that study – referred to as *the Utility Study* [1] – to Congress, and to regulate EGUs "if the Administrator finds such regulation is appropriate and necessary," after considering the results of that study.

The Utility Study included numerous analyses. The EPA first collected HAP emissions test data from 52 EGUs, including a range of coal-, oil-, and natural gas-fired units, and the test data along with facility-specific information were used to estimate HAP emissions from all 684 utility facilities. The EPA determined that 67 HAP were potentially emitted from EGUs. EPA conducted a screening level assessment of all 67 HAP to prioritize the HAP for further analysis. Six HAPs (mercury, radionuclides, arsenic, cadmium, lead, and dioxins) were considered a priority for multi-pathway assessment of exposure and risk. Based on these analyses, EPA determined that Hg from coal-fired EGUs was the HAP of greatest potential concern.

Congress also directed the EPA to conduct a study specifically on mercury emissions from EGUs, municipal waste combustion units, and other sources. This is referred to as *the Mercury Study*. In this study, the EPA was directed to consider the rate and mass of mercury emissions, the health, and environmental effects of such emissions, available control technologies, and the costs of those technologies. Congress also directed the National Institute of Environmental Health Sciences (NIEHS) to conduct a study to determine the threshold for mercury concentrations in the tissue of fish which may be consumed (including consumption by sensitive populations) without adverse effects to public health. In addition, Congress directed the EPA to fund the National Academy of Sciences (NAS) to perform an independent evaluation of the available data related to the health impacts of methylmercury (MeHg). Specifically, Congress required the NAS to advise the EPA as to the appropriate reference dose (RfD) for MeHg. The RfD is the amount of a chemical which, when ingested daily over a lifetime, is anticipated to be without adverse health effects to humans, including sensitive subpopulations.

As directed by Congress through different vehicles, the NAS Study and the NIEHS Study evaluated the same issues. The NIEHS completed their study in 1995 and the NAS study was completed in 2000.

On 20 December 2000, the EPA issued a finding that it was "appropriate and necessary" to regulate coal- and oil-fired EGUs under CAA Section 112 and added such units to the list of source categories subject to regulation. Once the source category was listed, the EPA was then required to establish technology-based emission standards. More specifically, the EPA was required to establish emission standards that reflect the "MACT" level of control. By statute, the MACT standards for existing sources must be at least as stringent as the average emission limitation achieved by the best performing 12% of existing sources in the category (for which the Administrator has emissions information). This level of minimum stringency is referred to as the *MACT floor*, and the EPA cannot consider cost in setting the floor. For new sources, MACT standards must be at least as stringent as the control level achieved in practice by the best controlled similar source. The EPA must also consider more stringent "beyond-the-floor" control options, but must take into account costs, energy, and nonair quality health and environmental impacts when doing so.

The EPA did issue standards for Hg emissions from coal- and oil-fired power plants. However, instead of issuing emission standards under CAA Section 112 (covering HAPs), the Agency, on 29 March 2005, issued the Section 112(n) Revision Rule that removed EGUs from the list of sources subject to regulation under CAA Section 112. This Revision Rule essentially reversed the Agency's previous finding and determined that it was neither appropriate nor necessary to regulate such units under CAA Section 112.

Subsequently, on 18 May 2005, the EPA issued the Clean Air Mercury Rule (CAMR). That rule established standards of performance for emissions of Hg from new and existing coal-fired EGUs under CAA Section 111 (New Source Performance Standards, NSPS).

A collection of environmental groups, states, and tribes challenged the Section 112 delisting action and the legality of the CAMR. On 8 February 2008, the D.C. Circuit Court vacated both the 2005 delisting action and the CAMR. The D.C. Circuit held that the EPA had failed to comply with the requirements for delisting source categories from Section 112. Thus, CAMR and the 2005 delisting action became null and void and the rule was never implemented.

On 18 December 2008, several environmental and public health organizations filed a complaint in the U.S. District Court for the District of Columbia. They alleged that the EPA had failed to perform a nondiscretionary duty by failing to promulgate final CAA Section 112(d) standards for HAP from coal- and oil-fired EGUs by the statutorily-mandated deadline. The EPA settled the litigation and agreed to issue final MACT emission standards for coal- and oil-fired EGUs by 16 December 2011.

3.1.3 Mercury and Air Toxics Standards ("MATS") – Existing Sources

On 16 December 2011, the EPA Administrator signed the Mercury and Air Toxics Standards (or "MATS") which requires that coal- and oil-fired EGUs meet HAP

Table 3.1 Final mercury emission limits in the U.S. EPA "Mercury and Air Toxics Standards (MATS)" for existing fossil fuel power plants.

Sources	lb $TBtu^{-1}$ (input)	lb GWh^{-1} (output)	~µg m^{-3}
Existing plants			
Coal > 8300 Btu lb^{-1}	1.2	0.013	1.40
Coal < 8300 Btu lb^{-1}	4.0	0.04	4.70
Solid oil-derived fuel	0.2	0.002	0.23
IGCC units	2.5	0.03	2.90

The emission limits for existing units are provided in pounds of mercury per trillion British thermal unit of heat input or alternatively in units of pounds of mercury per gigawatt-hour of power output, both based on a 30 day rolling average. The measured emission in micrograms per cubic meter is an approximate value only; the affected units must show compliance with the input or output based standard. The EPA did not set emission limits for natural gas-fired power plants. Solid oil-derived fuel is commonly known as *petroleum coke* or *pet coke*.

standards reflecting the performance of the MACT. The rule [2] established uniform emissions-control standards that affected sources can meet with proven and available technologies and operational processes. The rule set emission limits for mercury and other toxic metals (such as arsenic, cadmium, lead, and nickel), for hazardous acidic gases (such as hydrochloric and hydrofluoric acids) and set work practice standards to limit the emissions of toxic organic pollutants, including benzene and dioxins.

The specific limits for subcategories of existing EGUs are given in Table 3.1. The emission limits are provided for mine-mouth units designed for and burning low rank, virgin coal with a calorific value <8300 Btu lb^{-1} (this will represent primarily units utilizing lignite coal), all other coals, solid oil-derived fuel (petroleum coke), and integrated gasification combined cycle (IGCC) units (regardless of fuel source). If an EGU burns coal (either as a primary fuel or as a supplementary fuel) or any combination of coal with another fuel (except for solid waste) where the coal accounts for more than 10.0% of the average annual heat input during any three consecutive calendar years or for more than 15.0% of the annual heat input during any one calendar year after the applicable compliance date, the unit is considered to be coal-fired.

For coal-fired, IGCC, and solid oil-derived fuel-fired units, operators must use a Hg continuous emissions monitoring system (CEMS) or a sorbent trap monitoring system for both initial and continuous compliance.

CAA Section 112 specifies the dates by which affected sources must comply with this rule. New or reconstructed units must be in compliance immediately upon startup or the effective date of this rule, whichever is later. Existing sources may be provided up to 3 years after the effective date to comply with the final rule; if an existing source is unable to comply within 3 years, a permitting authority (usually the state) has the ability to grant such a source up to a 1 year extension, on a case-by-case basis, if such additional time is necessary for the installation

of controls. The EPA's Office of Enforcement and Compliance Assurance (OECA) also issued a memorandum describing the Agency's "intended approach regarding the use of administrative orders ("AOs") for sources that must operate in noncompliance with MATS for up to 1 year to address a specific and documented reliability concern."

3.1.4 Mercury and Air Toxics Standards ("MATS") – New Sources

On 16 December 2011, the final "MATS" also contained standards for new fossil fuel-fired EGUs (i.e., those that commence construction after 3 May 2011). The rule set emission limits for mercury and other toxic metals (such as arsenic, cadmium, lead, and nickel), for hazardous acidic gases (such as hydrochloric and hydrofluoric acids) and set work practice standards to limit the emissions of toxic organic pollutants, including benzene and dioxins. The CAA specifies that, for new sources, the emission limitation "shall not be less stringent than the emission control achieved in practice by the best controlled similar source."

Following promulgation of the final MATS rule, the EPA received several petitions for reconsideration of numerous provisions of both the MATS rules, including the achievability of the final new source standards. The EPA Administrator agreed to reconsider certain aspects of the final MATS rule and the reconsideration proposal was published on 30 November 2012 [3]. The reconsidered emission limits for new sources were finalized in March 2013.

The mercury emission limits for subcategories of new EGUs are given in Table 3.2. The original final emission limits are given along with final reconsideration emission limits. As with existing sources, the emission limits are provided for mine-mouth units designed for and burning low rank, virgin coal with a calorific value <8300 Btu lb^{-1} (this will represent primarily units utilizing lignite

Table 3.2 Final mercury emission limits in the U.S. EPA "Mercury and Air Toxics Standards (MATS)" for new fossil fuel power plants.

Sources	MATS original (lb GWh^{-1}) (output)	MATS revised (lb GWh^{-1}) (output)	Revised (~µg m^{-3})
New plants			
Coal > 8300 Btu lb^{-1}	0.0002	0.003	0.35
Coal < 8300 Btu lb^{-1}	0.04	0.04	4.70
Solid oil-derived fuel	0.002	0.002	0.23
IGCC units	0.003	0.003	0.35

The emission limits for new coal-fired or IGCC power plants are provided only in units of pounds of mercury per gigawatt-hour of power output, based on a 30 day rolling average. The measured emission in micrograms per cubic meter is an approximate value only; the affected units must show compliance with the output based standard. The EPA did not set emission limits for natural gas-fired power plants. Solid oil-derived fuel is commonly known as *petroleum coke* or *pet coke*.

coal), all other coals, solid oil-derived fuel (petroleum coke), and IGCC units (regardless of fuel source). New sources may only meet an output based emission limitation.

4
International Legislation and Trends

Lesley L. Sloss

4.1
Introduction

Some regions and countries in Europe, Australia, and Asia are actively monitoring and controlling mercury emissions. However, they are currently doing so without the apparent urgency incurred by national and regional binding legislation and specific mercury reduction targets that are being applied in Canada and introduced in the United States at the moment. That is not to say that mercury is not being controlled outside North America. Rather that this control of mercury is largely being achieved as a result of co-benefit effects.

There were a number of international treaties, set by the United Nations Environment Programme (UNEP), which included mercury. These were not challenging with respect to mercury limits and therefore did not require any action to be taken at coal-fired utilities. The UNEP Governing Council made a decision in February 2009 to further strengthen international action on mercury and initiated negotiations toward producing a "Global legally binding instrument on mercury." This instrument, is known as the *Minamata Convention*, was completed in February 2013. The convention promotes BAT at all new coal-fired power plants and requires a national action plan, with options for BAT, emission limits, reduction targets and so on, to be taken at all existing plants. There is enough flexibility in the wording to allow signatory countries to determine their own best approach to reducing mercury emissions from this sector.

Concern has been expressed that the rapid increase in coal use in countries such as those in Asia may override reductions in emissions achieved elsewhere. It is therefore essential that any international mercury legislation is made both technically and economically viable in developing countries to ensure that the current upward trend in global mercury emissions is controlled effectively. These are the kind of issues which have been addressed within the flexibility of the UNEP convention.

This chapter will summarize both international and national legislation (excluding the United States). Mercury legislation is currently in a state of extreme flux and, as a result, the information included in this chapter can only be regarded as a

Mercury Control: for Coal-Derived Gas Streams, First Edition.

snapshot of the issue as this document goes to print. However, it is clear that many countries, not just those in North America, are moving toward stringent control of all toxic emissions and so legislation for mercury control can be regarded as somewhat inevitable. It remains only to be seen what form this legislation may take in different regions and how soon it will be initiated.

4.2 International Legislation

There are a number of international agreements and action plans to co-ordinate activities to reduce mercury emissions. These include [1]

UNECE	The United Nations Economic Commission for Europe (UNECE) has a convention on long-range trans-boundary air pollution (LRTAP). This convention was published in 1998 and covers heavy metals including mercury. The protocol has been signed by Canada, Europe, Russia, and the United States. Although the protocol calls for the installation of BAT at new stationary sources, it does not go so far as to define BAT for coal-fired plants or to specify any reduction strategies.
OSPAR	Oslo and Paris Commission's program on reduction of land-based pollutants transported to the North Sea.
HELCOM	The Helsinki Commission program covering the North Sea.
Barcelona Convention	A program similar to OSPAR and HELCOM covering the Mediterranean Sea.
MEPOP	European political initiative studying the atmospheric cycling of mercury and persistent organic pollutants.
Nordic	Co-ordination of projects between Denmark, Finland, Norway, and Sweden to reduce mercury emissions.
Arctic	The Arctic Council's Environmental Protection Strategy includes mercury.
NARAP	North American Regional Action Plan between Canada, the United Mexican States, and the United States to reduce mercury fluxes.
Binational Toxics	Canada and the United States have a project for cleaning up substances, including mercury, in the Great Lakes Basin Area.

None of these agreements or programs includes guidelines on how the proposed reductions in emissions or concentrations should be achieved other than by recommending "best practices." The agreements rely on the individual governments of each signatory country to produce a successful strategy to reduce mercury emissions. They therefore do not necessarily guarantee results. Action is rarely, if ever, taken against countries that are not as successful as others in

reducing emissions. For the moment, there is no international treaty that requires specific mercury control at coal-fired utilities. However, this may change with the introduction of the UNEP "Minamata Convention."

4.2.1 UNEP International Legally Binding Instrument on Mercury ("Minamata Convention")

In February 2009, the Governing Council of the UNEP agreed on Decision 23/9 defining the need to develop a global legally binding instrument on mercury. The convention was completed in February 2014. The final text requires that signatory parties take measures to control and, where feasible, reduce emissions. New plants will have to apply BAT/BEP and BAT/BEP is an option, alongside emission limit values, reduction targets, multi-pollutant strategies or "alternative measures", for existing sources. The definition of BAT within the convention is to be determined by the conference of the parties but must take geographical, technical and economic considerations into account. And so, at this stage, it is up to each signatory country to determine how the convention will be applied to sources within their jurisdiction.

4.2.2 European Union (EU)

There are three established directives which are currently relevant to coal-fired utilities in the European Union (EU) member states:

- the Integrated Pollution Prevention and Control (IPPC) Directive;
- the Large Combustion Plant Directive (LCPD); and
- the Waste Incineration Directive (WID, applicable to plants co-firing waste with coal).

All these directives will continue to apply until they are replaced by

- the Industrial Emissions Directive (IED), which comes into force for coal-fired power plants in 2016.

It is therefore necessary to discuss each of these directives in turn to appreciate the ramifications for utilities in Europe. Although none of these Directives specifies emission limits or control requirements for mercury, the technologies that plants must install to meet SO_2 and NO_x limits will have a significant effect on mercury emissions.

EU-Directive on IPPC (2008/1/EC) (EC, European Commission) applies an integrated environmental approach to the regulation of around 45 000 industrial facilities, including large combustion plants, in the EU. The directive is based on a plant-specific permit which details the requirements relevant to each individual facility and can therefore take into account not only any international and national requirements (such as reduction targets for UNECE protocols and EU emission limits) but also regional and local considerations such as preservation of sensitive

watershed areas. For particulates, the BAT options are electrostatic precipitator (ESP) (99.5% efficiency) in combination with wet flue gas desulfurization (FGD); or bag houses (fabric filters) (99.95% efficiency) in combination with wet FGD. For SO_2, the BAT options are either low-sulfur fuel, wet FGD, spray dry FGD, seawater FGD, or combined SO_2 and NO_x systems. For NO_x, the BAT options are primary measures (air/fuel staging, low NO_x burners, re-burn) in combination with SCR (selective catalytic reduction) or SNCR (selective non-catalytic reduction) in some cases; or combined SO_2 and NO_x systems. However, the choice of which control combination is suitable as BAT for each individual plant has to be defined on a case-by-case basis under each permit and is based on extensive BAT reference documents (BREFs) provided by the EC.

The revised LCPD (2001/80/EC) applies to combustion plants with a thermal output of >50 MW. According to the directive, by 1 January 2008, all large combustion plants in Europe had to opt for one of the following three compliance options:

1) meet emission limit values (ELVs) for particulates, SO_2 and NO_x;
   a. 200 mg m^{-3} SO_2 for new plant and 400–2000 mg m^{-3} for existing plant (based on size);
   b. 200–400 mg m^{-3} NO_x for new plant and 500–600 mg m^{-3} for existing plant (based on plant size)
2) sign up to lower SO_2 and NO_x "bubbles" that are equivalent to the ELV reductions and which are part of a National Emission Reduction Plan (NERP); or
3) "opt-out" of ELVs and NERP and commit to close by 2015, operating for no more than 20 000 h over that period.

Therefore, to meet both the IPPC BAT requirements and the LCPD ELV with fuel switching alone, plants would need to be firing very low-sulfur coal to avoid having to install FGD [2]. In simple terms, the IPPC and LCPD together mean that all plants must install wet FGD (or a technology with similar or greater SO_2 control) and make at least combustion modifications to reduce NO_x (some plants will require SCR in addition to combustion modifications). Plants which could not comply with either option 1 or 2 above were to close by 2016 and run limited operating hours until that date.

Many plants within Europe regarded the ELVs defined by the LCPD as too challenging. Before the LCPD was replaced by the IED, almost 25 GW of coal units and 10 GW of lignite units decided not to install FGD, particularly in Spain, France, and the United Kingdom in Western Europe. These plants chose to opt-out of the LCPD and close by 2016 [3].

If co-combustion of other waste is to be applied at an existing coal-fired plant, the emission limits must be revised according to the EU WID (2000/76/EC). Table 4.1 includes a summary of the EU emission limits under the WID alongside the emission limits in Germany (*see* below) [4].

The WID limits are more stringent than those in the LCPD. Under the "mixing rule," plants firing waste materials defined under the WID must calculate a specific emission limit based on the amount of waste material being co-fired. However, this

Table 4.1 German emission limits for waste incineration plant and power plant [4].

Compound	Thirteenth BImSchv[a)]	Seventeenth BImSchv[a)]		EU-Directive

a) Bundesimmissionsschutz-Verordnung or BImSchv limits.

does not apply to mercury and its compounds, for which the limit is 0.050 mg m^{-3} for all co-incineration plants. The WID is far more challenging with respect to compliance than the LCPD and so existing coal-fired plants are generally reluctant to co-fire waste material that falls under the remit of the WID. In addition to the more stringent emission limits, the WID also has more demanding monitoring requirements.

In 2007, in recognition that the EU legislation at that time was somewhat piecemeal and confusing, the EC launched a review of the existing legislation with the aim of merging seven different directives into one. The directives which were merged were

- the Large Combustion Plant directive (LCPD);
- the Integrated Pollution Prevention and Control Directive (IPPC);
- the Waste Incineration Directive (WID);
- the Solvent Emissions Directive (SED); and
- the three existing directives on Titanium dioxide on (i) disposal (78/176/EEC), (ii) monitoring and surveillance (82/883/EEC), and (iii) programs for the reduction of pollution (92/112/EEC).

These directives were all merged into the new IED which was published by the EC in December 2010. The IED was to be drafted into national legislation within each of the Member States by 6 January 2013.

For coal-fired plants, the IED is effectively a combination of the IPPC and LCPD discussed above, containing aspects of both permitting and plant-specific requirements along with ELVs or equivalent reduction strategies. Each plant must have its own plant-specific permit with performance, based on a combination of BAT and ELVs.

The new IED allows some flexibility in the definition of BAT, according to the decisions of the local competent authority, and requires continued work at the EC level on BREFs. The IED also includes potential derogations where BAT is considered to be of a disproportionately high cost, as long as the ELV are still met. There is also still the option of a minimum desulfurization rate for plants which cannot comply with ELVs due to specific fuel characteristics.

As with the original LCPD, the IED allows the same three options for compliance: the ELV, the NERP (now referred to as the *National Action Plan*), or opt-out (eventual closure).

The new ELVs for SO_2 for combustion plants granted permits before 7 January 2013 are as follows:

Emission limit for SO_2 for plants permitted pre-2013 (mg m^{-3})

Plant size (MWt)	Coal, lignite, and other solid fuels	Biomass	Peat	Liquid
50–100	400	200	300	350
100–300	250	200	300	250
>300	200	200	200	200

The remaining plants must then meet more stringent SO_2 limits after 2016.

Emission limit for SO_2 for plants permitted post-2013 (mg m^{-3})

Plant size (MWt)	Coal, lignite, and other solid fuels	Biomass	Peat	Liquid
50–100	400	200	300	350
100–300	200	200	300	200
>300	150	150	150	150

For those plants, originally permitted prior to 2013, which cannot meet the prescribed ELV due to specific fuel characteristics, there is still the option of meeting a minimum rate of desulfurization, shown below.

Desulfurization rate for SO_2 for plants with challenging fuel, permitted pre-2013

Plant size (MWt)	Plants permitted before 27 November 2002 (%)	Other plants (%)
50–100	80	92
100–300	90	92
>300	96	96

All other plants must meet tighter reduction requirements.

Desulfurization rate for SO_2 for plants with challenging fuel, permitted post-2013

Plant size (MWt)	(%)
50–100	93
100–300	93
>300	97

Both these reduction requirements and the ELVs listed above would require, in most if not all instances, the use of FGD technologies.

For those plants firing low-sulfur fuel, there is a potential derogation period of 6 months, which will be permitted during instances of interruption in the supply of low-sulfur fuel (such as that resulting from a serious shortage).

The new NO_x limits (milligrams per cubic meter) for combustion plants granted permits before 7 January 2013 are as follows:

Emission limit for NO_x for plants permitted pre-2013 (mg m^{-3})

Plant size (MWt)	Coal	Lignite	Biomass and peat	Liquid
50–100	300	450	300	450
100–300	200	200	250	200
>300	200	200	200	150

Plants not permitted before 7 January 2013 must meet the following limits after 2016:

Emission limit for NO_x for plants permitted post-2013 ($mg\,m^{-3}$)

Plant size (MWt)	Coal	Lignite	Biomass and peat	Liquid
50–100	300	400	250	300
100–300	200	200	200	150
>300	150	200	150	100

For most plants, low NO_x burning systems may not be able to reach these limits and additional SCR or SNCR technologies will be required.

As with the original LCPD, under the new IED, plants may be exempt from the ELV if they agree to the following:

- to operate no more than 17 500 h between 1 January 2016 and 31 December 2023 (a more forgiving timescale than the LCPD);
- to report hours of operation on an annual basis; and
- ELVs prescribed in the plant permit on 31 January 2015 shall be maintained for the remaining operation period of the plant.

The IED carries with it requirements for continuous emission monitoring (CEM) of particulates/dust, SO_2, and NO_x on all plants. Although the IED does not set an ELV for mercury from coal-fired utilities, it does introduce a requirement for annual monitoring of mercury emissions.

Although this monitoring requirement for mercury is the only mention of mercury in the new IED, this does not mean that mercury is not under control. Studies carried out in the EU and elsewhere have consistently shown that the installation of control technologies for particulates, SO_2 and NO_x on coal-fired power plants can effectively reduce mercury emissions. For most plants and coals, the combination of particulate controls and wet FGD systems will mean at least 70% mercury reduction [5, 6]. If SCR is also included, as will be the case at many EU plants, mercury capture can be up to and over 90%. While this significant reduction rate is certainly not guaranteed, especially for some challenging coals, most plants will still achieve some co-benefit mercury control. By introducing the requirement for mercury monitoring at all plants, the EC will gather data on just how effective the control systems required under the IED are for mercury control and, based on this, may or may not set mercury specific legislation in the future. Although, for the moment, mercury emissions are regarded as largely under control, the new IED BREFs (currently being updated to include mercury) may well define BAT levels for mercury based on available information and reductions achieved so far and this could mean requirements for mercury on some plants in the future.

4.3
Regional and National Legislation

The following sections summarize the situation in several example countries and regions (excluding North America) that either have legislation for mercury control or have monitoring and compliance regimes that are potentially moving toward mercury specific legislation.

4.3.1
Europe

As discussed earlier, the existing IPPC and LCPD and their replacement, the IED, will not target mercury directly but are still likely to result in significant mercury reductions as a result of co-benefit effects.

Individual member states within the EU must adopt EU legislation as national legislation within a set time period. Over and above this, each country may set its own legislation or reduction targets based on more local environmental challenges or concerns. Countries such as Germany and the Netherlands often go above and beyond what is required by EU legislation.

4.3.1.1 Germany

The Thirteenth Ordinance of the Federal Immission Control Act (13 BImSchV) set an emission limit of 30 $\mu g\, m^{-3}$ for mercury at all coal-fired utility plants, and continuous emission monitors for mercury are also required at all plants. Daily average and half-hour average values are required. As all plants have FGD and SCR fitted, mercury is also captured efficiently and, as yet, no mercury specific control technologies have been required at any plants firing coal alone (H. Thorwarth, Personal Communication, 2008). Germany has around 20 plants co-firing sewage sludge with coal, as summarized by Fernando [7]; these plants face a significant challenge with respect to mercury emissions and control.

Under the IPPC/IED permitting scheme, individual plants may be granted a permit that sets emission limits or control requirements which are more challenging than those for other national plants. Unpublished information suggests that a new coal-fired plant (Staudinger) in Germany will be facing a mercury emission limit in the order of 15 $\mu g\, m^{-3}$. No more details are available at this time.

4.3.1.2 Netherlands

Similar to Germany, the Dutch Government takes a pro-active approach to emission control and often sets national and regional legislation, which is significantly more stringent than that set by the EU. Although the current IED for the EU specifies BAT requirements only for particulates, SO_2 and NO_x, permits for Dutch coal-fired plants must also consider BAT for mercury. This is based on an estimated mercury input (fuel content) and the yearly average removal efficiency of the air pollution control devices (APCDs), as measured during monitoring campaigns.

KEMA in the Netherlands have developed the KEMA TRACE MODEL® (KTM), an empirical and statistical model developed from mass balance studies

at all the coal-fired plants in the Netherlands over 25 years. The model can cope with co-firing secondary fuels such as biomass up to 30% on a mass base. The model covers 46 elements, including mercury. The calculated emissions, based on the fuel data, are compared to relevant emission regulations such as the LCPD or IED and any national regulations. The KTM is well trusted and is used in the impact statements and permit applications of coal-fired plants in the Netherlands (H. Te Winkel, Personal Communication, 2011).

Although there has been nothing published as yet, it would appear that three new coal-fired plants in the Netherlands, including units at Maasvlakte and Datteln, could face plant-specific mercury regulations that would limit mercury emissions to around 3 $\mu g\, m^{-3}$ on an annual basis.

4.3.2 Asia

Asia contains some of the cleanest and some of the dirtiest coal-fired plants in the world. Several areas of Asia, such as Japan and South Korea, have already retrofitted most if not all of their plants with state-of-the-art emission control systems. Other areas, such as China and India, have such rapidly growing populations and economies that bringing all plants up to satisfactory emission limit standards is a challenge. The majority of environmental work being undertaken in India under a national government program is to improve the efficiency of existing coal-fired plants. Significant improvements in efficiency can be achieved, resulting in extended plant lifetime, reduced fuel consumption, increased energy output, and reduced emissions. For most of the plants studied, this rehabilitation makes more economic sense than the construction of new plants.

China has a range of plans and programs to reduce emissions of SO_2 based on limits and emission fees. The Chinese Government has recently introduced a new policy based on the phasing out of smaller, less-efficient coal-fired units. Other Asian nations face their own local challenges. To date, the environmental performance of each plant in many developing Asian nations depends on the location (for example, whether it is causing noticeable local effects) or on the operator/utility (depending on the level of pro-activeness). Emission monitoring is not common in most of Asia and therefore it is hard to determine compliance with any applicable emission standards. It is also difficult to determine which plants should receive priority when it comes to investment for rehabilitation or retrofitting without emission information. A move toward increased measurement and monitoring in these areas would help evaluate areas of concern to produce the most effective national policies.

The following sections summarize the situation in selected countries in Asia.

4.3.2.1 China

Chinese emission legislation is defined within 5- and 10-year plans. These plans are not law, but are rather targets that are achieved through agreements, performance, incentives, or existing laws [8]. Recently, the Chinese government's

efforts have concentrated on sulfur emissions. Despite some missed reductions in the past, the reduction target for SO_2 under the Eleventh 5 year plan (2006–2010; 10% reduction below 2005 levels) was met early and exceeded (a 14% reduction was achieved). This reduction was achieved largely due to the installation of FGD. The success of this Eleventh plan may be due to the strengthening of the approach with binding agreements with provinces and key emitters, economic and administrative incentives, performance audits, and stronger enforcement of existing laws. There has also been an unprecedented installation rate of FGD in China. In 2005, only 14% of the installed coal-fired generating capacity had been fitted with FGD but this had increased to 86% by the end of 2010 [9]. This would no doubt have resulted in significant co-benefit mercury reduction.

The *Emission Standard of air pollutants for thermal power plants* (GB 13223-2011) was adopted by the Chinese Ministry for Environmental Protection (MEP) on 18 July 2011 and should be effective starting 1 January 2012 [10]. The standard applies to particulate, SO_2, NO_x, and mercury emissions from coal-fired plants but does not apply to plants co-firing waste or biomass. Emissions of mercury will be controlled from 1 January 2015. The limit for mercury is set at 0.03 mg m^{-3}. However, because of known co-benefit effects, the limits for SO_2 and NO_x are also relevant. The full emission limits are listed in the table below.

Emission limits for coal-fired boilers in China, from 2011 (for particulates, SO_2 and NO_x) to 2015 (for mercury)

Pollutant	Conditions	Limit (mg m^{-3})
Soot	All units	30
	Plants in "key regions"[a)]	20
SO_2	New boiler	100
		200[b)]
	Existing boiler	200
		400[b)]
	Plants in "key regions"[a)]	50
NO_x (as NO_2)	All	100
		400[c)]
	Plants in "key regions"[a)]	100
Hg and compounds	All	0.03

[a)] Plants in "key regions" are defined as those situated where development is concentrated and environmental capacity is low (such as existing weak environmental capacity, vulnerable ecological environment, and major air pollution problems, as defined by the MEP).
[b)] Applies in Guangxi Zhuang Autonomous Region, Chongqing Municipality, Sichuan Province, and Guizhou Province.
[c)] W-type thermal power generation boilers, furnace chamber flame boilers, circulating fluidized bed boilers, and boilers in operation before 31 December 2003.

The limit set for mercury, 30 μg m^{-3}, is equivalent to the general emission limit for coal-fired units in Germany (see below) and applies to both existing and new

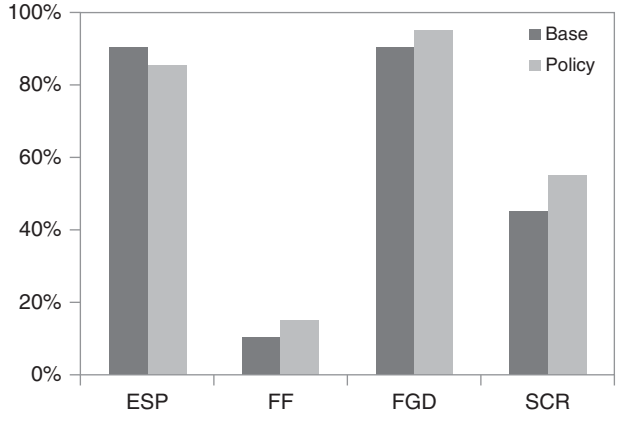

Figure 4.1 Chinese projections: application rate of emission controls in 2020.

plants. It is therefore significantly less stringent than the limits set in the United States and would be achieved by most modern plants fitted with ESP or baghouse systems firing standard coals. However, the limits set for SO_2 and NO_x will be challenging and are likely to result in FGD on all plants and upgrades on many existing FGD systems, SCR on almost all plants, and upgrading of ESPs with potential retrofitting of fabric filters in some cases. This will mean that, although the mercury limit will not itself result in mercury control, the co-benefit effects of the new SO_2, NO_x, and particulate limits are likely to result in significant mercury reduction.

A report produced by Tsinghua University for MEP under a UNEP Coal Partnership project included emission estimates for mercury from coal-fired utilities in China for 2005 and 2008 along with predictions for mercury reduction under future energy scenarios in 2020 [11]. The scenarios are summarized in Figure 4.1 and the predicted reductions as a result of each of these are summarized in Figure 4.2. It is important to note that these scenarios were produced prior to the new 2011 standards and so the predicted mercury reduction may be even more significant.

The new Chinese limits are challenging and are predicted to cost the Chinese economy at least 260 billion yuan ($40.74 billion) [12]. It is not clear whether this cost will include potential new monitoring requirements including CEM systems to ensure compliance. It therefore remains to be seen whether the Chinese coal sector can afford to comply with the new limits, bearing in mind the current increase in coal prices.

4.3.2.2 Japan

Environmental legislation in Japan is set on an individual company/plant basis and it is not simple to summarize the requirements that apply. There is a very high priority based on social responsibility and most companies wish to enhance their public credibility by not exceeding any requirements set. Most, if not all, coal-fired

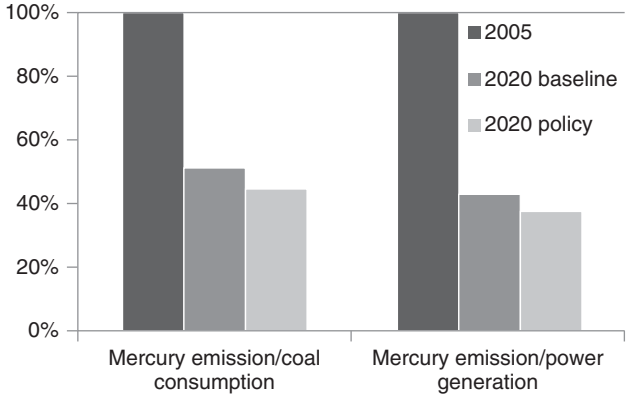

Figure 4.2 Chinese projections: mercury emission intensities in 2020.

units in Japan already have FGD and deNO_x systems in place and many plants pride themselves in fitting the most up-to-date systems [1]. By 2000, over 90% of plants had wet scrubber systems installed and <3% had no flue gas treatment for sulfur. Over 75% of plants have both low NO_x burners and SCR systems installed and the remainder had one or the other [13].

4.3.2.3 **Other Asian Countries**

The Philippines have a mercury emission limit from any source of 5 mg m^{-3}. At the moment, there are 12 coal-fired plants in the country, four of which are FBC systems (fluidized bed combustion) systems. New plants are required to install FGD systems and low NO_x burners. There is also a fee levied, which is proportional to emissions. However, some plants obtained a "grace period" from these fees to help fund the installation of control technologies, for which tax credits are also available [14].

Prior to 2010, there was no limit for mercury from coal-fired plants in *Korea* other than the general limit for mercury emissions for all industrial emissions set at 5 mg m^{-3}. However, the new standards, promulgated in 2010, set an emission limit for mercury and its compounds for all coal-fired facilities at 0.1 mg m^{-3}. As can be seen in Figure 4.3, this limit can easily be met by almost any plant fitted with an ESP system. New legislated emission limits for SO_2 are set at 100 ppm for existing plants >100 MW (in operation before 1996) and 80 ppm for new plants. The limit for NO_x is 150 ppm for existing plants and 80 ppm for new plants. This is equivalent to around 300 mg m^{-3}. This may require SCR systems on some plants, which will improve mercury capture due to co-benefit effects. However, it has been proposed that mercury CEMs be introduced at plants in Korea to monitor the effectiveness of the potential co-benefit effects of the SO_2 and NO_x control systems, which would provide information for a future review of the legislation by policy makers to potentially tighten mercury emission limits [15].

NB – the limit cited for Germany in this figure may be lower in practice as the standards are currently 50 μg m^{-3} for 30 min averages and 30 μg m^{-3} for 24 h

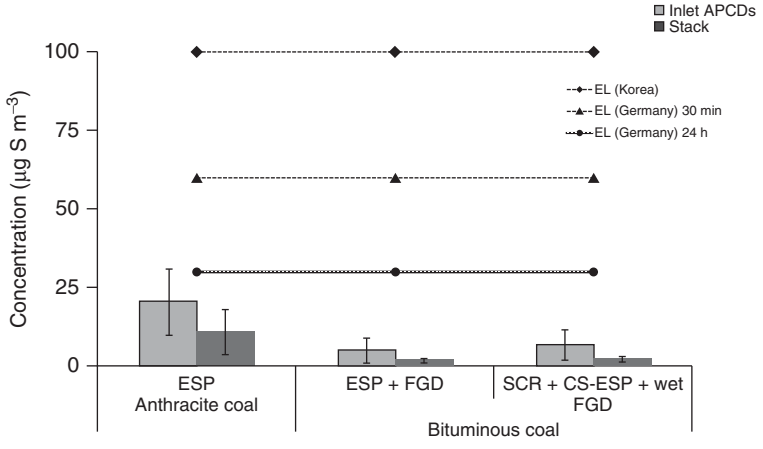

Figure 4.3 Measured mercury emission concentration and the permissible emission limit in current Korean and German regulations [15].

averages. However, the standards are still well above that which can be achieved in most plants fitted with APCD.

4.3.3 Other Countries

The following short sections summarize the situation on mercury emissions and control in selected countries.

4.3.3.1 Australia

Individual states in Australia have the jurisdiction to set their own emission legislation, including targets for greenhouse gas reduction. Over and above this, National Environmental Protection Measures (NEPM) can be set, based on goals, standards, protocols and/or guidelines. At the moment, although there is a National Pollutants Inventory (NPI) for the quantification of emissions, there are no binding national emission standards for SO_2 or NO_x. Emission guidelines for SO_2 and NO_x have been issued by the National Health and Medical Research Council (NHMRC). However, the limits are very general and were set at levels which could be met relatively easily. Australian coals are generally low in sulfur and therefore SO_2 emissions are not regarded as a high priority for control and there are, to date, no FGD or similar controls on any Australian coal-fired plants. Although NO_x limits have been specified in some states, it is thought that these are relatively lenient and have not required the installation of any NO_x control technologies [1].

The focus of Australian emission legislation is very much on the development of new clean coal technologies and low carbon options. So, for the moment at least, existing coal-fired power plants are not facing any retrofit requirements. Morrison and Nelson [16] have looked at future strategies for energy in Australia toward 2050. Most of the strategies considered relate to the reduction of mercury

and CO_2 emissions through the use of brown coal in IGCC (integrated gasification combined cycle) with and without CCS (carbon capture and storage). Australia's future energy strategies appear more concerned with greenhouse gas reductions and energy efficiency while SO_2 and NO_x emissions have much lower priority. It can therefore be assumed that there will be limited co-benefit reductions in mercury emissions, based on current legislation.

4.3.3.2 **Canada**

When the United States first introduced its Clean Air Mercury Rule (CAMR), Canada was quick to follow suit. However, the format the Canadian standard took differs from the CAMR and therefore, although the CAMR has now been abandoned, the Canada-Wide Standard (CWS) still applies. The CWS sets stringent emission reduction targets. There are provincial caps for each province, which apply to existing plants that require a total reduction of 60–70%. BAT is required on new plants. Individual provinces must decide the most appropriate means of meeting the required reduction targets and the approaches vary from enhanced co-benefit controls to activated carbon injection, and even complete plant closure [1].

4.3.3.3 **Russia**

In 1991, a national emissions charge system was introduced in Russia, which applied to over 300 air and water pollutants from a large number of stationary sources. However, monitoring and administrative capabilities are limited and the final charge is often open to negotiation between the source and the local authority. It is not uncommon for fees to be waived for sources experiencing financial problems. There does not appear to be any imminent move toward requirements for SO_2, NO_x, or mercury control [1].

4.3.3.4 **South Africa**

In March 2010, the South African Government established updated requirements for sulfur emission control. The limits are 3500 mg m^{-3} for SO_2 from existing coal-fired power plants and 500 mg m^{-3} for new plants (>50 MW). The emission limits for NO_x are 1100 and 750 mg m^{-3} for existing and new plants respectively [17]. There is also a move toward requiring the installation of FGD on all large coal-fired units in the country. However, the financial constraints and, perhaps more importantly, the limited availability of water in the country, will make the installation of FGD within the required time period a significant challenge. However, once FGD or equivalent sulfur control is required, some level of co-benefit mercury control can be expected.

4.4 Summary

At the moment, the majority of mercury control requirements apply in North America. Although there are international and national mercury emission limits

outside North America, the majority of these are not currently set at levels that require any significant action to be taken. This does not, however, mean that mercury is not being controlled. In fact, mercury reduction rates of over 50% and even over 95% are being achieved in countries which require state-of-the-art technologies for particulate, SO_2 and NO_x control as a result of co-benefit effects. Significant reduction in mercury emissions from the coal combustion sector have been achieved and are continuing in the EU and in countries such as Japan, Korea and, more recently, in China. And so, as a result, there is currently no real urgency to take specific action to control mercury. This may well change in the future if international and national bodies decide that current rates of mercury reduction in these regions are not sufficient.

5
Continuous Mercury Monitors for Fossil Fuel-Fired Utilities

Dennis L. Laudal

5.1
Introduction

Instrumentation to measure mercury has been available for many years. However, until recently, these monitors were designed to measure ambient mercury and mercury in liquids. It has only been since about 1990 that the concept of using mercury instrumentation to measure mercury in flue gas generated by burning fossils fuels, such as coal, has been considered. Until that time, mercury measurements were made using wet-chemistry methods such as U.S. Environmental Protection Agency (EPA) Method 29, EPA Method 101A and, later, the Ontario Hydro method. Although these methods could be highly accurate, they were expensive and difficult to apply. As a result, a serious effort was made to further develop and optimize continuous mercury monitors (CMMs). CMMs have the following advantages over traditional wet-chemistry methods:

- Yield real- or near-real-time results
- Able to assess process variability
- May be used for system optimization
- Provide feedback for Hg control strategies
- Have the potential to be less costly and are less labor-intensive
- Give direct measure of pollutants
- May promote better public relations.

Before these monitors could be reliably used in utility applications, many challenges had to be overcome:

- Reliability
- Ability to accurately measure low mercury concentrations
- Measurement environment
- Dynamic range
- National Institute of Standards and Technology (NIST) traceability for calibration.

To resolve some of these issues, as well as others, CMMs have become complex, with multiple parts, and new definitions were needed. For the purposes of this chapter, the entire mercury measurement system is called a *CMM*. The section of the CMM that actually analyzes the mercury in the gas steam is referred to as a *mercury analyzer*. Even this is a bit of a misnomer in that these instruments are not actually continuous. With the exception of a few *in situ* systems, all mercury monitors draw flue gas into an analyzer utilizing a pump and there is a time lag between instrument readings, which can be minutes or seconds depending on the instrument. The exact number of CMMs installed is unknown because many of the CMMs that were installed were not verified and/or removed following the vacature of the Clean Air Mercury Rule (CAMR). However, it is known that about 600 CMMs have been sold to the utility industry with about two-thirds

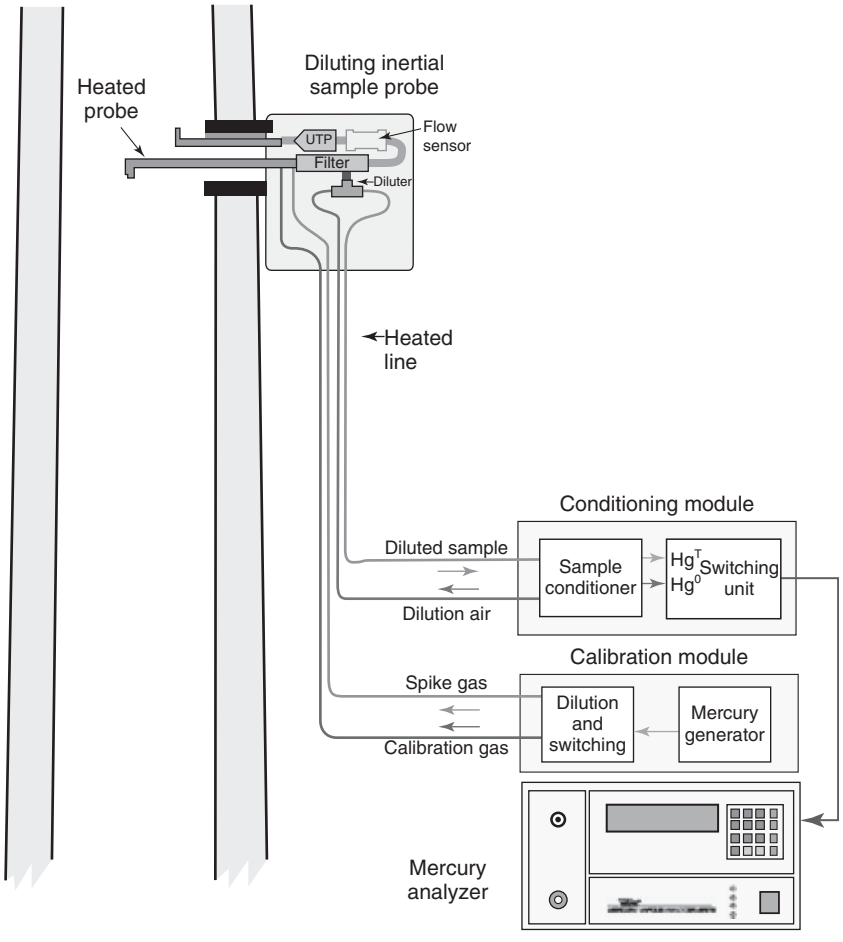

Figure 5.1 Diagram of a CMM.

manufactured by Thermo Scientific and about one-third by Tekran, with a small number supplied by other CMM vendors [1].

5.2 Components of a CMM

In general, a CMM designed for combustion flue gas has four main sections: the probe, the pretreatment and conversion system, the mercury analyzer, and the calibration system. How each of these sections is configured is highly dependent on the vendor. A diagram illustrating this is shown in Figure 5.1.

5.2.1 Mercury Analyzer

With several exceptions, all mercury analyzers measure mercury using either cold-vapor atomic absorption spectroscopy (CVAAS) or cold-vapor atomic fluorescence spectroscopy (CVAFS).

5.2.1.1 Cold-Vapor Atomic Absorption Spectrometry

The most popular method for determining mercury in almost any type of sample in the past has been based on CVAAS and the technique is still widely used today. Mercury is unique among metals in that it has a very high vapor pressure at relatively low temperatures and can be introduced quantitatively to the spectrometer as a vapor without difficulty. Absorption at 253.65 nm in the ultraviolet (UV) region has been measured with the use of mercury vapor lamps as well as hollow cathode lamps as the light source. Such methods are quite old; mercury vapor meters were first developed in the 1930s [2]. A typical CVAAS scheme is shown in Figure 5.2. CVAAS systems typically are considered to have detection limits somewhere in the $0.05-1.0\,\mu g\,m^{-3}$ range, depending on the design of the system.

When mercury concentration in a mixed gas stream is measured, a number of gases such as SO_2 can interfere with a CVAAS detector. A number of approaches have been taken to either remove these interference gases or greatly reduce their impact [3]. These include the use of a dual path with two detectors, gold amalgamation of the mercury, and the Zeeman effect.

In the dual-path method, the gas stream is split, with one of the streams having the mercury removed using a gold or activated carbon cartridge. The absorbance of the two streams is then subtracted, resulting in the absorbance due to the mercury. The second technique, gold amalgamation, is based on the selective adsorption of mercury on a gold surface at room temperature. Mercury is released from the gold trap by heating and then introduced into the spectrometer using an inert gas. As a result, the only gas analyzed is the mercury. The method has the advantage of not only removing interferences but also allowing for the mercury to be concentrated, making it possible to achieve increased sensitivity without actually

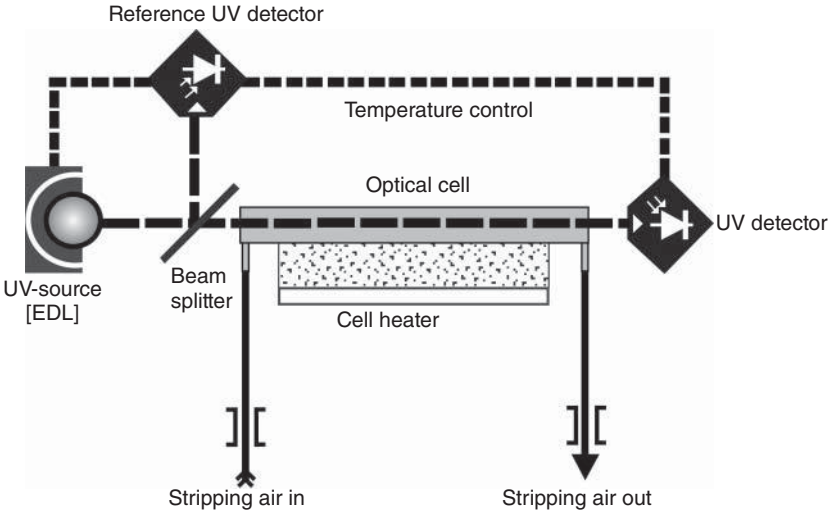

Figure 5.2 Simplified diagram of a CVAAS analyzer with dual beam (EDLs, electrodeless discharge lamps).

changing the detection limit. Because of this concentration effect, it is possible to use dilution to help minimize gases that could poison the gold trap, which is a concern when this technique is used.

As stated previously, one of the flue gas constituents that greatly reduces the sensitivity of CVAAS for mercury is SO_2, particularly in concentrations >100 ppm. Unfortunately, the UV absorption peak for SO_2 is a broad band that partially overlaps the mercury absorption peak of 253.65 nm. As a result, several mercury analyzers use the Zeeman effect to offset this. The Zeeman effect was first used as a background correction in the mid-1960s. The radiation source (mercury lamp) is placed in a permanent magnetic field, resulting in a frequency splitting. The total absorbance of the sample gas is measured at the center frequency. The absorbance of everything except mercury is measured on the slightly shifted frequency. The results are then subtracted, providing the absorbance due to the mercury present in the gas stream. Although this has proved effective, there is still a dependence on the concentration of the interfering gases [4].

5.2.1.2 Cold-Vapor Atomic Fluorescence Spectrometry

CVAFS makes use of the unique characteristic of mercury that allows measurement at room temperature. Free mercury atoms in a carrier gas are excited by a collimated UV source at a wavelength of 253.65 μm [5]. The excited atoms reradiate their absorbed energy (fluoresce) at this same wavelength. The fluorescence is omnidirectional and can be detected with a photomultiplier tube. The excitation path and viewing path are perpendicular to each other to allow separation. The CVAFS technique differs from the CVAAS technique in that it is more sensitive, more selective, and linear over a wide range of concentrations. However, any

molecular species, particularly diatomic molecules such as O_2 and N_2 present in the carrier gas, will quench the fluorescence signal. One method of circumventing this is to use gold-coated traps to collect mercury from the flue gas stream. The traps are then heated, releasing the mercury from the gold and using an inert carrier gas such as argon to carry the mercury to the detector. The method is highly sensitive, with a detection limit of $<0.1\ pg\ m^{-3}$, and inherently linear (greater than five orders of magnitude) [6].

However, several CMM vendors have taken the approach of simplifying the process by not using gold traps but directly analyzing the flue gas after diluting with N_2 to reduce the interfering gases. In this approach, the resulting quenching of the fluorescence is not considered significant when measuring mercury in combustion flue gases. The detection limit is still generally considered to be $<0.03\ \mu g\ m^{-3}$ [7].

5.2.1.3 Other Analytical Methods

Although almost all of the CMMs that have been developed for measuring mercury in fossil fuel-fired flue gases use either CVAAS or CVAFS, other techniques have been developed. One such method is plasma emission spectroscopy (PES). This method is the basis for the Envimetrics Argus-Hg CMM. In this process, a plasma source is generated using microwave technology. Because the plasma emits light that is characteristic of the induced molecule, a low-resolution spectrometer can then identify that molecule based on the UV spectrum [8].

At one point, Opsis introduced a true *in situ* analyzer based on differential optical atomic spectroscopy. However, this analyzer could only measure elemental mercury, with no possibility of measuring total mercury. Therefore, this analyzer had very limited application for measuring mercury in fossil fuel combustion streams [9].

Cooper Environmental has developed a CMM based on X-ray fluorescence (XRF). When materials are exposed to short-wavelength X-rays or gamma rays, ionization of their component atoms takes place. Ionization consists of the ejection of one or more electrons from the atom. The removal of an electron in this way renders the electronic structure of the atom unstable and electrons in higher orbitals "fall" into the lower orbital to fill the hole left behind. In falling, energy is released in the form of a photon, the energy of which is equal to the energy difference of the two orbitals involved. Thus the material emits radiation, which has an energy output that is characteristic of the atoms present. With a solid-state detector, the concentration of the atoms present in the gas can be determined, based on the emitted radiation [10]. This type of detector has the advantage of not only measuring the mercury concentrations but also other metals.

5.2.2 Pretreatment/Conversion Systems and Probe

For all CMMs, essential parts of the system are the pretreatment/conversion system and the probe. These have four major functions, which are as follows:

1) To provide a stinger and probe that is inserted into the flue gas to sample the flue gas.
2) To convert all mercury forms into elemental mercury.
3) To remove or greatly reduce gases that may interfere with the mercury analyzer.
4) To provide mercury speciation for some CMMs.

5.2.2.1 Sampling Probe

During the early development stage of CMMs, the probe consisted only of the stinger, the filter, and the filter holder. Some type of filter was necessary to prevent the fly ash from ruining the optics of the analyzer. However, depending on the flue gas and fly ash, it was discovered in the early 1990s that the fly ash captured on the filter could adsorb mercury and/or change the speciation [11]. As a result, methods were developed to remove the fly ash but minimize the contact between the collected fly ash and the mercury-containing flue gas. The most successful method was a concept called an *inertial separation probe* (*ISP*) [12]. A diagram of an ISP developed by ADA-ES is shown in Figure 5.3. As shown in Figure 5.3, a large amount of flue gas (>20 l min^{-1}) is pulled through the annulus of the ISP using an eductor. Typically, only about 0.5 l min^{-1} (may vary depending on the CMM) is needed for the CMM. The analyzer pump pulls the small amount of needed gas through the sintered-metal filter portion of the ISP, removing the particulate matter. The high velocity of flue gas passing through the annulus of the ISP continually removes the particulate matter, resulting in minimal contact between the particulate matter and flue gas passing into the mercury analyzer. A detailed diagram of the sintered-metal portion of the ISP is shown in Figure 5.4.

Although most of the CMMs currently available use some type of ISP, there have been several design changes over the past several years. One of the major changes occurred as a result of wet stacks [13]. The ISPs were being corroded by the acidic flue gas (see Figure 5.5) and also had severe plugging problems. As a result, more exotic alloys such as Hastelloy® are being used. Also, the flue gas flow rates through the ISP have been changed to help prevent plugging.

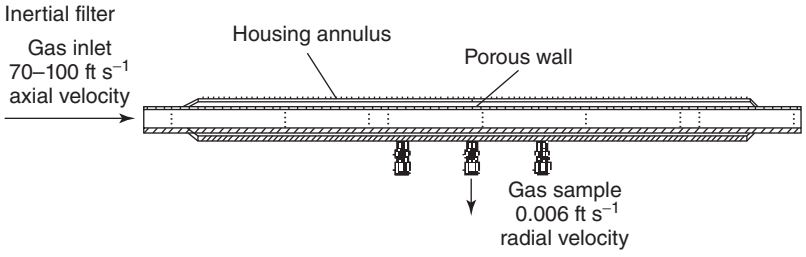

Figure 5.4 Detailed diagram of the inertial filter portion of the ISP. (Courtesy of ADA-ES, Littleton, CO.)

Figure 5.5 Photograph of a sampling probe after 1 month in a wet stack.

5.2.2.2 **Pretreatment and Mercury Conversion**

Pretreatment/conversion systems are essentially classified into two main types. The first are those based on wet chemistry and the second are those based on thermal decomposition. Almost all of the mercury research done in the 1990s and early 2000s used wet-chemistry systems. These systems can be utilized with either CVAAS- or CVAFS-based CMMs. A diagram of a typical wet-chemistry pretreatment conversion unit is shown in Figure 5.6 [14].

Because of the research nature of most of the work being done prior to the introduction of CAMR, it was also necessary that a CMM provide mercury speciation data. Therefore, the wet-chemistry pretreatment/conversion systems were designed such that the CMM would provide speciated data. As shown in Figure 5.6, the speciation was done by splitting the gas flow and passing each gas stream through a separate solution. To measure total mercury, the flue gas passed through a solution of $SnCl_2$/NaOH, which removed the acid gases and reduced all mercury forms to elemental mercury. To measure only elemental mercury, the flue gas passed through a solution of KCl or other Hg^{2+} solution, which removed oxidized forms of mercury. The difference between the two measurements is the concentration of oxidized mercury. For CVAAS mercury analyzers, it has been

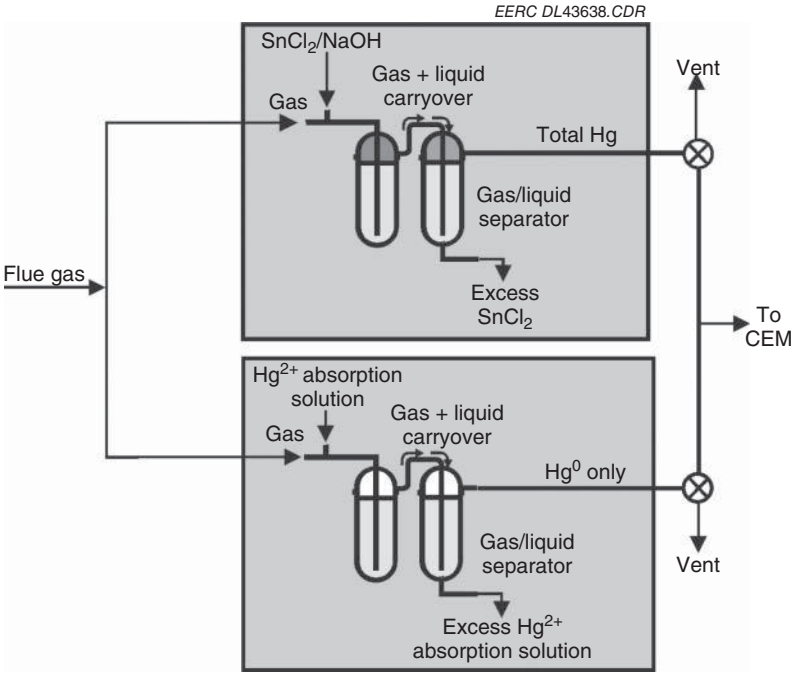

Figure 5.6 Diagram of a wet-chemistry pretreatment/conversion system for a CMM.

reported [15] that the efficiency of mercury conversion is greatly decreased by high levels (>500 ppm) of SO_2 in the gas stream. For a CVAFS mercury analyzer using gold traps, the acid gases must also be removed but for a different reason. If HCl and NO_2 are present in the flue gas, the gold trap is permanently poisoned [16]. To prevent this, it is necessary that the HCl (much easier to remove than NO_2) be removed prior to the flue gas passing through the gold trap.

Although the wet-chemistry pretreatment/conversion systems have worked well for research, they are not suited for long-term compliance monitoring for the following reasons:

- Extensive engineering or technician support is required.
- The NaOH solution will remove CO_2 from the sample gas, requiring that the CO_2 flue gas concentration be known.
- Tin plating and crystallization of solutions can cause problems.
- It is difficult to ensure that no cold spots accumulate mercury, which will show up as mercury spikes in the data.

For these reasons, the mercury CMM vendors developed other pretreatment/conversion systems that did not rely on wet chemistry.

Currently, almost all CMM pretreatment/conversion systems are based on thermal reduction of the Hg^{2+} forms of mercury to Hg^0. Because very high temperatures (near 900 °C) are needed to ensure complete reduction, it is

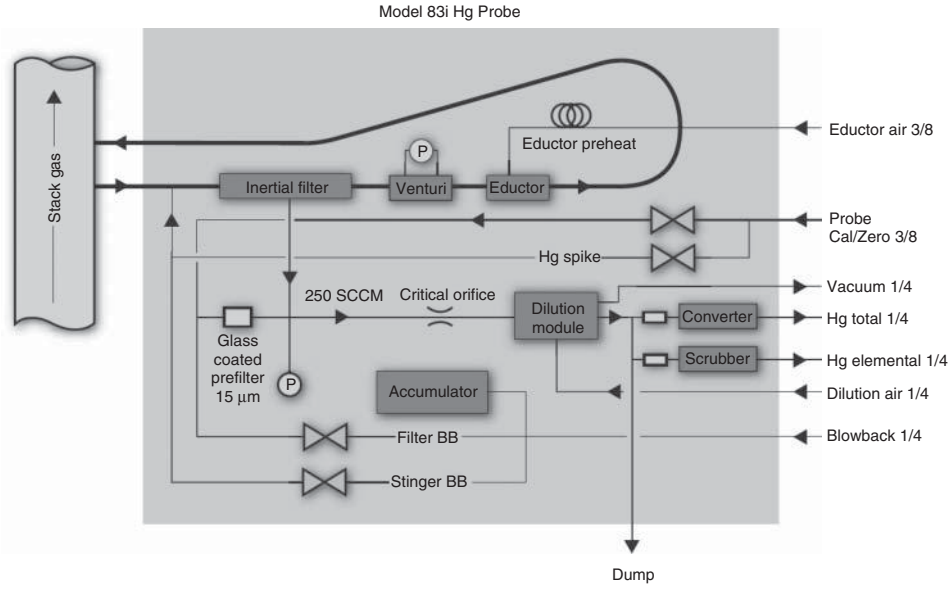

Figure 5.7 Diagram of the Thermo Scientific probe.

not practical to maintain these temperatures. If the temperature is allowed to decrease, the mercury will recombine, resulting in a low bias in the measurement [17]. Therefore, most CMM vendors use some form of catalytic dilution to reduce the temperature and, at the same time, prevent recombination. The actual catalyst used is considered propriety to the vendor. In addition, by diluting the gas stream, the potential of interference from other flue gas constituents is greatly reduced. Depending on the vendor, the pretreatment/conversion system is part of the probe (Thermo Scientific) or is a separate unit generally located near the analyzer section of the CMM (Tekran). A diagram of a pretreatment/conversion system is shown in Figure 5.7.

Typically, dilution systems are mostly associated with CVAFS mercury analyzers because of their inherent lower detection limits. However, some of the CVAAS systems that use gold traps to preconcentrate the mercury also use dilution. Although CVAAS systems have inherently higher detection limits than CVAFS systems, if the mercury is concentrated on the gold trap, low mercury concentrations can still be accurately measured by sampling and allowing more collection time.

5.2.3 CMM Calibration System

A critical component of any CMM is the ability to calibrate the monitor to ensure accurate results. In most continuous emission monitors (CEMs) such as those for

SO_2 or NO_x that are routinely used in power plants, calibration is done using certified calibration gas cylinders. However, because of the low mercury concentrations and the stability required, the development of these calibration gases has been difficult. NIST has been working with Spectra Gases in an attempt to certify calibration gases [18]. Because of the cost and volume of gas needed to conduct a CMM calibration prescribed by Performance Specification (PS)-12A, most likely these calibration gases will have limited uses. As a result, all CMM systems sold today provide an elemental mercury calibrator. These calibrators are either internal to the mercury analyzer or a separate unit. The elemental mercury calibration gas is generated either by heating a pool of elemental mercury so that a carrier gas is saturated and then the concentration is determined, based on the mercury vapor pressure curves or by using permeation devices. In either case, it is critical that the temperature and flow rates of the calibration devices be maintained very precisely. In most CMMs, the generated elemental mercury calibration gas can be sent to a variety of points within the system, from the probe tip to directly into the mercury analyzer. This allows not only for instrument calibration but also for troubleshooting the instrument and providing quality control checks. A diagram of a typical elemental mercury calibration system is shown in Figure 5.8.

When the CAMR was promulgated, the calibration requirements for CMMs stated that the calibrators were to be NIST-traceable. The same NIST traceability is also part of the new National Emission Standards for Hazardous Air Pollutants (NESHAPs) for coal-fired power plants as NIST traceability is required under PS-12A. In 2005, with funding from EPA, NIST began developing protocols for producing vendor prime calibration systems. To date, NIST has certified and recertified its NIST Prime elemental Hg generator and has certified the first round of the vendor prime generators. Vendor prime generator recertification is

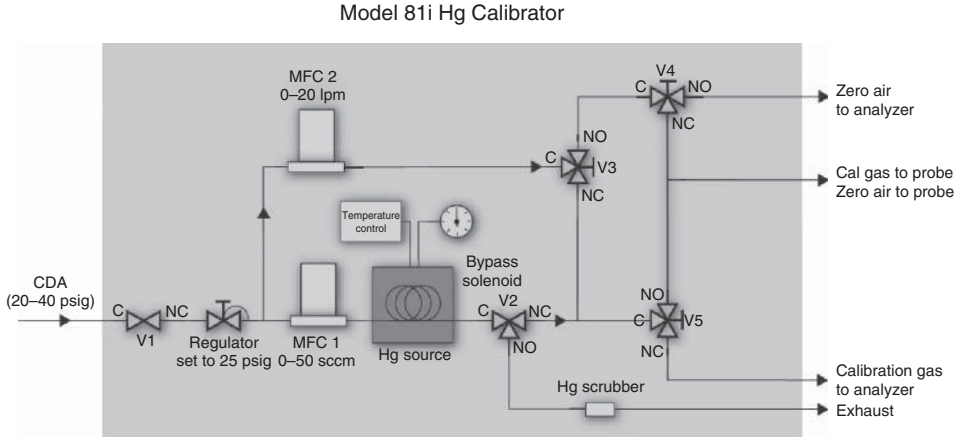

Figure 5.8 Diagram of the Thermo Scientific elemental calibrator.

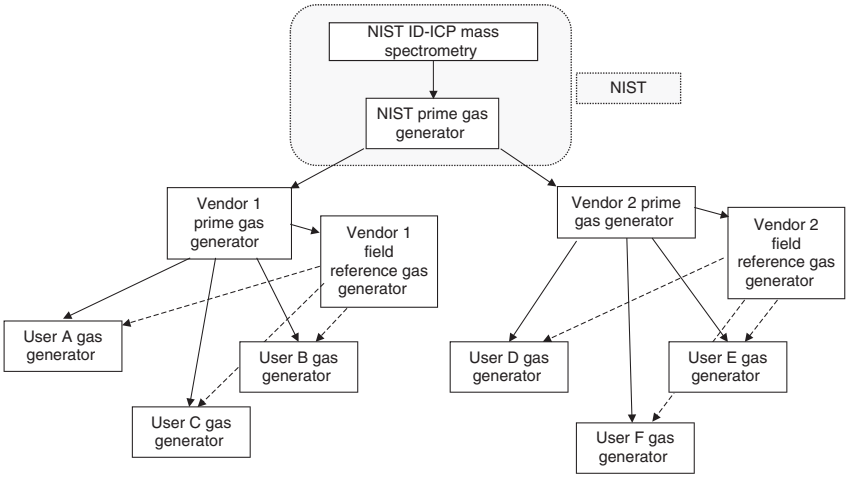

Figure 5.9 NIST traceability scheme for CMM calibration.

expected to begin in the near future [18]. The overall NIST traceability scheme for CMMs is shown in Figure 5.9.

PS-12A requires that compliance CMMs be calibrated using both NIST-traceable elemental mercury calibrators and oxidized mercury calibrators. The primary purpose of the oxidized mercury calibrator is to ensure that the conversion system is converting all mercury to Hg^0 and not creating a low bias. Rather than actually providing vendor prime NIST-traceable oxidized mercury calibrators, it was determined by EPA that NIST-traceability would be accomplished by certifying that all parts of the system be NIST-traceable. For example, the source of mercury, mass flow controllers, and temperature controllers would need to be NIST-traceable. As a result, NIST-traceable protocols for oxidized mercury calibrators were not needed.

There have been essentially two approaches to the manufacture of oxidized mercury calibrators. The first approach is to use the HovaCal® gravimetric approach. A NIST-traceable $HgCl_2$ solution is made or bought and weighed precisely on a continuous basis. A small amount of the $HgCl_2$ solution is continuously pumped in an evaporator, resulting in gaseous $HgCl_2$. Using mass flow controllers, a mercury-free carrier gas is then mixed with the $HgCl_2$ vapor, which is introduced into the CMM. This is the procedure used by Tekran and also by Cemtrex. A diagram of the technique is shown in Figure 5.10.

The second approach is to convert the mercury generated by a NIST-traceable elemental mercury calibrator to $HgCl_2$. This is done by passing the output of the elemental mercury calibrator over a heated catalyst and introducing Cl_2. This the procedure used by Thermo Scientific for its oxidized mercury calibrator. Spectra Gases also has patented a version of this calibrator called *MerCal*™ [19].

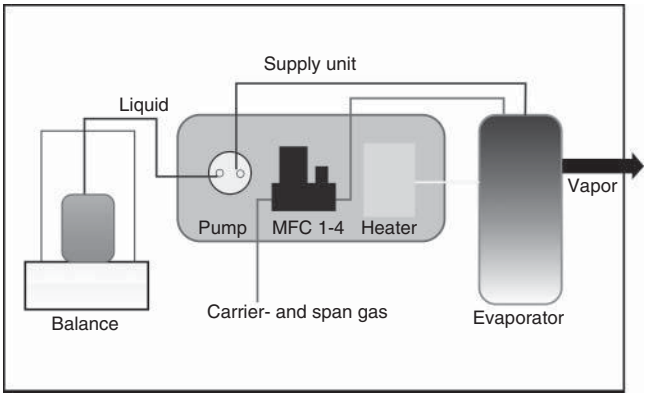

Figure 5.10 Basic diagram of a gravimetric oxidized mercury generator.

5.3 Installation and Verification Requirements

Installation and verification of CMMs for power plants are detailed in PS-12A. The following is a brief summary of PS-12A, which assumes that the vendor recommendations for installation are also being followed.

5.3.1 Installation

Obviously, for compliance purposes, the CMM must be installed following the last air pollution control device. This most often will be at stack location. However, it is important that the CMM probe be installed in a location that is readily accessible, as some maintenance will be required. Therefore, a duct location may also be considered. Because a CMM is a single-point monitor, it is required that the location be chosen such that the flue gas is representative with little or no stratification. As such, the chosen location must follow the requirements of EPA Method 1 and be at least two equivalent diameters downstream of the nearest control device or any other point at which a change in gas flow or mercury concentration could occur. This may require mercury stratification testing using EPA Method 30B or, alternatively, SO_2 stratification testing.

Once the sampling location has been chosen, the stinger is inserted such that it is no <1.0 m from the stack wall or duct. Also, it must be within the centroidal velocity traverse area of the stack or duct cross section.

5.3.2 CMM Verification

Three tests must be performed to certify a CMM installation:

1) Measurement error (ME)

2) Seven-day calibration drift (CD)
3) Relative accuracy test audit (RATA).

5.3.2.1 Measurement Error

This test requires that three levels (zero, midlevel, and high) of a mercury reference gas be sequentially injected into the CMM such that all sections of the CMM are challenged. This test is done in triplicate. Using the average CMM value, the ME for each of the three reference gas concentrations is calculated using the following equation:

$$\mathrm{ME} = \frac{|R - A|}{\mathrm{Span}} \times 100\% \tag{5.1}$$

where R is the reference gas concentration and A is the average of the CMM reading for the three injections at that reference gas level. The span gas is defined in PS-12A as gas concentration no greater than twice the emission limit. To pass the ME test, each of the values calculated using Equation 5.1 must be ≤5%.

5.3.2.2 Seven-Day Calibration Drift

The purpose of the CD test is to verify the ability of the CMM to conform to the established response used for determining emission concentrations. The test is conducted with a zero gas and either the mid-level or high-level gas used for the ME test. The gases are added to the probe sequentially. The CD is calculated using Equation 5.2. This test is done for seven consecutive operation days.

$$\mathrm{CD} = \frac{|R - A|}{\mathrm{Span}} \times 100\% \tag{5.2}$$

To pass the CD test, each of the values calculated using Equation 5.2 must be ≤5% for each of the 7 days.

5.3.2.3 Relative Accuracy Test Audit

The third CMM verification test that must be performed is a RATA. This test involves comparison of the mercury concentration measured using a reference method (RM) to the average CMM concentration measured over the same time period. Although an instrumental RM (EPA Method 30A) can be used in almost all cases, the procedures outlined in EPA Method 30B (sorbent traps) are used.

A RATA using EPA Method 30B requires that nine paired sorbent samples (C_a and C_b) be taken at a representative location in the same duct or stack as the CMM. Depending on the potential for the flue gas to be stratified, this may or may not involve traversing. To be a valid pair, the relative difference between the two paired samples (Equation 5.3) must be ≤10% at Hg concentrations ≥1.0 μg m^{-3}. If the average Hg concentration is ≤1.0 μg m^{-3}, then the relative difference between the paired samples must be ≤20% or have an absolute difference of ≤0.2 μg m^{-3}.

$$\mathrm{RD} = \frac{|(C_a - C_b)|}{(C_a + C_b)} \times 100\% \tag{5.3}$$

The relative accuracy (RA) is calculated using Equation 5.4. Note that the mercury concentrations for the CMM and RM must be on the same basis, either wet or dry.

$$\mathrm{RA} = \frac{|\overline{d}| + |\mathrm{cc}|}{\overline{\mathrm{RM}}} \times 100\% \tag{5.4}$$

where $\overline{d}$ is the sum of the difference between the RM concentrations and the corresponding CMM concentration, cc is the value of the confidence coefficient (Equation 5.5), and $\overline{\mathrm{RM}}$ is the mean of the RM values.

$$\mathrm{cc} = t_{0.025} \frac{S_\mathrm{d}}{\sqrt{n}} \tag{5.5}$$

where $t_{0.025}$ is the Student t value based on n (from statistical tables), S_d is the standard deviation (Equation 5.6), and n is the number of paired RM tests.

$$S_\mathrm{d} = \sqrt{\frac{\sum_{i=1}^{n} d_i^2 - \frac{\left(\sum_{i=1}^{n} d_i\right)^2}{n}}{n-1}} \tag{5.6}$$

To pass the RATA, the calculated value RA in Equation 5.4 must not exceed 20%. Alternatively, if an average RM concentration is $<5.0\ \mu g\ m^{-3}$, the results are acceptable if the absolute value of the difference between the mean RM values and CMM does not exceed $1.0\ \mu g\ m^{-3}$.

5.4 Major CMM Tests

Over the last 15 years, a number of tests have evaluated the ability of CMMs to measure mercury at fossil fuel-fired boilers. These tests have been conducted by the vendors themselves and/or the utilities as well as by independent agencies such as the U.S. Department of Energy (DOE), EPA, and the Electric Power Research Institute (EPRI). Below is a summary of some of these tests.

One of the first systematic tests was funded by EPA and DOE at a cement plant in Holly Hills [20]. Three different CMMs were tested at the Holly Hills cement plant in 1995. The installed CMMs were compared to the RM, EPA Method 29. In general, these tests were not very successful for a number of reasons. The cement plant burned a wide variety of fuel, including hazardous wastes and, as such, the flue gas constituents changed widely during the testing. Because the effects of these flue gas constituents were not very well known at the time, the CMM mercury measurements were not very accurate. Also, there were several mechanical and engineering problems because these instruments were still in the development stage.

EPA's Environmental Technology Verification Program's Advanced Monitoring Systems Center, operated by Battelle under a cooperative agreement with EPA, between 2001 and 2007, evaluated 10 different instrumental CMMs and a sorbent trap CMM. The verification testing was conducted in three phases. It should be noted that not all CMMs were tested in all three phases. In the first phase, four CMMs were tested under conditions simulating (i) coal-fired flue gas and (ii) municipal incinerator flue gas. The tests took place at a pilot-scale incinerator in Research Triangle Park, North Carolina, over a 3-week period. In the second phase, five CMMs (including two of the technologies tested in the first phase) were evaluated at a full-scale hazardous waste incinerator in Oak Ridge, Tennessee. The third phase was conducted at a coal-fired power plant. The reports for each of these systems are available on EPA's Web site at *www.epa.gov/etv/vt-ams.html#mcem*. As would be expected, the results were mixed. Some of the systems compared very well to the RM, while others had more difficulties.

One of the more extensive field tests was completed at Tennessee Valley Authority's Trimble County Power plant, Unit 1 [21]. This plant burns an eastern bituminous coal, utilizes selective catalytic reduction for NO_x removal (operates during the ozone season), an electrostatic precipitator, and a wet scrubber. As a result, the mercury concentration at the outlet of Unit 1 was low, typically $<2.0\,\mu g\,Nm^{-3}$. Testing began in November 2004 and continued through September 2005. The purpose of this field test program was to collect data to assess the ability of commercially available CMMs to provide reliable and accurate data over an extended time period while meeting certification, durability, data availability, and setup/maintenance requirements. In particular, data were collected to assess the ability of the CMMs to satisfy the requirements of PS-12A. The testing was divided into two phases (Phases 1 and 2). Phase 1 consisted of the setup and verification of four different CMMs at the power plant. In addition, some data were gathered as to the maintenance requirements. In Phase 2, two additional CMMs (plus the original four) were added and verified. Phase 2 saw 7 months of testing.

The results of this test program demonstrated that the source characteristics can have a significant effect on CMM performance. Regardless of the vendor supplying the CMMs, it is clear that CMMs should be appropriately modified for the source. For instance, the source sampled for this demonstration project had a wet stack and thus required a CMM with efficient sample transfer and conditioning capabilities in order to function properly. Detailed results of this test program can be found at *www.epa.gov/ttn/emc/cem/hgcemsdemo.pdf*.

With the promulgation of the Utility NESHAPs Mercury and Air Toxics (MATs), mercury limits are based on maximum achievable control technology (MACT). Obtaining this level of control will often require measuring mercury at concentrations $<1.0\,\mu g\,m^{-3}$. There is little data in the literature as to the validity of using CMMs to consistently and accurately measure mercury concentrations $<1.0\,\mu g\,m^{-3}$. As a result, the Energy & Environmental Research

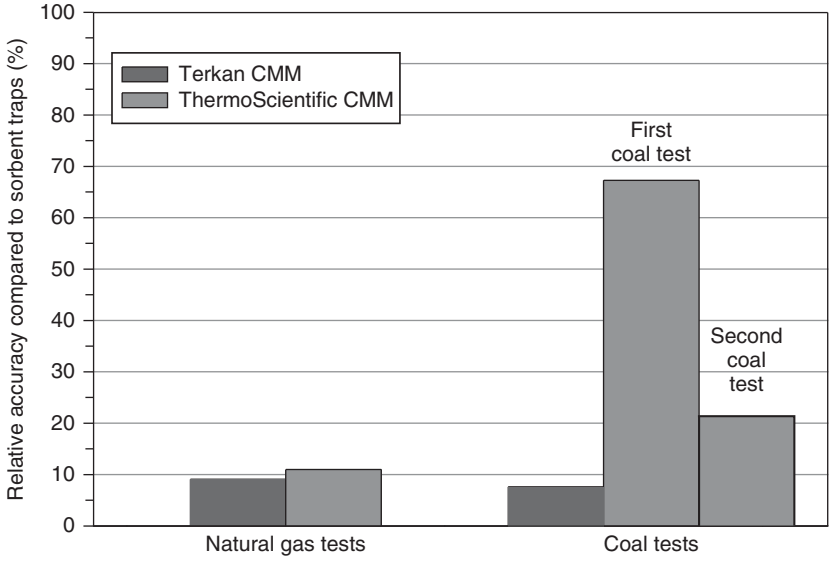

Figure 5.11 Summary of the low-level mercury testing at the EERC.

Center (EERC), with funding from the Illinois Clean Coal Institute (ICCI), DOE, EPRI, and the EERC Center for Air Toxic Metals®, conducted a pilot-scale test program to systematically determine the precision and accuracy of the two most widely used CMMs by the utility industry – Tekran and Thermo Scientific CMMs – when measuring mercury at these levels [22]. The first portion of the test was conducted firing natural gas with 0.5–1.0 $\mu g\,Nm^{-3}$ of elemental and oxidized mercury spiked into the flue gas. The second portion of the test involved firing an Illinois bituminous coal with a baghouse and wet scrubber in operation. Again, the outlet mercury concentration was $<1.0\,\mu g\,Nm^{-3}$. A summary of the results are shown in Figure 5.11. As can be seen in Figure 5.11, the results for the Thermo Scientific CMM were problematic. This was believed to be a result of a software error; therefore, a second week firing coal was conducted using only the Thermo Scientific CMM. The results were considerably better the second week. In general, it was concluded that both instruments provided quite good agreement with the RM even at these low mercury concentrations. Detailed results of this test program can be found at the ICCI Web site at *www.icci.org/reports/10Laudal6A-1.pdf*.

Under the MATs rule, the reliability of CMMs will be a critical issue as utilities will be penalized for incomplete or missing data. Although the experiences of the utilities with CMMs have been varied, in general, once these instruments have been installed, are operating correctly, and properly maintained, they are highly reliable. Figure 5.12 shows the percent availability for 10 different Tekran monitors over the year 2009 [23]. As can be seen, the average reliability was >91%, with the lowest being about 87%. This is typical of many of the CMM installations.

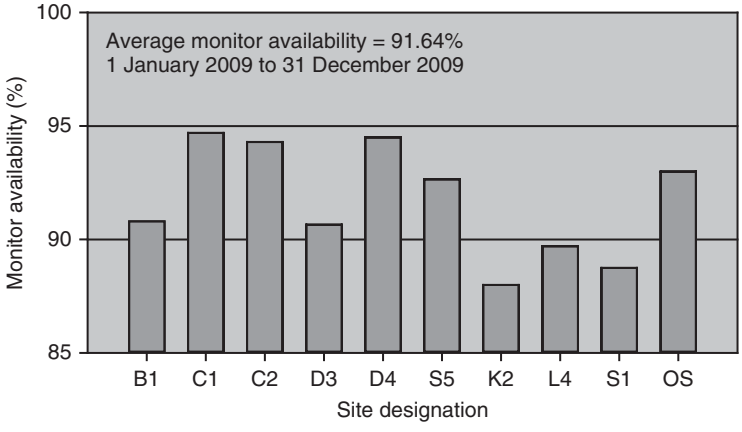

Figure 5.12 Availability of Tekran CMM during the 2009 calendar year.

5.5 CMM Vendors

As stated earlier, most of the CMM sales to the utility industry have been either Tekran or Thermo Scientific. However, a number of other vendors are also offering complete systems. Table 5.1 provides a listing of vendors that have the potential to provide complete mercury measurement systems to the utility industry as of 2011. Currently, these other instruments have primarily been used to measure mercury for non-utility industries such as incineration, natural gas refining, mining, or the manufacture of cement. For a detailed description of the CMMs, Web sites are provided in Table 5.1.

6
Batch Methods for Mercury Monitoring

Constance Senior

6.1
Introduction

The previous chapter discussed continuous emissions monitoring systems (CEMS) for quantifying mercury concentrations in combustion flue gas. In this chapter, several batch methods for quantifying mercury concentration are discussed. A number of batch, wet-chemistry based methods are available for measuring mercury in flue gas. Recently, dry batch methods, also known as *sorbent trap methods*, have been preferred for many applications. In the United States, sorbent trap methods have been specified by the U.S. Environmental Protection Agency (EPA) as being acceptable for compliance with federal mercury emissions standards for a number of industrial combustion sources.

6.2
Wet Chemistry Batch Methods

6.2.1
Early EPA Total Hg Methods

EPA developed several wet chemistry methods for measuring mercury in industrial stack gases in order to quantify emissions. Descriptions of these methods can be found at the EPA website [1]. EPA Method 101A was developed for determination of gaseous and particulate mercury emissions from sewage sludge incinerators, but is often applied to coal-fired boilers to measure total mercury emissions. EPA Method 29 was developed to measure mercury and other metals in stack emissions.

Figure 6.1 gives a schematic of Method 101A. A probe is inserted into the flue gas with a nozzle designed for isokinetic sampling of the flue gas. A pitot tube probe and a thermocouple are also inserted into the duct. The size of the nozzle is matched to the gas velocity in the flue gas. The probe is traversed in the flue gas during the test in order to collect a representative sample. The sample is

Mercury Control: for Coal-Derived Gas Streams, First Edition.

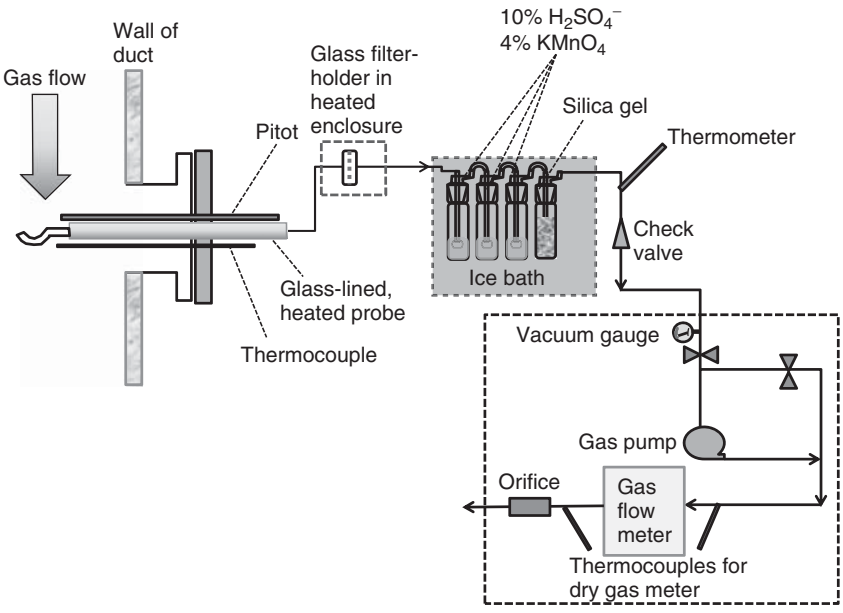

Figure 6.1 Schematic of EPA Method 101A.

withdrawn through the probe and into a heated filter. The filter collects the particulate matter (PM). After the filter, the sample gas is pulled through a series of four glass impingers in an ice bath. The first three impingers contain a solution of 4% $KMnO_4$ – 10% H_2SO_4 (wt% basis). The fourth impinger contains silica gel to dry the gas. Following the impingers, there is a pump and dry gas meter.

EPA Method 29 is designed to measure the solid particulate and gaseous emissions of mercury and 16 other trace elements (antimony, arsenic, barium, beryllium, cadmium, chromium, cobalt, copper, lead, manganese, nickel, phosphorus, selenium, silver, thallium, and zinc). The equipment and sampling train are similar to that for Method 101A, with the exception of the impingers. In Method 29, gaseous metals and mercury are collected in two impingers in series containing an acidic peroxide solution (5% HNO_3/10% H_2O_2). An empty impinger follows the first two impingers in the train. Elemental mercury that passes through the first three impingers is collected in the two following impingers in series containing acidified permanganate (10% H_2SO_4/4% $KMnO_4$). A final impinger containing silica gel is used to dry the sample gas. After the measurement, the contents of the peroxide impingers are saved separately from the contents of the permanganate impingers in an attempt to quantify mercury speciation.

A minimum sampling time of 2 h is recommended for Method 101A. Similar sampling time is usually used for Method 29. The limits of detection of the methods may be improved by increasing the sample time. In Method 101A, if there is an excess of oxidizable organic matter in the gas stream, it may be impossible to

sample for the minimum time. This problem will be indicated by the loss of the purple color of the $KMnO_4$ solution.

Both methods require leak-checking before and after the test. Post-test, the glassware, including the glass-lined probe, must be rinsed, and the rinsate saved for analysis. The method also requires the use of blanks for the impinger solutions and the filter in the field. After the test, the filter, collected solutions, and blanks are analyzed in a commercial laboratory using cold-vapor atomic absorption (CVAA) spectroscopy.

Three replicate measurements are usually conducted for these methods. These can be done in 1 day, but are often completed over 2 days. The methods require considerable time to set up and recover samples from each measurement. A high level of quality assurance/quality control (QA/QC) and well-trained personnel are needed for these wet chemistry methods.

6.2.2 Development of Wet Chemistry Methods to Speciate Hg

EPA Method 29 was not originally designed for mercury speciation analysis. In the 1980s, various research groups evaluated the method for mercury speciation, because it was thought that the gaseous oxidized (Hg^{2+}) and elemental (Hg^0) species would be selectively absorbed in the separate acidified hydrogen peroxide and acidified permanganate solutions, respectively. However, experience from data validation experiments showed that the two different impinger solutions were not effective for reliably separating the Hg^{2+} and Hg^0 species in a coal-combustion flue gas containing high levels of SO_2. As a consequence, several groups proposed modifications to the impinger solutions used in EPA Method 29. These included the Ontario Hydro, Tris buffer, and Research Triangle Institute (RTI) methods. All three methods used the framework of Method 29, but substituted different impinger solutions for the speciation of mercury [2].

The Ontario Hydro method was developed by Dr. Keith Curtis and colleagues at Ontario Hydro Technologies in late 1994. In this method, three aqueous 1 N potassium chloride (KCl) impinger solutions were substituted for one of the HNO_3–H_2O_2 solutions. Originally, no acidified peroxide impingers were included in the sampling train. However, it was discovered that when SO_2 concentration in the flue gas was >~750 ppm, the SO_2 reacted with the $KMnO_4$ neutralized, which meant that sampling time had to be very short. To avoid this problem, an impinger of acidified peroxide solution was used directly after the KCl impingers in order to absorb the SO_2. It is assumed that any mercury collected in the acidified peroxide solution was Hg^0, as the KCl solutions would collect all of the Hg^{2+}. Early testing also showed a substantial portion of the mercury was lost from the solutions [3]. To prevent this, acidified permanganate, dichromate, or acidified peroxide solution was added to the KCl solution immediately following sampling.

Formal evaluation of the Ontario Hydro method was completed with dynamic spiking of Hg^0 and $HgCl_2$ into a flue gas stream [3]. The Ontario Hydro method

Table 6.1 Comparison of wet chemistry methods.

Method	Sampling train configuration		Impinger configuration (number of impingers – impinger set solution)			Analytical method
	Front-half collection (PM and Hg_p)	Back-half collection (gaseous Hg)	First set	Second set	Third set	
EPA Method 101A	Glass fiber filter	Impinger solutions	$3H_2SO_4$ – $KMnO_4$	None used	None used	CVAA
EPA Method 29	Glass fiber filter	Impinger solutions	$2HNO_3$ – H_2O_2	1 dry	$2H_2SO_4$ – $KMnO_4$	CVAA
Ontario-Hydro Method	Glass fiber filter	Impinger solutions	3KCl	$1HNO_3$ – H_2O_2	$3H_2SO_4$ – $KMnO_4$	CVAA

is now ASTM Method D6784-02 [4]. The method outlines QA/QC procedures, including leak-checking, calibration, and the use of blanks. The three wet chemistry methods discussed are compared in Table 6.1.

6.2.3 Method Application and Data Quality Considerations

The precision of measurement of particulate, oxidized, and elemental mercury is influenced by many factors: flue gas concentration, source, procedural, and equipment variables. To ensure that precise results are achieved, the sampling system must be leak-free, system components must be accurately calibrated, the proper sampling locations must be selected, glassware must be thoroughly cleaned, and prescribed sample recovery, preparation, and analysis procedures must be followed.

In the ASTM method description [4], 0.5 $\mu g\,m^{-3}$ is estimated as the lower limit for most applications. Ryan and Keeney [5] stated that, assuming a 50–50 split between oxidized and elemental mercury in a flue gas, the lower limit of quantitation for total mercury in the Ontario Hydro Method ranges from 0.31 to 0.62 $\mu g\,m^{-3}$. The lower limit of quantitation can be reduced by using low mercury calibration standards. However, at such low concentrations, achieving adequate blank samples may be difficult.

The impinger-based methods were designed to be used downstream of the plant's particulate control device. In many cases (for research or survey purposes), these wet methods are used before the particulate control device, when there is a lot of particulate matter present in the flue gas. In these situations, reactive particulate matter can bias the speciation. This bias can be manifest as either artificially high oxidized mercury (in the case of the Ontario Hydro Method) or high particulate mercury. All the sample gas must pass through the filter. Gaseous mercury species in flue gases can interact with fly ash particles collected

on the filter and can produce a positive particulate mercury bias. In some cases, particulate-bound mercury collected on the filter can volatilize because of flue gas exposure, and be collected in the impingers. Such vaporization losses of mercury result in a negative particle-bound mercury bias.

There are practical limitations to the impinger-based methods arising from the complex sample trains, which are composed of relatively large amounts of glassware and tubing. Furthermore, the glass impingers contain strongly oxidizing and acidic reagents requiring labor-intensive sample recovery and analytical procedures. Usually, these solutions must be shipped to a laboratory quickly. In some cases, testing contractors have brought complete analytical laboratories on-site for analysis. This reduces the turnaround time for obtaining results, but can substantially increase the cost of the measurements.

6.3
Dry Batch Methods

6.3.1
Sorbent Trap Method History

In this section, the general concept of sorbent trap methods will be discussed, in addition to specific methods such as Performance Specification 12B (PS-12B) and Method 30B. In addition, speciation sorbent traps, which are used for research and demonstrations, will also be discussed.

Sorbent trap methods for measuring mercury in combustion gas were developed in the early 1990s in the United States and have been used, in one form or another, for the last 20 years. The first method was developed by Frontier Geosciences and was called the *mercury speciation adsorption* (*MESA*) method [6]. The MESA method was used in a number of pilot and field demonstrations of mercury control technology on coal-combustion systems in the mid- to late-1990s [7]. Improvements were made to the method, under sponsorship of the Electric Power Research Institute (EPRI), and the resulting method was known as *QuickSEM*. In 2004, U.S. EPA adopted the method as part of the draft Utility Mercury Reduction Rule and called it *Method 324*. In 2005, EPA proposed a different utility regulation on mercury emissions called the *Clean Air Mercury Rule* (*CAMR*); CAMR utilized a sorbent trap method known as the *Appendix K method*. CAMR was ultimately not promulgated by EPA. In 2010, EPA included PS-12B in the compliance monitoring procedures promulgated as part of the Portland Cement Maximum Achievable Control Technology (MACT) rulemaking [8]. In February 2012, EPA finalized the Mercury and Air Toxics Standard (MATS) rule for utility boilers, and this rule included PS-12B as an acceptable method for mercury measurement for compliance with the rule.

Total mercury measurement is needed for compliance with regulations. However, scientists and engineers need to measure speciated mercury in flue

gas in order to evaluate control technology options. As discussed above, the wet method, the Ontario Hydro Method, provides speciated mercury information, but this method is complicated and time-consuming to implement. Therefore, speciation sorbent trap methods have been developed.

The MESA sorbent trap method uses a trap containing KCl/soda lime to collect oxidized mercury. It has been used for measurement of both total Hg and speciated Hg in flue gas as for the EPRI PISCES program [9, 10] and performance-tested for total mercury using EPA Method 301 [11, 12]. It was evaluated for speciated Hg in coal flue gas [13, 14]. Total Hg results were within acceptable limits for sensitivity, accuracy, and precision [13, 15].

Frontier Geosciences developed the flue gas mercury sorbent speciation (FMSS) method in which a semi-isokinetic sample was pulled from the flue gas through a mini-particulate filter and a heated solid sorbent sample train, consisting of parallel sorbent traps. Analysis of the filter was carried out for particulate mercury and the sorbents were analyzed for gaseous Hg species. In the sorbent trap section, the first trap contained dry KCl-coated quartz chips and was used to capture the oxidized mercury. The second trap contained iodine-impregnated activated carbon to capture the elemental mercury. The FMSS method was validated according to the modified EPA Method 301 [16]. EPA Method 301 [17] specifies procedures for determining the precision and bias of measured emissions using a specific method at the concentrations typical of the specific standard for the source.

Currently, the most widely used speciated Hg sorbent trap method is the flue gas adsorption for mercury speciation (FAMS) method [18], which uses the KCl/quartz trap to remove oxidized mercury and an activated carbon trap to remove elemental mercury. The FAMS method was also developed by Frontier Geosciences.

As both CEMS and sorbent trap methods for compliance with mercury emissions regulations were being developed, there was a need for a reference method (RM) to verify the performance of the measurement system once installed at a specific plant. This performance verification was initially conducted using wet chemical methods, such as the Ontario Hydro Method (ASTM D6784) as the RM. However, such methods proved to be complex, slow, and cumbersome. In 2007, the EPA issued a direct final rule to add two reference measurement methods for coal-fired power plants. The two methods, Method 30A and Method 30B, were intended for use in relative accuracy audits (RATAs) of mercury emissions monitoring systems installed in combustion systems. Method 30A was based on a continuous monitoring instrument, while Method 30B was a sorbent trap method [19].

Monitoring of mercury emissions from coal-combustion systems for compliance purposes in the United States can be carried out using either a continuous emission monitoring system (CEMS) (as specified in EPA's PS-12A) or a sorbent trap (PS-12B). A part of the certification process for either emissions monitoring system is a RATA, which can be performed using the Ontario Hydro Method, Method 30A (instrumental RM) or Method 30B (sorbent trap RM).

6.3.2 Method Overview

In a sorbent trap method, a known volume of flue gas is pulled through paired, pre-spiked traps located in the stack or duct. The exposed traps can be analyzed by any method that meets the specified QA/QC criteria. The collection of paired samples is needed to determine the method precision.

Figure 6.2 shows a general schematic of the sampling set-up for sorbent trap methods. Two sorbent traps are located in the flue gas duct (detail not shown in figure). Gas is drawn through the traps in parallel. The sample is not isokinetic. Sorbent trap methods are intended for use only under conditions of relatively low particulate loading (i.e., sampling after particulate control devices); in cases where significant amounts of particle-bound Hg may be present, an isokinetic sampling method for Hg should be used.

The rest of the sampling system consists of a system to remove moisture, a pump, and dry gas meter. The measurement of the temperature and pressure at the dry gas meter (sampling console) is critical for calculating an accurate sample volume. The actual temperature and pressure of the sampled (flue) gas is not required. For a continuous mercury monitor, the flow rate is adjusted to maintain sample flow rate in proportion with total flue gas flow rate in the duct.

6.3.3 Total Hg Measurements

6.3.3.1 PS-12B

The purpose of this method is continuous monitoring of mercury from combustion stacks. Each trap must have the sorbent configured into three sections

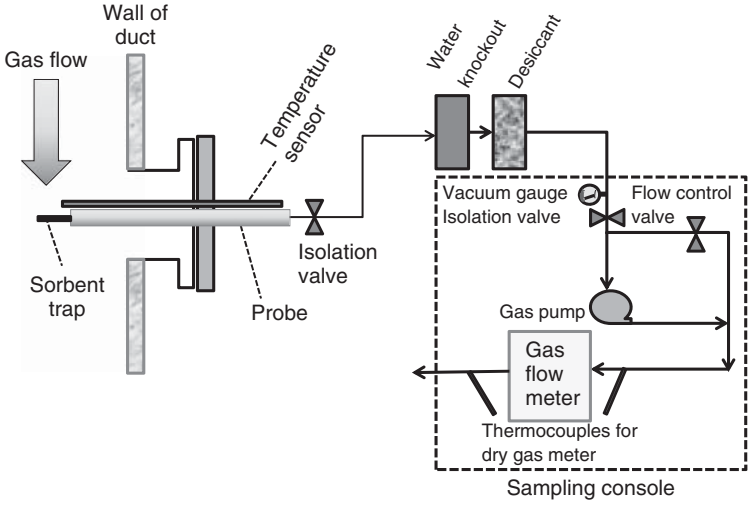

Figure 6.2 Schematic diagram of sorbent trap sampling system.

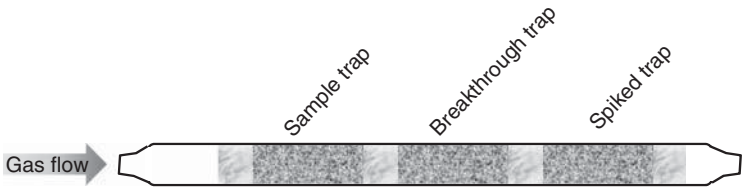

Figure 6.3 Three-section trap for PS-12B.

that can be tested independently (Figure 6.3). Plugs of quartz wool separate the sections. There is also a quartz wool plug before the first section and after the last section. A common trap sorbent material is activated carbon impregnated with a halogen such as iodine or bromine. The first section is for primary mercury collection. The second section is to provide an indication of mercury breakthrough. If there is too much breakthrough (i.e., too much mercury in the second trap), the sample could be invalidated. The third section is for spike recovery testing.

The spiked section is prepared in advance, using a mercury sample gas, which is flowed through the section. The method allows the use of any method for generating a known mass of gaseous elemental mercury as long as National Institute of Standards and Technology (NIST)-traceable standards are used. For example, an elemental mercury gas generator or cylinder of mercury calibration gas can be used to generate the mercury for the spike.

6.3.3.2 **Method 30B**

For RATA testing, Method 30B is used. The Method 30B trap has two sections, as shown in Figure 6.4. Quartz wool plugs separate the sections and an initial quartz wool plug removes any particles in the sample gas. There is no separate section for spiking but the first section of one of the paired traps is spiked with elemental mercury to assess the measurement bias and to verify data acceptability in the field.

6.3.4 Speciation Measurements

Speciation traps have been developed as an alternative to the Ontario Hydro Method for speciation of mercury in flue gas. As noted above, the most widely

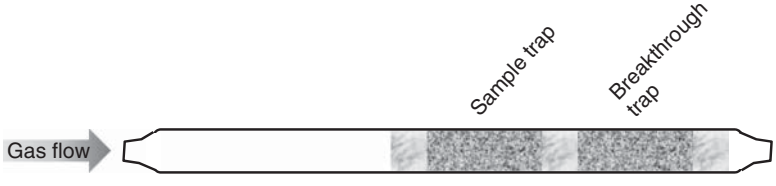

Figure 6.4 Two-section trap for Method 30B.

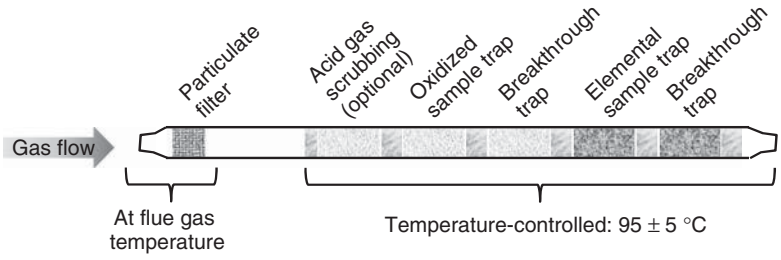

Figure 6.5 Sorbent trap configuration for speciated Hg measurement.

used speciation sorbent trap method is based on Method 30B [18]. Figure 6.5 shows a schematic of the sections in each trap.

In this method, there is a particulate collection section, followed by two sections to collect oxidized mercury (primary and breakthrough), which contain KCl on quartz chips, and two sections to collect elemental mercury (primary and breakthrough), which contain iodated or brominated carbon. An acid-gas scrubbing trap may also be used to remove acid gases like SO_2. In some implementations of speciation traps, the particulate collection section of the trap is at the temperature of the flue gas being sampled, and in other implementations, a quartz wool plug is used upstream of the first trap. In any case, the other sections of the traps are controlled to $95 \pm 5\,°C$ to prevent breakthrough of mercury on the KCl sections. One manufacturer of speciation traps also recommends that the trap should be kept 20–30 °C above the dew point of the sample gas in the duct [20].

Speciation sorbent traps use the same sampling apparatus as that for the total mercury methods, with the exception of a special probe to control the temperature of the sections intended to collect gaseous mercury.

6.3.5 Sampling Protocol

6.3.5.1 Procedure and Apparatus

The assembled system is leak-checked before the sampling begins and after the sampling ends. After a period of sampling, the traps are removed and the individual sections are analyzed to measure the total amount of mercury in the traps. The mass of mercury collected in the traps divided by the total gas volume over the period of the sampling indicates mercury concentration in the gas.

As noted above, the speciation trap method requires a temperature-controlled probe, which the total mercury trap methods do not.

During the sampling period, it is important to measure the characteristics of the flue gas, for example, the oxygen content, flue gas velocity, and the moisture content. These will be used to determine the sample rate (for proportional sampling) and to convert the results to the units of emissions (pound per trillion British thermal unit or pound per gigawatt hour). To compare the sorbent trap result to that

of a mercury CEMS, the results might have to be converted to concentration on a wet volume basis, because this is how some CEMS measure mercury in flue gas.

The sampling period is not specified in the methods. There are several factors that influence the sampling period. The total amount of mercury collected on an individual trap depends on the concentration in the flue gas, the sampling time, and the sample flow rate. The amount of mercury collected on a trap must fall within the range of the calibration curve for the analytical method. Furthermore, the spikes of mercury added to section 3 (PS-12B) or section 1 (Method 30B) must have a mass of mercury that is in the expected range of mercury to be collected in the sample (section 1). For Method 30B, the spiked amount of mercury must be within ±15% of the expected mass of mercury on section 1. Method 30B is not intended for long sample times, as is PS-12B. If the sample period for PS-12B is too long (days to weeks), there may be breakthrough of mercury from section 1 to section 2, which will invalidate the run. Finally, if the sampling time is too short (<30 min), then small errors in the start and end times might result in substantial errors in the measured concentration.

6.3.6 Trap Analysis

The two most widely used approaches to analyzing the traps for mercury are (i) a wet digestion method using cold vapor atomic fluorescence (CVAF) spectroscopy and (ii) direct pyrolysis into a CVAA analyzer. The latter approach can be done on site with the proper equipment, adherence to standards of cleanliness, and proper calibration. Analysis of the traps is destructive; if there is a problem with the analysis, it cannot be repeated. Elemental mercury will absorb 253.7 nm UV light, and a CVAA detector will have exquisite low detection limits for mercury. However, contaminants such as sulfur dioxide, water, oxygen, halogens, and organic species can interfere with the determination of elemental mercury by CVAA.

6.3.7 Relative Accuracy and Quality Assurance/Quality Control

The sorbent trap methods are performance-based, which means that while some specifics of the method are not dictated (e.g., sample time, trap composition), the method must meet rigorous QA/QC criteria. The QA/QC criteria for PS-12B [8] and Method 30B [19] are similar, as seen in Tables 6.2 and 6.3.

For PS-12B, initial certification of the system requires a RATA using an RM. Acceptable RMs are the Ontario Hydro Method, Method 30A, or Method 30B. Twelve RM samples must be taken and the best nine samples compared to corresponding sorbent traps. The average relative difference between the sorbent trap measurements and the RM can be no >20%. If the RM concentration is $\leq 5\ \mu g\ m^{-3}$, then the relative accuracy (RA) criterion is satisfied, if the difference between the average values of the continuous measurement and the RM is not $>1\ \mu g\ m^{-3}$.

Table 6.2 QA/QC criteria for PS-12B.

QA/QC test or specification	Acceptance criteria	Frequency	If criteria not met
Pre-monitoring leak check	≤4% of target sampling rate	Prior to monitoring	Cannot start sampling
Post-monitoring leak check	≤4% of target sampling rate	After monitoring	Data from pair traps invalidated, or if certain conditions met, report adjusted data from a single trap
Ratio of stack gas flow rate to sample flow rate	Hourly ratio may not deviate from the reference ratio by more than ±25%	Every hour throughout the monitoring period	Data from pair traps invalidated, or if certain conditions met, report adjusted data from a single trap
Sorbent trap section 2 breakthrough	≤5% of section 1 Hg mass	Every sample	Data from pair traps invalidated, or if certain conditions met, report adjusted data from a single trap
Paired sorbent trap agreement	≤10% relative deviation (RD) if the average concentration is $>1.0\,\mu g\,m^{-3}$ ≤20% relative deviation (RD) if the average concentration is $\leq 1.0\,\mu g\,m^{-3}$ Results also acceptable if absolute difference between concentration from parallel traps is $\leq 0.03\,\mu g\,m^{-3}$	Every sample	Either invalidate the data from the paired traps or report the results from the trap with the highest Hg concentration
Spike recovery	Average recovery between 85% and 115% for each of the three spikes' concentration levels	Prior to analyzing field samples and prior to the use of new sorbent media	Field samples must not be analyzed until the percent recovery criteria are met
Multipoint analyzer calibration	Each analyzer reading within ±10% of true value and $r^2 \geq 0.99$	On the day of analysis, before analyzing any sample	Recalibrate until successful

(*continued overleaf*)

Table 6.2 (*Continued*)

QA/QC test or specification	Acceptance criteria	Frequency	If criteria not met
Analysis of independent calibration standard	Within ±10% of true value	Following daily calibration, prior to analyzing field samples	Recalibrate and repeat independent standard analysis until successful
Spike recovery from section 3 of both sorbent traps	75–125% of spike amount	Every sample	Data from pair traps invalidated, or if certain conditions met, report adjusted data from a single trap
Relative accuracy (RA)	RA ≤20.0% of reference method (RM) value; or if RM value ≤5.0 μg m^{-3}, absolute difference between RM and sorbent trap monitoring system mean values ≤1.0 μg m^{-3}	RA specification must be met for initial certification	Data from the system are invalid until an RA test is passed
Gas flow meter calibration	An initial calibration factor (Y) has been determined at three settings; for mass flow meters, initial calibration with stack gas has been performed. For subsequent calibrations, Y within ±5% of average value from the most recent three-point calibration	At three settings prior to initial use and at least quarterly at one setting thereafter	Recalibrate meter at three settings to determine a new value of Y
Temperature sensor calibration	Absolute temperature measured by sensor within ±1.5% of a reference sensor	Prior to initial use and at least quarterly thereafter	Recalibrate; sensor may not be used until specification is met
Barometer calibration	Absolute pressure measured by instrument within ±10 mm Hg of reading with a NIST-traceable barometer	Prior to initial use and at least quarterly thereafter	Recalibrate; sensor may not be used until specification is met

Table 6.3 QA/QC criteria for Method 30B.

QA/QC test or specification	Acceptance criteria	Frequency	If criteria not met
Pre-monitoring leak check	≤4% of target sampling rate	Prior to monitoring	Cannot start sampling
Post-monitoring leak check	≤4% of target sampling rate	After monitoring	Data from pair traps invalidated, or if certain conditions met, report adjusted data from a single trap
Sorbent trap section 2 breakthrough	≤10% of section 1 Hg mass for Hg concentration is >1.0 μg m^{-3} ≤20% of section 1 Hg mass for Hg concentration is ≤1.0 μg m^{-3}	Every sample	Sample invalidated
Paired sorbent trap agreement	≤10% relative deviation (RD) if the average concentration is >1.0 μg m^{-3} ≤20% relative deviation (RD) or ≤0.2 μg m^{-3} if the average concentration is ≤1.0 μg m^{-3}	Every sample	Run invalidated
Multipoint analyzer calibration	Each analyzer reading within ±10% of true value and $r^2 \geq 0.99$	On the day of analysis, before analyzing any sample	Recalibrate until successful
Analysis of independent calibration standard	Within ±10% of true value	Following daily calibration, prior to analyzing field samples	Recalibrate and repeat independent standard analysis until successful
Temperature sensor calibration	Absolute temperature measured by sensor within ±1.5% of a reference sensor	Prior to initial use and at least quarterly thereafter	Recalibrate; sensor may not be used until specification is met
Barometer calibration	Absolute pressure measured by instrument within ±10 mm Hg of reading with a NIST-traceable barometer	Prior to initial use and at least quarterly thereafter	Recalibrate; sensor may not be used until specification is met

(*continued overleaf*)

Table 6.3 (*Continued*)

QA/QC test or specification	Acceptance criteria	Frequency	If criteria not met
Sample analysis	Within valid calibration range (within calibration curve)	All section 1 samples where stack Hg concentration is $\geq 0.5\,\mu g\,m^{-3}$	Reanalyze at more concentrated levels if possible, samples invalidated if not within calibrated range
Sample analysis	Within bounds of Hg^0 and $HgCl_2$ analytical bias test	All section 1 samples where stack Hg concentration is $\geq 0.5\,\mu g\,m^{-3}$	Expand bounds of Hg^0 and $HgCl_2$ analytical bias test; if not successful, samples invalidated
Field recovery test (spiked trap)	Average recovery between 85% and 115%	Once per field test	Field sample runs not validated without successful field recovery test
Gas flow meter calibration (at three settings)	Calibration factor Y within ±2% of average value of Y	Prior to initial use and when post-test check is not within ±5% of Y	Recalibrate at three points until acceptance criteria met
Gas flow meter calibration, post-test (single-point)	Calibration factor Y within ±5% of average value from the most recent three-point calibration	After each field test. For mass flow controllers must be done on-site using stack gas	Recalibrate at three points to determine new Y. For mass flow meters, must be done on-site using stack gas. Apply new Y values to field test data
Analytical matrix interference test (wet chemical analysis only)	Establish minimum dilution (if any) needed to eliminate sorbent matrix interferences	Prior to analyzing any field samples; repeat for each type of sorbent used	Field sample results not validated
Analytical bias test	Average recovery between 90% and 110% for Hg^0 and $HgCl_2$ at each of the two spike levels	Prior to analyzing field samples and prior to use of new sorbent media	Field samples shall not be analyzed until the percent recovery criteria has been met
Analysis of continuing calibration verification standard	Within ±10% of true value	Following daily calibration, after analyzing ≤10 field samples, and at end of each set of samples	Recalibrate and repeat independent standard analysis, reanalyze samples until successful, if possible; for destructive techniques, samples invalidated
Test run sample volume	Within ±20% of total volume sampled during field recovery test	Each individual sample	Sample invalidated

6.4 Recommendations

For long-term monitoring of mercury emissions or for short-term testing of mercury control technologies, CEMS or batch methods can be used. The two types of methods have advantages and disadvantages. Consideration should be given to some of the following factors when choosing a mercury measurement method.

6.4.1 Particulate Matter

If there is a need to sample a gas that has a high dust loading and there is an expectation that there will be a significant component of mercury in the particulate matter, the best option is one of the wet chemistry methods, which collect an isokinetic sample on a filter (bearing in mind the potential for bias because of the particulate matter on the filter). When sampling after the particulate control device, the mercury in the flue gas will be almost entirely gaseous mercury and a CEMS or sorbent trap will give representative results.

6.4.2 Total Versus Speciated Mercury

For evaluating emissions from a combustion source for compliance purposes, only total mercury is required. This can be measured with a CEMS or with one of the batch methods that measure total mercury (Method 101A, Method 29, PS-12B). For research or testing reasons, it is sometimes necessary to measure gaseous speciation; for example, if there is a need to quantify re-emission of elemental mercury across a wet scrubber, speciated mercury measurements (CEMS, Ontario Hydro Method, FAMS) should be made at the inlet and outlet of the scrubber.

6.4.3 Expected Mercury Concentration in the Flue Gas

The Ontario Hydro Method is generally accurate above a total mercury concentration in the flue gas of $0.5\,\mu g\,m^{-3}$, although the lower limit of detection can be higher, depending on the care taken by the test personnel. At present, NIST-traceable calibration gases for Hg CEMS provide concentrations from ~0.2 to $>40\,\mu g\,m^{-3}$. Most commercial CEMS can accurately measure mercury in flue gas down to the lower concentration of $0.2\,\mu g\,m^{-3}$. Sorbent traps can measure even lower concentrations of mercury in flue gas, because the sampling time can be increased to ensure that an adequate mass of mercury is collected in the traps. When very low levels of mercury are expected in the flue gas, sorbent traps are preferred.

6.4.4
Need for Real-Time Data

In some instances, a concentration of mercury averaged over 30 min to several hours (or even days) will suffice. In this case, batch sampling methods can be used. However, in some cases (for example, process control or short-term technology demonstrations), a continuous mercury measurement is required, and a CEMS must be used. Furthermore, batch methods use destructive analysis; if a measurement is lost or invalidated, there are no data for a specific period. CEMS provide data every 1–2 min typically.

6.4.5
Complexity of Installation and Operation

Sorbent trap methods are less expensive and complicated to install than CEMS or wet chemistry methods. Sorbent trap systems are less complex than CEMS and do not require as much training of technical personnel over long-term operation. Wet chemistry methods are not used for continuous monitoring of a source. These methods require specifically trained personnel and great care in preparation, set-up, and post-test sample collection and stabilization.

7
Mercury Behavior in Coal Combustion Systems

Constance Senior

7.1
Introduction

Control of mercury emissions from coal combustion systems relies on an understanding of the chemistry of mercury and its interactions with various elements in the combustion system. In coal utilization systems, mercury can take on different chemical forms in flue gas: gaseous elemental (Hg^0), gaseous oxidized (Hg^{2+}), and particulate-bound (Hg_p). As discussed in Chapter 1, the form in which mercury is emitted to the atmosphere determines its fate and transport in the environment. In this chapter, the factors influencing the forms of mercury found in coal combustion flue gas are elucidated.

Coal combustion systems that are used in electricity generating unit (EGU) boilers or industrial, commercial, and institutional (ICI) boilers have a variety of designs. The compositions of coals, which are burned to generate electricity and/or steam in these boilers, vary considerably. Finally, there are different types of air pollution control devices (APCDs) in use on coal-fired boilers to control emissions of NO_x, SO_x, and particulate matter (PM). These three factors – combustion system, coal type, and existing APCD configuration – affect the form and speciation of mercury that is emitted to the atmosphere and the degree of difficulty in controlling the emission of mercury to the atmosphere.

Later chapters in this book will discuss control technologies that are specific to mercury capture from coal-fired boilers. In this section, the groundwork will be laid for understanding mercury control technologies applied to coal combustion systems. The characteristics of coal combustion boilers and APCDs will be described. Then, the chemistry of mercury in coal combustion systems will be discussed. Finally, the behavior of mercury in the existing APCDs on coal-fired boilers will be explored.

7.2
Coal Combustion Boilers

The purpose of EGU or ICI boilers is to generate steam, which is used to generate electricity in EGU boilers and certain ICI boilers or to generate steam for chemical processes or heating in ICI boilers. Generating steam from coal combustion is accomplished by creating a high temperature gas and then transferring energy from the gas to water or steam, first in a radiant zone and then in a convective zone [1]. After this heat has been transferred, the flue gas has a temperature of 340–370 °C (650–700 °F). The combustion air is preheated in a gas–gas heat exchanger, called an *air preheater* (*APH*). The flue gas that exits the convective heat exchangers then passes through the APH, and its temperature drops to 135–175 °C (275–350 °F) as illustrated in Figure 7.1. The temperature of the flue gas drops rapidly from the combustion temperatures in the range of 900–1500 °C (1650–2750 °F) to post-APH temperatures in a few seconds [2]. The peak combustion temperature depends on the type of combustion system. This rapid quench of the flue gas has consequences for the chemistry of mercury in the gas, as discussed below.

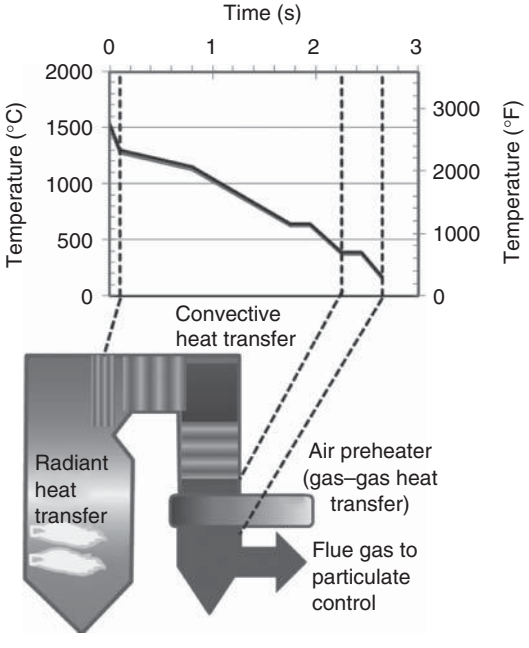

Figure 7.1 Time–temperature history in a coal-fired boiler from radiant section to air preheater.

7.3
Mercury Chemistry in Combustion Systems

Mercury is present in coal in low concentrations, on the order of 0.1 $\mu g\, g^{-1}$, as discussed in Chapter 2. In the combustion zone of a coal-fired boiler, all the mercury in coal is vaporized as elemental mercury, yielding vapor concentrations of mercury in the range of 5–40 $\mu g\, m^{-3}$. At furnace exit temperatures, all of the mercury is expected to remain as the thermodynamically favored elemental form in the gas. As the gas cools in the convective heat transfer zone, oxidation reactions can occur, significantly reducing the concentration of elemental mercury by the time the post-combustion gases reach the stack. Measurements of the concentration of mercury species taken in the stacks of pilot and full-scale coal combustion systems show that the range of the values of the fraction of oxidized mercury is broad: studies have reported anywhere from almost no Hg^{2+} to 95% Hg^{2+} upstream of the particulate control device (PCD) [3]. Laboratory experiments [4] have shown that mercury is not oxidized in the gas phase by O_2 at temperatures up to 700 °C (1290 °F). Combustion experiments in laboratory combustion systems have shown an increase in oxidized mercury post-combustion with increasing chlorine or bromine content [5–8]. Quench rate has been shown to affect the degree of homogeneous oxidation [6, 7].

Comparison of mercury speciation data from full-scale coal-fired boilers with those from particle-free laboratory combustion studies [9] shows higher amounts of oxidized Hg in the former, for similar amounts of chlorine in the fuel. Two conclusions arise from such comparisons:

- Oxidation of mercury by chlorine in practical coal combustion systems must be kinetically limited [10, 11].
- Heterogeneous oxidation of mercury on fly ash particles in coal-fired boilers is as important, or more important, than homogeneous oxidation of mercury [12, 13].

Gas-phase oxidation relies on the reaction between elemental mercury and halogen radicals. The inherent concentrations of these halogens in coal as well as the specific halogen species formed in the combustion system affect homogeneous mercury oxidation.

The range of concentrations of chlorine and bromine species in coal combustion flue gas depends on the concentrations in the coal. In U.S. coal-fired power plants, the concentration of HCl in the flue gas is on the order of 1–10 ppmv when low-rank coals (subbituminous and lignite) are burned, but HCl concentrations can be as high as 150 ppmv when bituminous coals are burned. These estimates assume coal chlorine concentrations of up to 100 $\mu g\, g^{-1}$ in subbituminous and lignite coals and up to 2000 $\mu g\, g^{-1}$ in bituminous coals. Bromine concentrations in coals are significantly less than chlorine concentrations, as discussed in Chapter 2. The concentrations of bromine (expressed as HBr) in the flue gas of coal-fired combustion systems is estimated to be <0.5 ppmv in boilers firing subbituminous or lignite coals and up to 3.5 ppmv in bituminous-fired boilers.

The differences between the speciation of chlorine and bromine in combustion flue gas have implications for the oxidation of mercury by halogens. As flue gases cool in a practical combustion system, most of the chlorine is predicted to be HCl, with a very minor amount as the free radical Cl, the species thought to be responsible for the homogeneous oxidation of elemental mercury [2]. Recent kinetic modeling [12] results suggest that bromine speciation is different from chlorine speciation in coal combustion flue gases. In contrast, the concentrations of HBr and Br are comparable at flame temperatures and, as the flue gases cool, the concentration of Br is on the same order as that of HBr.

Experiments on the gas-phase oxidation of mercury by halogens were conducted in a bench-scale, laminar, methane-fired (300 W), quartz-lined reactor in which gas composition (HCl, HBr, NO_x, SO_2) was varied [7]. In the experiments, the post-combustion gases were quenched from flame temperature to about 350 °C, and then speciated mercury was measured using a wet conditioning system and continuous emissions monitor system (CEMS). Bromine was shown to be much more effective than chlorine in the post flame, homogeneous oxidation of mercury, on an equivalent molar basis, as illustrated in Figure 7.2.

In these experiments, the addition of NO to the flame (up to 400 ppmv) had no impact on mercury oxidation by chlorine or bromine. Addition of SO_2 had no effect on mercury oxidation by chlorine at SO_2 concentrations below about 400 ppmv; some increase in mercury oxidation was observed at SO_2 concentrations of 400 ppmv and higher. The addition of chlorine caused minor increases in the extent of oxidation by bromine.

Smith *et al.* [8] obtained similar results in a different methane-fired laboratory furnace: homogeneous oxidation of mercury was <30% when the concentration of HCl was as much as 500 ppmv. The researchers observed inhibition or enhancement of mercury oxidation by chlorine when SO_2 was added, and

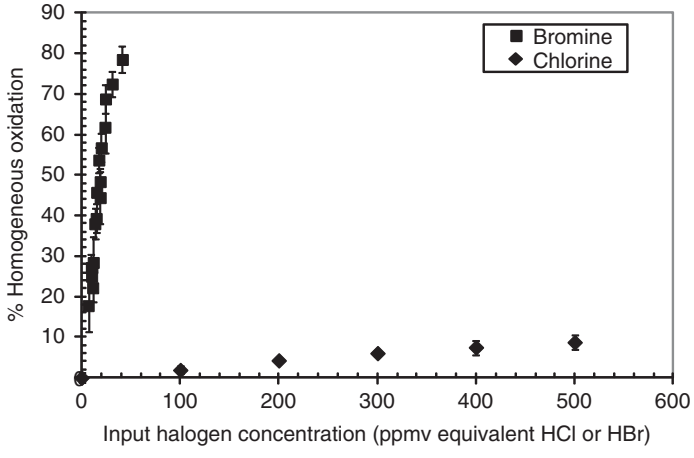

Figure 7.2 Homogeneous oxidation of mercury by halogens in a laboratory combustor as a function of initial halogen concentration [7].

the effect depended on the concentrations of SO_2 and HCl. There was little effect when the concentration of SO_2 was 400 ppmv with up to 550 ppmv HCl. However, at an HCl concentration of 200 ppmv and lower concentrations of SO_2 (100–200 ppmv), SO_2 did affect the level of mercury oxidation observed.

A detailed chemical kinetic mechanism for mercury oxidation by chlorine species in flue gas was applied to pilot-scale coal combustion results by Niksa and Fujiwara [13], but was unable to predict the extent of mercury oxidation. The authors concluded, based on gas-phase kinetic modeling, that the quench rate in the pilot-scale system was not high enough to produce sufficient chlorine radicals to oxidize elemental mercury. A heterogeneous pathway, utilizing the interaction of mercury and HCl on carbon surfaces, was suggested to explain the results.

In coal-fired boilers, concentrations of HCl are expected to be <150 ppmv, which means that the contribution from homogeneous oxidation of mercury by chlorine in practical combustion systems should be 10% or less. The concentration of bromine native to coal is too low to promote significant gas-phase oxidation, although the addition of bromine to the coal or the flue gas does yield increased oxidation, as discussed in Chapter 14.

Gas-phase oxidation of mercury by chlorine has been shown to be inadequate for explaining the observed mercury oxidation in coal-fired furnaces (see Part VI for details of gas-phase mercury models). Heterogeneous oxidation (that is, catalyzed by surfaces) must be responsible for much of the mercury oxidation observed in coal combustion systems.

Transition metal oxides have been shown to oxidize mercury in coal flue gas. Studies have shown that vanadium oxide can oxidize mercury in simulated coal combustion flue gas, and that mercury oxidation increases with increasing concentration of HCl in the gas [14–16]. Studies on V_2O_5 have been carried out at temperatures on the order of 350 °C, which is the temperature of selective catalytic reduction (SCR) reactors in power plants. (This is discussed in more detail in Chapter 15.) At these temperatures, other oxides also catalyze mercury oxidation in the presence of HCl. Kamata *et al.* [17] reported that the activity for mercury oxidation was as follows: $MoO_3 \sim V_2O_5 > Cr_2O_3 > Mn_2O_3 > Fe_2O_3 > CuO > NiO$.

Metal oxides have been demonstrated to oxidize mercury in simulated flue gas at post-APH temperatures (120–180 °C) in many different published works. For example, in fixed-bed experiments with simulated ash (mixtures of oxides), Ghorishi *et al.* [18] showed that the transition metal oxides, CuO and Fe_2O_3, acted as catalysts for the oxidation of Hg^0 in the presence of HCl. Galbreath *et al.* [19] flowed coal combustion flue gas from a pilot-scale combustor through a fixed bed of γ-Fe_2O_3 at 150 °C and observed the conversion of Hg^0 to Hg^{2+} and/or Hg_p. Smith *et al.* [8] injected either α-Fe_2O_3 or montmorillonite clay particles into combustion flue gas from a methane flame doped with mercury and HCl. Mercury oxidation increased in the flue gas with respect to pure homogeneous oxidation when iron oxide particles were injected, but not when the clay particles were injected.

Efforts to find such a relationship between oxidation and metal oxides have produced ambiguous results when using actual coal fly ash (containing mixed inorganic oxides and unburned carbon).

In fixed-bed studies using simulated flue gas and fly ash from two different coal combustion boilers, Norton *et al.* [20] concluded that HCl and NO_2 were of primary importance to mercury oxidation, with NO and SO_2 being of secondary importance. Tests were performed at 120 and 180 °C (248 and 356 °F). The extent of mercury oxidation generally correlated well with the surface areas of the different ash samples. One iron-rich ash sample did not show significantly more oxidation than a low-iron ash sample.

Ash samples from a variety of sources and coal types were tested by Dunham *et al.* [21] in a fixed-bed reactor using elemental mercury in simulated flue gas mixtures at 121 and 177 °C (250 and 350 °F). Oxidation of elemental mercury increased with increasing amounts of magnetite in the fly ash. However, one high-carbon subbituminous ash with no magnetite showed considerable mercury oxidation that may have been due to the carbon surface area. Galbreath *et al.* [22] also noted that the presence of maghemite (γ-Fe_2O_3) in fly ash and HCl in flue gas promoted oxidation of elemental Hg. These works suggest that an iron oxide with a spinel-type structure is active in fly ash with respect to mercury oxidation. The importance of surface area suggests that unburned carbon and/or soot (which have much higher surface areas than inorganic ash particles) dominate the oxidation of mercury at these temperatures.

Fly ash can adsorb elemental and oxidized mercury, in addition to catalyzing the oxidation of elemental mercury. Early experimental work by Hall and coworkers [4] on the adsorption of mercury by activated carbon or fly ash in the presence of O_2 suggested that physisorption of mercury dominated at temperatures below 100 °C (212 °F), but that chemisorption dominated between 100 and 300 °C (212 and 572 °F). The rate of mercury adsorption peaked at a temperature of 200 °C (392 °F) in their experiments, and there was no mercury adsorption observed above 350 °C (662 °F).

A large body of work (much of it summarized by Hower *et al*. [23]) suggests that the unburned carbon in fly ash from coal combustion systems can adsorb mercury in flue gas. For example, in the fixed-bed study of Dunham *et al.* [21], all the fly ash samples that acted as oxidation catalysts for elemental mercury also adsorbed elemental mercury in simulated flue gas mixtures. The adsorption capacity of the ash for elemental mercury was similar to that for $HgCl_2$. There was a correlation between fly ash surface area and adsorption of elemental Hg and $HgCl_2$, although the correlation was better for $HgCl_2$. The adsorption capacity had an inverse dependence on temperature, over the range studied (121–177 °C). Most of the fly ash surface area is due to the presence of unburned carbon and/or soot, which seems to dominate the adsorption process.

Fly ash, and in particular the unburned carbon in fly ash, has been observed to both oxidize mercury and adsorb mercury. Most of the theoretical and experimental work carried out to date on the fundamental mechanisms of mercury–carbon reactions in combustion systems has focused on activated

carbon, instead of unburned carbon in fly ash. Part VI of this book discusses mechanisms and models for the interaction of mercury and carbon surfaces in detail, and these will be discussed only briefly here.

The review by Hower *et al.* [23] provides detailed information on the properties of unburned carbon as related to mercury adsorption in flue gas. Acid gases in flue gas – for example, HCl, Cl_2, H_2SO_4 – promote the oxidation of mercury in the presence of carbon surfaces at post-APH temperatures. However, some of these species are not oxidants; therefore, other species in the flue gas must be responsible for oxidation of mercury on carbon surfaces. As discussed in Chapter 25, a mechanism has been hypothesized and validated in which acid gas species such as HCl bind to the carbon surface, forming a site at which elemental mercury can bind and subsequently be oxidized, principally by NO_2. Furthermore, there is a competition for these active carbon sites between mercury species and H_2SO_4, which has profound implications for capture of mercury by carbon in practical combustion systems. Sulfuric acid can occupy surface sites either by adsorption of gaseous SO_3 or H_2SO_4 or by adsorption of SO_2 and subsequent oxidation by NO_2 on the surface. As H_2SO_4 accumulates on the surface, the bound, oxidized mercury species are displaced and desorbed, probably as $HgCl_2$. The rate of mercury adsorption decreases as temperature increases, but the rate of oxidation of elemental mercury increases as temperature increases [24].

Alkaline species in fly ash, particularly calcium oxide, if present, have been shown to adsorb oxidized mercury in flue gas. As discussed above, mercury–halogen compounds are the most likely gas-phase oxidized mercury species present in combustion flue gas. Chapter 13 provides a detailed discussion of the interaction between mercury and calcium species in combustion flue gas.

The coal combustion boiler represents a series of chemical reactors, which change the elemental mercury produced in the flame to gaseous oxidized mercury and particulate-bound mercury. The transformations of mercury in coal combustion flue gases are influenced by gas-phase species (halogens, NO_x, SO_x) and the PM (unburned carbon, inorganic ash) suspended in the gas as well as the quench rate and gas temperatures. The most significant of these transformations take place in the APCDs downstream of the boiler. Therefore, an understanding of the APCDs used on coal-fired boilers is essential for understanding the mercury emissions and the potential for control of mercury on a wide variety of combustion systems.

7.4
Air Pollution Control Devices on Utility and Industrial Boilers

Before discussing the chemistry of mercury in APCDs, a brief overview will be presented of the major pollution control equipment in use on coal-fired boilers. These APCDs have been installed to control the major pollutants NO_x, SO_2, and

wFGD	Wet flue gas desulfurization

PM. In this section, the major types of APCDs for coal-fired boilers are introduced. Table 7.1 contains a glossary of the processes.

7.4.1 PM Control

Combustion processes emit both primary and secondary PM. Primary PM emissions are called *fly ash* (e.g., non-combustible inorganic matter and unburned solid carbon). Secondary PM emissions are the result of substances that condense in the stack, such as sulfuric acid, to produce PM in the atmosphere. PM control technologies include fabric filters (FFs) or "baghouses," wet and dry electrostatic precipitators (ESPs), venturi scrubbers, and mechanical collectors (cyclones). ESPs are the most widely used PM control device on coal-fired boilers. Most ESPs are located after the APH (see Figure 7.1) and operate at temperatures of 120–190 °C (250–370 °F); these are called *cold-side electrostatic precipitators* (*C-ESPs*). A small fraction of ESPs are located upstream of the APH at temperatures in the range of 350–400 °C (650–750 °F); these are called *hot-side electrostatic precipitators* (*H-ESPs*). ESPs charge fly ash particles and then collect the charged particles in an electric field. Particles are collected on electrically charged plates and periodically removed by mechanical means. The particles drop from the plate into a hopper. FFs, in contrast, collect particles on a filter or bag, such that the flue gas must pass through the "cake" of collected particles. Periodically, the dust cake is removed by agitating the bag so that the cake falls off into a hopper. FFs operate in the same temperature range as C-ESPs. FFs and ESPs represent about 97% of the PM control devices on EGU boilers. Other PM control devices, like wet particulate scrubbers and cyclones, are more commonly found on ICI boilers.

7.4.2 NO_x Control

Emission control strategies for NO_x fall into two categories: combustion controls and post-combustion technologies. Combustion control technologies minimize the formation of NO_x in the furnace and include combustion tuning, low-NO_x burners (LNBs), and overfire air (OFA). LNBs (or staged combustion conditions) may introduce higher carbon monoxide and unburned carbon in fly ash, which reflect lower plant efficiency. In an OFA system, the primary combustion zone is operated at less than a stoichiometric air/fuel ratio, and additional air is added in the upper furnace. Unburned carbon in ash can still increase in boilers using OFA, depending on the type of fuel and design of the system.

Post-combustion technologies reduce the amount of NO_x that has been formed during combustion. In selective non-catalytic reduction (SNCR), a nitrogen-containing reagent is injected into the furnace in the temperature range of 900–1100 °C (1600–2000 °F). NO_x reduction with SNCR is in the range of 30–50%, depending on the residence time and degree of mixing achieved. Higher NO_x reduction (80–90%) is achieved using SCR. In this process, ammonia is injected over a vanadia-based catalyst at temperatures in the range of 350–400 °C (650–750 °F) in order to chemically reduce NO_x to nitrogen and water.

7.4.3 SO_2 Control

SO_2 emission control technologies are post-combustion devices that remove SO_2 by reacting it with an alkaline reagent. The two most commonly used SO_2 controls are dry flue gas desulfurization (FGD) units and wet FGD units. In the former, an aqueous slurry (usually lime) is sprayed into a contacting vessel in order to contact the alkaline reagent with SO_2. The reagent dries and is collected in a PCD (usually a FF). A lower-cost version of a dry process is dry sorbent injection (DSI) in which there is no dedicated contacting vessel; instead, the dry reagent (sodium carbonate or sodium sesquicarbonate) is injected into the flue gas duct and then collected in the PCD. Dry FGDs can achieve 90–95% reductions, although they are used when the coal sulfur content is less than about 2 wt%. DSI results in more modest SO_2 reductions, but the low capital cost of this technology makes it attractive for some boilers.

In a wet FGD, a solution of water and limestone or lime contacts the flue gas. The scrubbing solution is sprayed into the gas and collected as a liquid in the bottom of the scrubber; in some designs, the flue gas is bubbled through a liquid solution. Wet FGDs turn SO_2 into either calcium sulfite or calcium sulfate. The end product is either a sludge or gypsum, depending on the oxidation potential in the solution. Wet FGDs are the most efficient for removal of SO_2 and are typically used when the coal sulfur content is higher than 1–2 wt%; removals of >95% can be achieved.

7.4.4 Boiler Populations in the United States

There are ~1100 coal-fired EGU boilers in the United States with capacities >25 MW at more than 500 facilities [25]. The generating capacities of EGU boilers are generally in the range of 150–1300 MW. According to a survey of industrial and commercial boilers in the United States in 2005 [26], there were about 2600 coal-fired industrial and commercial boilers. The fuel firing rate of these coal-fired boilers averaged 37 MJ s^{-1} (125 million Btu h^{-1}), which is much smaller than the firing rate of EGU boilers; for comparison, the firing rate of a 500 MW EGU boiler is about 1700 MJ s^{-1}.

The distribution of APCDs on EGU boilers is summarized in Table 7.2 [27]. The table indicates the number of APCDs in individual categories. Some boilers have only a PCD, while other boilers have scrubbers and SCRs in addition to PCDs. Those boilers with both an SCR and a scrubber are called out separately in Figure 7.3, because, as discussed below, this combination of APCDs can remove a significant fraction of mercury from the flue gas.

Bituminous coals have higher sulfur contents than low-rank coals (i.e., subbituminous and lignite), which results in a different distribution of APCD equipment on bituminous plants as compared to low-rank plants. Many bituminous-fired plants are located in the Eastern half of the United States, where NO_x emissions are regulated in order to reduce the formation of ground-level ozone. Thus, bituminous-fired boilers are more likely to have a combination of SCR for

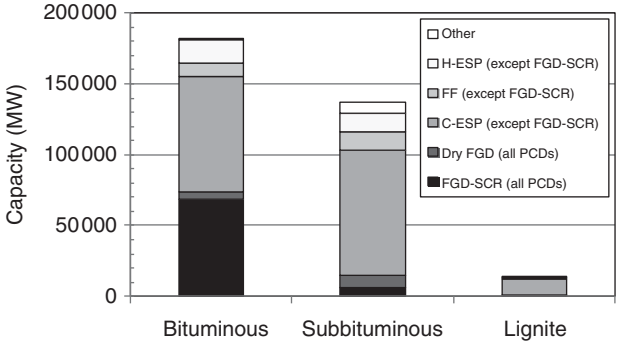

Figure 7.3 Distribution of APCDs on EGU boilers in the United States by boiler capacity [27].

NO_x control and wet FGD for SO_2 control. Subbituminous-fired plants have a larger share of dry FGDs, because the fuels have <1% sulfur. For all types of fuel, the largest category of APCDs is a C-ESP alone, with no scrubber and no post-combustion NO_x control. (Most boilers have some form of combustion control of NO_x, whether or not they have post-combustion NO_x controls.)

New APCD equipment will be installed by 2015 on EGU boilers in the United States as a result of the new Mercury and Air Toxics Standards (MATSs) regulation and the Cross-State Air Pollution Rule (CSAPR). US EPA's analysis of EGU boilers [25] projects an additional 20 GW of dry FGD, 44 GW of DSI, 102 GW of additional FFs, 63 GW of scrubber upgrades, and 34 GW of ESP upgrades by 2015.

ICI boilers tend to have less pollution control equipment than EGU boilers. For example, a survey of ICI boilers firing wood or coal in four states in Northeastern USA [28] showed that about half the boilers had no air pollution controls, 40% of the boilers had only PM control, and 8% of the boilers had a combination of NO_x control and PM control. There were no boilers with SO_2 controls in this population.

7.5
Mercury Behavior in Coal-Fired Boilers

7.5.1
Data Sources

Understanding the behavior of mercury in full-scale coal-fired boilers requires a large body of data from the field. Laboratory and pilot-scale data can provide useful information but the complexity of coal combustion boilers necessitates full-scale data. Over the past 15 years, a large body of data has been generated in the United States and it is largely from these data that the mechanisms and pathways presented here have been drawn.

Table 7.3 Types of coal-fired boilers sampled in 1999 ICR by coal type and APCD, compared with total boiler population [29].

APCD equipment	Coal type	% units tested	% existing units
Cold-side ESP	Bituminous	7.2	48.3

US EPA has carried out two Information Collection Requests (ICRs) as part of rulemaking for the electric utility industry. These ICRs have provided much data on the speciation and removal of mercury in various APCD configurations.

The first ICR was carried out in 1999. Part 3 of the ICR consisted of measurements of mercury speciation from 83 coal-fired power plants. Plants were selected based on the configurations of air pollution control equipment and fuel type. For each plant, the mercury content of the coal was measured (along with other coal composition data). Mercury measurements were made at the stack and at the inlet to the last APCD using the Ontario Hydro method (see Part II for a description of the method); the result was a set of gaseous elemental, gaseous oxidized, and particulate-bound mercury at the inlet and outlet of APCDs. Table 7.3 summarizes the configurations for the ICR data sets, comparing the distribution of units tested with the distribution of the boiler population in the United States. As the table shows, a wide range of APCD configurations were tested, which proved valuable for understanding mercury behavior.

The 1999 ICR was used to support the creation of the Clean Air Mercury Rule (CAMR), which was proposed in 2005. The CAMR was ultimately vacated by the courts. EPA decided to issue another ICR in order to support development of a new rule for EGU boilers, because there had been considerable changes in the APCD configurations since the original ICR. At the end of 2009, EPA issued another ICR to the electric utility industry, requesting information on emissions of mercury and other hazardous air pollutants (HAPs) from EGUs firing coal or

oil. In 2010, a subset of coal-fired EGUs was required to conduct measurements of mercury and non-mercury HAP metals (antimony, arsenic, beryllium, cadmium, chromium, cobalt, lead, manganese, nickel, and selenium) in the boiler stack. Mercury was measured using CEMS or sorbent traps (see Part II for descriptions of methods) at the stack, as well as measured in a coal sample taken concurrently with each stack test. This ICR data set represents a range of fuel types and APCD types, as shown in Table 7.4.

There were many changes in APCD configurations in the industry in the 11 years between the two ICRs. The 1999 ICR dataset contained very few boilers that had post-combustion NO_x control (SCR and SNCR) and no boilers that had activated carbon injection (ACI) for mercury control or DSI for acid gas control. Furthermore, the 2010 ICR dataset contains more data from fluidized bed combustors (FBCs) as compared to the 1999 dataset.

Part IV of this book discusses the substantial research and development efforts undertaken by US DOE, EPA, and EPRI in the mercury control area. Sampling campaigns and technology demonstrations at coal-fired power plants sponsored by these organizations have also provided much valuable information on mercury behavior in coal-fired power plants.

7.5.2 Mercury Behavior in APCDs

In this section, the reader will follow the path of mercury through a coal-fired boiler, using full-scale data from DOE- and EPRI-sponsored mercury measurement campaigns at coal-fired utility boilers [30], unless otherwise noted.

As discussed above, mercury is released from the coal in the flame as gaseous Hg^0 and halogens present in the gas are the primary pathway for gas-phase oxidation. In an evaluation of homogeneous models and data for mercury oxidation by chlorine in combustion systems, Krishnakumar and Helble [11] concluded that oxidation of Hg^0 occurs at temperatures below 625 °C (1160 °F) and the chlorine radical is the most important reactive species for mercury oxidation in the gas phase. Halogens are also involved in the heterogeneous oxidation of mercury, catalyzed either by SCR catalysts or by fly ash.

Oxidation of mercury by SCR catalysts is discussed in detail in Chapter 15. The primary variables that affect the oxidation of mercury across SCR catalysts are halogen content of flue gas, temperature, space velocity (residence time), and catalyst design. Without the injection of additional halogens (Chapter 14), the halogen content of the flue gas is primarily related to the chlorine content of the coal. As Figure 7.4 shows, mercury oxidation across SCR reactors is strongly correlated with the chlorine content of the coal.

All coal-fired utility boilers and most coal-fired industrial boilers have a gas–gas heater exchanger to preheat the combustion air by contacting it with the flue gas. This APH decreases the flue gas temperature from typically 350 to 150 °C, while heating the combustion air to ~300 °C. There are two types of APHs: regenerative and tubular. The majority of APHs are drum-type regenerative heat exchangers,

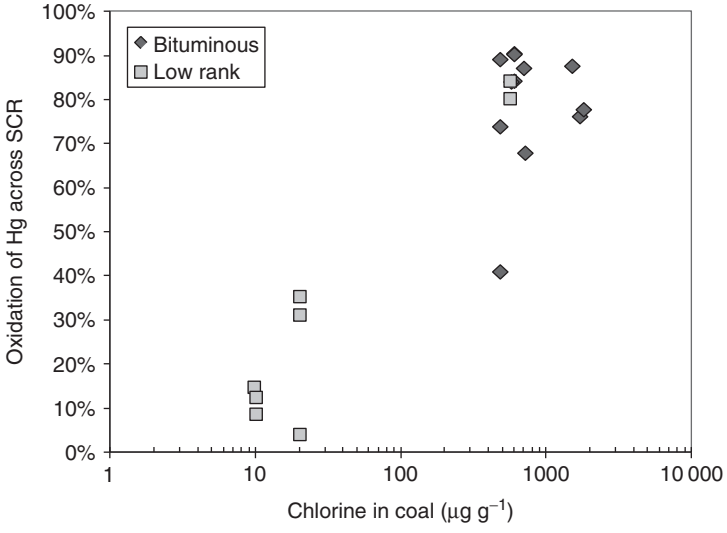

Figure 7.4 Oxidation of mercury across full-scale SCRs as a function of coal chlorine content.

in which a large wheel containing metal surfaces rotates through the flue gas path, alternating contact with the hot flue gas and the cold combustion air. Tubular APHs are shell-and-tube heat exchangers in which the flue gas passes through tubes and the combustion air flows outside the tubes. In either case, there is a lot of cold metal surface area, which can become coated with ash particles. The large surface area in APHs can promote oxidation of elemental mercury. Figure 7.5 shows full-scale data on the oxidation of elemental mercury across APHs as a function of coal chlorine content. Chlorine is not the only important parameter for mercury oxidation across APHs; the unburned carbon in the fly ash (which can act as a catalyst), the temperature, and the quench rate (determined by the design of the APH) are also important for mercury oxidation. The variation in unburned carbon in fly ash can be large, because the amount of unburned carbon depends on the coal rank and on the combustion system [23]. Unless the chlorine content of the coal is very low, a significant amount of mercury oxidation can be expected across an APH.

In almost all coal-fired boilers, a PCD follows the APH. The exceptions to this are a boiler with a H-ESP in which the ESP is located upstream of the APH or a boiler with a spray dryer (dry FGD) for SO_2 control in which the spray dryer is located between the APH and the PCD. Only about 9% of coal-fired utility boilers employ a H-ESP as the only PCD and about 8% of coal-fired utility boilers have a dry FGD (Table 7.2). C-ESPs are the most common PCD on coal-fired utility boilers. These devices remove mercury that has been converted to a particulate form upstream of the ESP by reaction with unburned carbon in fly ash. There is little contact between the flue gas and the ash collected in the ESP; therefore, mercury does not oxidize or adsorb on fly ash within the ESP.

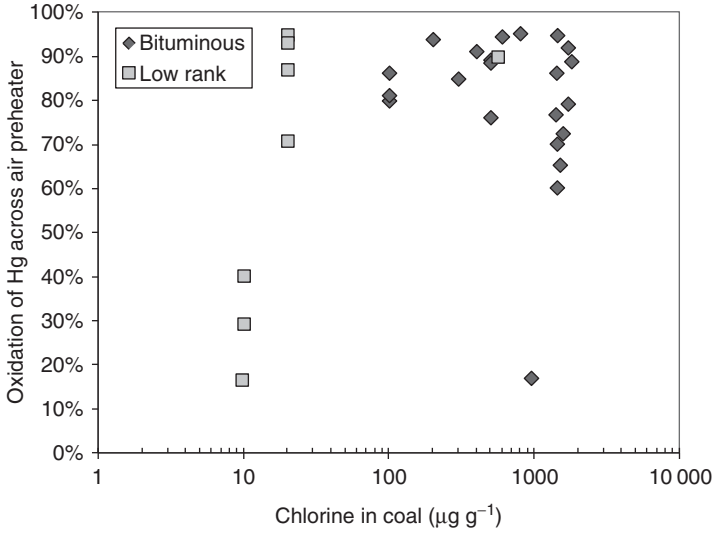

Figure 7.5 Oxidation of mercury across air preheaters on full-scale, coal-fired boilers as a function of coal chlorine content.

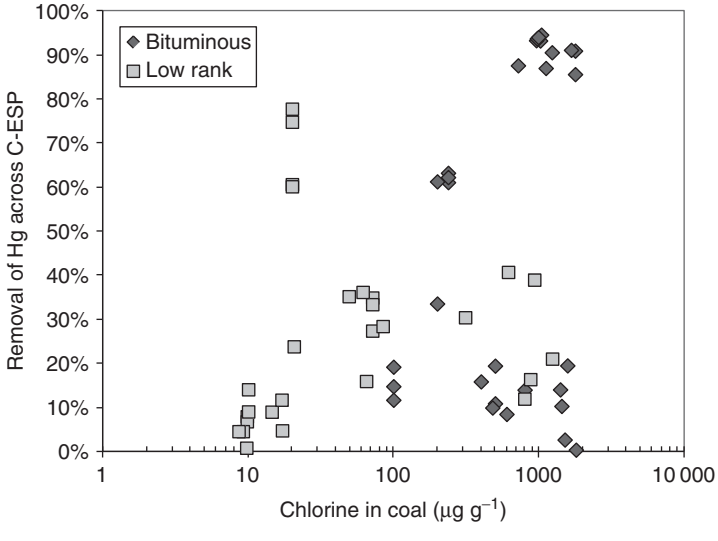

Figure 7.6 Removal of Hg across cold-side ESP as a function of coal chlorine content.

The chlorine content of the coal has an influence on how much of the mercury is converted to a particulate form via reaction with the fly ash upstream of the ESP. However, as Figure 7.6 illustrates, chlorine is not the only factor that determines how much mercury is removed across C-ESPs. There are other factors that influence how much mercury adsorbs on the fly ash [18–24] as was noted previously in the discussion of fixed-bed experiments on mercury interactions with fly

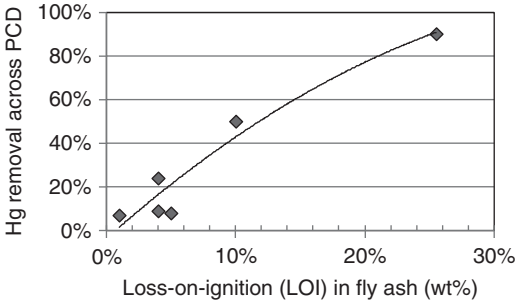

Figure 7.7 Mercury removal across cold-side ESPs as a function of LOI, for bituminous pulverized-fired boilers [31].

ash. The amount of unburned carbon in the fly ash is also important. Figure 7.7 shows mercury removal at full-scale bituminous coal-fired boilers as a function of loss-on-ignition (LOI), that is, unburned carbon, in the fly ash [31]. For pulverized coal-fired boilers with C-ESPs, there is a good correlation between LOI and mercury removal.

In FFs, there is more contact between the flue gas and the fly ash, because the fly ash builds up on the filter over a period of several hours before being removed. Thus, in addition to removing particulate-bound mercury, which is formed upstream of the PCD, FFs also remove oxidized elemental mercury and gaseous mercury. The fixed-bed experiments using fly ash and simulated flue gas discussed previously [18–21] are similar to a FF in that the gas must pass through a layer of ash. The temperature, composition of the flue gas, unburned carbon in the fly ash, and baghouse cleaning frequency all affect the removal of mercury across FFs.

Figure 7.8 illustrates the removal of both gaseous mercury and total (gas plus particulate-bound) mercury across the FF on a 170 MW tangential boiler burning a low-sulfur bituminous coal [32]. The unburned carbon in ash was varied by changing combustion conditions and the FF temperature was 130 °C (265 °F).

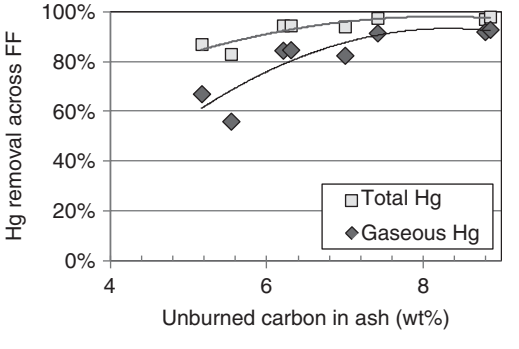

Figure 7.8 Mercury removal across fabric filter as a function of unburned carbon in fly ash [32].

The FF removed both gaseous and particulate mercury, and the mercury removal increased with increasing unburned carbon in ash. In certain situations (temperature, gas composition), unburned carbon in fly ash can be effective at capturing mercury. However, reliance on unburned carbon alone as a mercury control strategy is not without risk of non-compliance, because changes in combustion conditions affect the amount of unburned carbon, and such changes are not always predictable or controllable. Furthermore, increasing the amount of unburned carbon in ash means decreasing the efficiency of the combustion process, which is not desirable.

Thus, both C-ESPs and FFs can remove mercury from the flue gas. H-ESPs operate at too high a temperature to remove significant amounts of mercury. Particulate-bound mercury that has formed upstream of the PCD is removed by a C-ESP; in contrast, FFs remove both particulate-bound mercury and gaseous mercury. The degree to which mercury is removed in PCDs depends on the amount of unburned carbon in the fly ash, the halogens present in the flue gas, and the temperature of the PCD. The design and operation of a FF can also have an effect on its ability to remove mercury.

Both wet and dry FGD scrubbers remove mercury, if it is in the oxidized form. Mercuric halides (such as $HgCl_2$) are soluble in water but elemental mercury is not. Thus, the removal of mercury across FGD scrubbers depends on how much oxidized mercury enters the scrubber, as illustrated in Figure 7.9. The removal of mercury across wet FGD scrubbers is complicated by the aqueous reactions that take place in the scrubbing solution [33], as discussed in Chapter 16. The complex aqueous chemistry can result in some of the absorbed Hg^{2+} being reduced back to

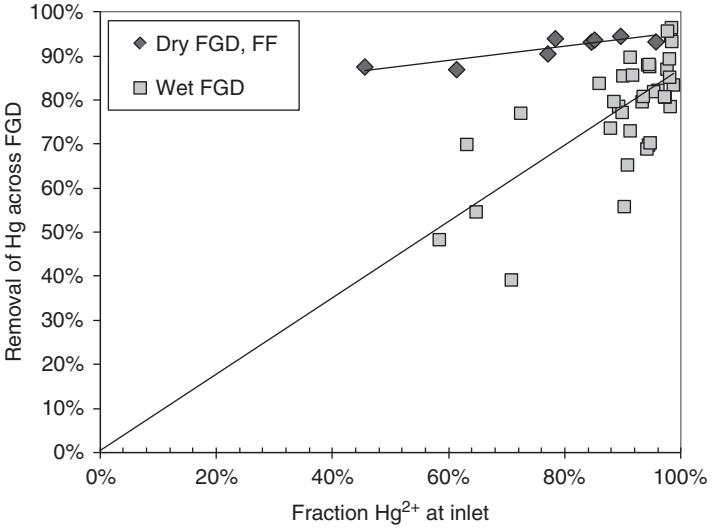

Figure 7.9 Mercury removal across dry and wet FGD scrubbers on bituminous-fired boilers as a function of the fraction of oxidized mercury at the inlet.

Hg^0. This re-emission of Hg^0 can reduce the efficiency of mercury capture across wet FGD scrubbers.

7.6 Summary

The transformations of mercury in coal-fired boilers and APCDs are summarized in Figure 7.10. Although Hg leaves the combustion zone as gaseous elemental mercury, varying amounts can be transformed to gaseous oxidized mercury and particulate-bound mercury as the flue gas passes through the economizer and air heater. The efficiency of Hg capture by APCDs depends on the gas-phase speciation as well as on the partitioning between gaseous and particulate forms. In turn, the coal composition (Cl and S content, ash composition) and boiler operation (unburned carbon content, gas cooling rate, and residence time) affect the Hg speciation and partitioning in the flue gas. Existing APCDs provide a range of "native" Hg removals; FFs and scrubbers have the highest Hg removals, as much as

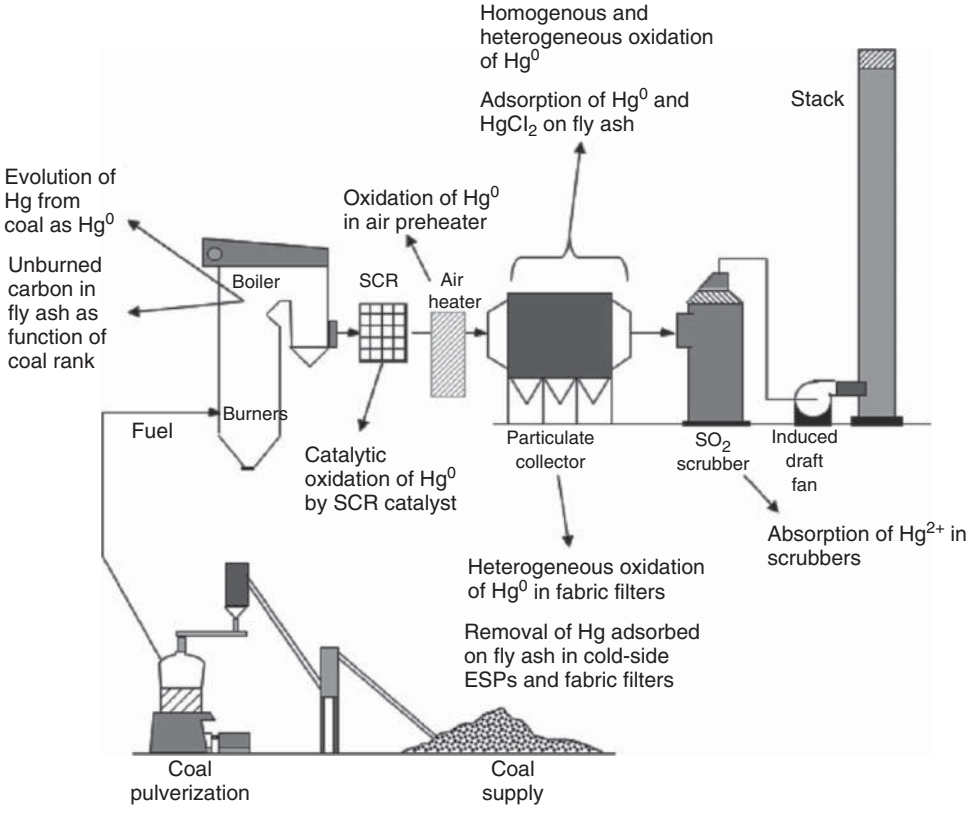

Figure 7.10 Summary of mercury behavior in coal-fired boilers.

90%, for units burning bituminous coal. Moderate to low levels of natural capture are typically found in units that burn either subbituminous coals or lignites.

Gasification Systems

Nicholas Lentz

8.1
Principles of Coal Gasification

Coal gasification processes employ fixed-bed, fluidized-bed, or entrained-flow reactor systems to react coal with air or oxygen and steam over a range of temperatures from 650 °C (1202 °F) for fixed- and fluidized-bed gasification to about 1500 °C (2732 °F) for entrained flow gasifiers. The ash byproducts are dry, agglomerated, or slagging ash, depending on the gasifier type, operating pressure, and operating temperature. Process pressures range from near atmospheric to up to 82 bar (1200 psig). Gasification reactions can be classified into the following groups: pyrolysis, combustion, steam gasification, and secondary reactions among gaseous products and with carbon. Each reaction group produces a significantly different gas composition. The common coal gasification reactions and enthalpy energies are presented below:

Pyrolysis and tar cracking	
Coal → char + tar, light oil, H_2O, H_2, CO, CO_2, and hydrocarbon gases	
Tar, light oil → CH_4 and other HC gases + CO + H_2 + CO_2	
Combustion	ΔH ($Btu\,lbmol^{-1}$)
$C + O_2 \rightarrow CO_2$	−169 300
$C + (1/2)O_2 \rightarrow CO$	−47 600
$CO + (1/2)O_2 \rightarrow CO_2$	−121 700
Steam gasification	
$C + H_2O \rightarrow CO + H_2$	+56 490
Secondary reactions	
$C + CO_2 \rightarrow 2CO$	+74 200
$H_2 + (1/2)O_2 \rightarrow H_2O_{(g)}$	−104 000
$C + 2H_2O_{(g)} \rightarrow CO_2 + 2H_2$	+38 780
Water–gas shift reaction	
$CO + H_2O_{(g)} \rightarrow CO_2 + H_2$	−17 700

Mercury Control: for Coal-Derived Gas Streams, First Edition.

Methanation reactions	
$C + 2H_2 \rightarrow CH_4$	−32 200
$CO + 3H_2 \rightarrow CH_4 + H_2O$	−88 700
$CO + H_2 \rightarrow (1/2)CH_4 + (1/2)CO_2$	−53 200

(−) indicates exothermic and (+) indicates endothermic.

The primary products of gasification are CO, H_2, and CH_4, along with some carbon dioxide and nitrogen when air is used as the oxidant. If water–gas shift catalysts are being used, the shift catalysts will convert the majority of the CO into CO_2 so that the main syngas products are H_2 and CO_2. This is desirable when carbon capture is required. Other byproducts produced during gasification can include tars, oil, phenols, chars, hydrogen sulfide, carbonyl sulfide, ammonia, and hydrogen cyanide. The primary reactions involving pyrolysis and steam gasification are endothermic and heat must be provided either externally or by the combustion of carbon. Smaller bench and pilot-scale systems typically require external heat sources to maintain consistent gasification conditions due to their small size and increased thermal effects related to scaling of the equipment. Heat from combustion can also be supplied indirectly by recycling bed material to provide either sensible heat or chemical energy (e.g., the CO_2 acceptor process). The water–gas shift and methanation reactions are exothermic and contribute to the energy balance at lower temperatures and high pressures where CH_4 is a principal product. The particular gas composition obtained from various types of gasifiers depends on the effects of temperature, pressure, flow patterns (e.g., cocurrent vs countercurrent), fluid dynamic intensity, solid and gas residence times, and catalysis on chemical kinetics and equilibrium.

8.2 Gasification Technologies Overview and Gasifier Descriptions

Different gasifiers are utilized for different applications and fuel sources. A comprehensive review of the different gasifier types is provided by Sondreal and Benson [1]. Table 8.1 summarizes the different gasifier types and characteristics. Gasifiers are typically categorized into three main classes: entrained-flow, fixed-bed, or fluidized-bed systems followed by describing the system as either a slurry or dry coal feed. Another classification can be if the system has a dry ash, or a slab byproduct discharge. Designs and classifications are typically based on the type of coal to be gasified and the desired syngas exit conditions for subsequent downstream processes and desired syngas conditions.

Figure 8.1 shows the diagrams and temperature profiles for the fixed bed (moving bed), fluidized bed, and entrained flow gasifiers. Each gasifier has a very unique temperature profile which affects the fuel types and ranks that provide optimal performance as well as the syngas composition. Entrained flow gasifiers exhibit the highest temperature profile and also have the hottest syngas exiting the gasifier.

Table 8.1 Gasifier types and characteristics [2].

Gasifier type	Fixed bed	Fluidized bed	Entrained flow
Coal feed size	6–50 mm	6–10 mm	<100 μm
Acceptability of fines	Limited	Good	Unlimited
Oxidant demand	Low	Moderate	High
Outlet temperature	Low (425–600 °C)	Moderate (900–1050 °C)	High (1250–1600 °C)
Ash conditions	Dry ash or slagging	Dry ash or agglomerating	Slagging
Other characteristics	Methane, tars, and oils are present in the syngas	Low carbon conversion	Pure syngas and a high carbon conversion

8.3 Gasification Applications and Downstream Gas Cleanup and Processing

Syngas produced as a result of coal gasification can be a very flexible feedstock for a wide range of applications and manufacturing processes. Electrical power output is oftentimes not the primary function of a gasification plant. In addition to chemical production, syngas can also be directly used to produce power and/or steam for municipal purposes. Syngas is commonly comprised mainly of H_2 and CO and the ratio between H_2 and CO can be adjusted via water gas shift catalyst reactions in order to provide a specific syngas composition to a downstream process such as a Fischer Tropsch reactor. Gasification plants often are equipped with multiple product production streams and can sometimes modify the syngas composition to shift product stream yields in order to maximize profit as commodity prices and/or outlooks change. A list of potential products from syngas includes

- Gaseous fuels
- Synthetic natural gas
- Liquid fuels
- Chemicals
- Fertilizers
- CO_2 for use in enhanced oil recovery (EOR) applications
- Hydrogen as a fuel and/or for power generation.

8.4 Mercury Transformations and Fate

Mercury has been measured for over 20 years from stationary sources to assess emissions, develop control technologies, and set appropriate mercury regulations. Mercury is present in three different forms, particulate bound, oxidized, and

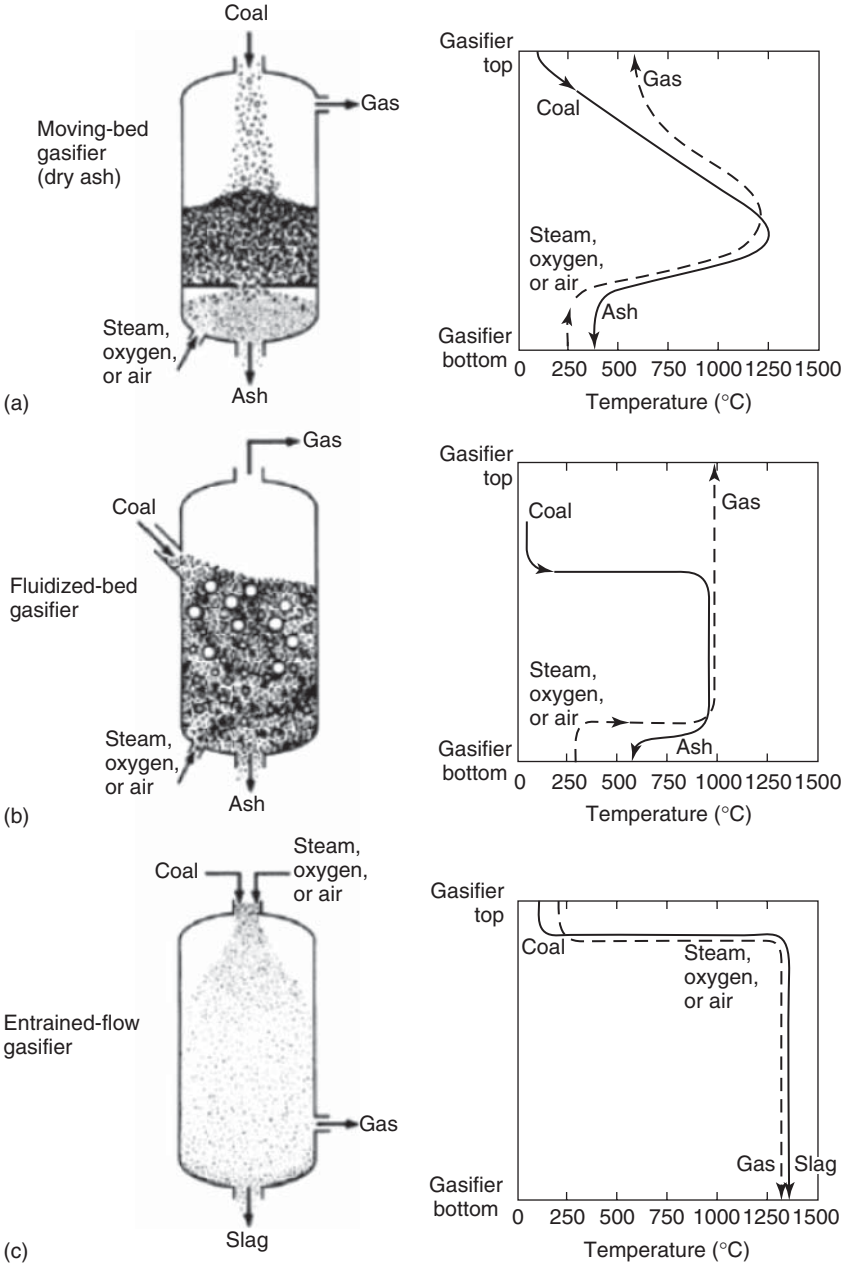

Figure 8.1 (a–c) The three major types of gasifiers [3].

elemental (Hg[p], Hg^{2+}, and Hg^0), which greatly complicates the measurement process. The low mercury concentrations (low-parts per billion by volume range) also make measuring mercury difficult.

Five measurement methods are used to measure mercury from combustion sources: continuous mercury monitors (CMMs), the Ontario Hydro (OH) method, EPA M30B, EPA M29, and EPA M101A (EPA, U.S. Environmental Protection Agency) (see Chapters 5 and 6). Of these methods, the OH method is the only method validated to obtain speciated mercury measurements. Each method is able to provide accurate and reliable data, provided that the mercury concentrations are within the range of the method. All of the methods require samplers who are extremely familiar with the methods and their corresponding biases and/or interferences. Most mercury measurement methods were developed for combustion applications and later tested on gasification systems. Further discussion will show their applicability in gasification systems.

Under gasification conditions, mercury typically only exists in the elemental form due to the reducing conditions in the gasifier. Research conducted at the Energy and Environmental Research Center (EERC) confirmed the presence of elemental Hg during simulated gasification conditions and speculated that CH_3Hg may also be possible [4, 5]. In combustion systems, mercury can exist in both the elemental and oxidized forms with a wide range depending on the fuel type, boiler type, and place in the pollution control system. Elemental Hg is usually found in the higher temperature regions of combustion systems and is also likely why elemental Hg is the predominant form in gasification systems. The high gasification temperatures and reducing environment make it challenging for any oxidized forms to remain stable and favor the formation of Hg^0. Erickson *et al.* [6] investigated the volatility of elements under gasification conditions. They found that the majority of elements behaved similar to combustion systems but arsenic, lead, and cadmium were found to volatilize in the finer sized particle fractions.

8.5 Hg Measurement in a Reducing Environment

In previous chapters, Laudal and Senior have provided extensive reviews of mercury measurement technologies. Mercury measurements in a reducing (gasification) environment present a significant challenge, especially for any method that utilizes liquid impingers or scrubbing systems such as a CMM wet conversion system. Syngas constituents such as H_2, H_2S, CO, and CO_2 often react with the chemical solutions and render them ineffective at either capturing the Hg or performing their specific function [7]. The result is that there can be very fast mercury breakthroughs that invalidate the test. Traditional 2 h EPA impinger tests exhibit breakthrough and render the tests invalid. Shorter sampling times often to not capture enough mercury for a good data point with the tests that utilize

impingers. Measurement methods such as M29, OH, and CMMs with wet conversion systems all have exhibited challenges in obtaining consistent mercury data in reducing environments [8].

The most favorable mercury measurement methods are the methods that do not utilize liquid solutions and impinger trains. Dry conversion CMM systems and sorbent traps are the most widely used systems that do not use liquids as a part of their sampling process and are the most widely used methods on gasification systems. Sorbent traps are not able to provide continuous data, but suffer the least interferences in a gasification environment and have provided the most accurate values [9].

8.6 Hg Control Technologies for Gasification

Mercury control technologies for gasification are commonly a part of the cold, warm, or hot gas cleanup system that is designed to remove an array of pollutants including Hg, H_2S, halogens, and other trace metals such as As and Se. Currently, hot gas cleanup technologies are not mature and most of the focus through Department of Energy (DOE) and National Energy Technology Laboratory (NETL) has subsequently concentrated on warm gas cleanup systems. Warm gas cleanup systems are also favorable because they operate at temperatures that are suitable for phase shift catalysts, such as Fischer Tropsch catalysts, which allow the syngas stream to be converted into numerous useful byproducts. A hot gas filter vessel is commonly utilized for gasification particulate removal upstream of the gas cleanup system. The filter vessel is able to remove most of the particulates as well as the particulate bound Hg. The mercury control technologies are typically fixed beds and can be grouped into two main categories: carbon-based sorbents and metal-based sorbents. Chapter 22 discusses these in more detail; a brief description is provided here.

Carbon-based sorbents are commonly utilized in cold or warm gas cleanup systems and have a very high capacity with respect to mercury. Carbon-based sorbents have been extensively used at municipal waste-to-energy facilities for many years and have demonstrated the ability to cost effectively remove high levels of mercury. The carbons are typically either iodine or sulfur impregnated in order to facilitate Hg capture. Select tests under integrated gasification combined cycle (IGCC) conditions have utilized sulfur impregnated sorbents to successfully remove mercury and other contaminants [10]. A Parsons-GTI group conducted a study that demonstrated a carbon bed mercury capacity as high as 20 wt%, which correlates to a bed lifetime of ~2 years [11]. Often, pressure drop across the bed, water buildup, and other operating factors determine when a bed is replaced, rather than the Hg capacity of the sorbent bed [12].

Metal-based sorbents are another mercury control technology that has been tested. Metal-based sorbents are designed to target warm gas and hot gas cleanup systems. Most of the developed sorbents are precious metal based, with Pd, Pt, Au, Ir, and Rh being the most widely used metals. Of these, Pd has been identified as the best absorber of mercury [13, 14]. Even though metal-based sorbents have shown some promise, the technology is currently not a cost effective option for mercury capture, largely due to the cost of the precious metals required for the sorbents. Further research is required to identify cheaper surrogate metals that will also maintain sufficient activity and capture rates in warm and hot gas cleanup systems.

8.7 Hg and the MATS Rule for Gasifiers

The Mercury and Air Toxics Standards commonly called the *MATS rule* was recently finalized with the latest version published in the Federal Register on 16 February 2012. The MATS rule regulates filterable particulate matter (PM) (as a trace metal surrogate), mercury, and HCl (as an acid gas surrogate) emissions from coal-fired electricity generating units (EGUs), including IGCC units. The gasifier emission limits (PM, HCl, and Hg) for new and existing sources are presented in Table 8.2.

The data for existing units is based on a limited dataset because there are very few operating IGCC gasifiers in the United States. The only two IGCC plants in operation are the Polk Power Station operated by TECO Energy, and the Wabash River Generating Station operated by Duke Energy. These gasifiers have shown high native mercury captures of around 60%, with most of the mercury emitted in the elemental form [15]. The emission limits for the new IGCC units were based on permit data for some of the units that are either in the planning phase or the construction phase. An example is the Kemper County IGCC plant that is currently in the construction phase.

Table 8.2 Emission limits for coal-fired IGCC EGUs.

Subcategory	Filterable PM	HCl	Mercury
Existing IGCC	4.0E−2 lb $MMBtu^{-1}$ (4.0E−1 lb MWh^{-1})	5.0E−4 lb $MMBtu^{-1}$ (5.0E−3 lb MWh^{-1})	2.5E0 lb $TBtu^{-1}$ (3.0E−2 lb GWh^{-1})
New IGCC	7.0E−2 lb MWh^{-1} a) 9.0E−2 lb MWh^{-1} b)	2.0E−3 lb MWh^{-1} c)	3.0E−3 lb GWh^{-1} d)

a) Duct burners on syngas; based on permit levels in comments received.
b) Duct burners on natural gas; based on permit levels in comments received.
c) Based on best-performing source.
d) Based on permit levels in comments received.

9
Mercury Emissions Control for the Cement Manufacturing Industry

Robert Schreiber Jr., Shameem Hasan, Carrie Yonley, and Charles D. Kellett

9.1
Introduction

The manufacturing of portland cement is performed in a large industrial process that is raw material and fuel intensive. The industry is considered as one of the anthropogenic contributors of mercury to the environment. During the pyroprocessing step that occurs in the cement kiln system, the mercury compounds are vaporized from the fuels and raw materials due to the very high temperatures achieved inside the kiln. There are different types of pyroprocessing systems used in the cement industry, and the specifics of each system have been shown to have an effect on reactions and emissions/emissions control of mercury. However, the state of knowledge on the fate of mercury, speciation of emissions from the kiln system, and potential for control is still in the early stages of development and testing, although knowledge is being amassed more rapidly over recent years. This chapter describes the specifics of the cement manufacturing process and the corresponding effects of the process chemistry and temperatures within the kiln system on mercury speciation. The discussion includes the current state of the study of mercury in the industry and knowledge on mercury control.

9.2
Cement Manufacturing Process Description

Portland cement (hereinafter, cement) is the gray powder that is the active chemical binder used to produce concrete by mixing it with sand, gravel, and water. Cement manufacturing is performed in a large-scale industrial production process using large volumes of raw materials and fuels. The basic steps of cement production are generally as follows:

- Raw material procurement
- Raw material feed preparation

Mercury Control: for Coal-Derived Gas Streams, First Edition.
Edited by Evan J. Granite, Henry W. Pennline and Constance Senior.
© 2015 Wiley-VCH Verlag GmbH & Co. KGaA. Published 2015 by Wiley-VCH Verlag GmbH & Co. KGaA.

- Pyroprocessing of raw material in the kiln system (formation of cement "clinker")
- Clinker cooling
- Clinker grinding and cement packaging.

The basic raw materials used to manufacture cement include sources of calcium carbonate, silica, alumina, and iron, with trace amounts of other compounds such as alkalis (sodium, potassium), sulfur, chlorine, and metals naturally occurring in the raw materials. Typical raw feed to a kiln contains about 80–85% calcium carbonate, 10–15% silica, and small amounts of alumina and iron. Maintaining the quality of raw feed is an important step in manufacturing quality cement. Traditional mineralogical sources of the cement ingredients include the calcareous component such as limestone, marl, or chalk; the argillaceous components such as clay, shale, slate, or sand which provide the silica and alumina; and iron components, in some cases provided by mill scale or a similar material. Cement plants are generally located in areas that have an abundant supply of readily available raw materials. With about 80–85% of the raw materials being limestone, plants are usually located at or near abundant limestone quarries for economics related to raw material transportation costs.

Raw material feed preparation involves sizing through crushers and mixing and grinding raw materials in a raw mill(s) to obtain correct size and chemical composition for kiln feed, also termed as *raw mix* or *raw meal* (Figure 9.1). The process used to prepare raw meal is dependent on the type of pyroprocessing system being used.

The main types of systems used in the cement industry include the wet process and the dry process. The dry process is further subdivided into the

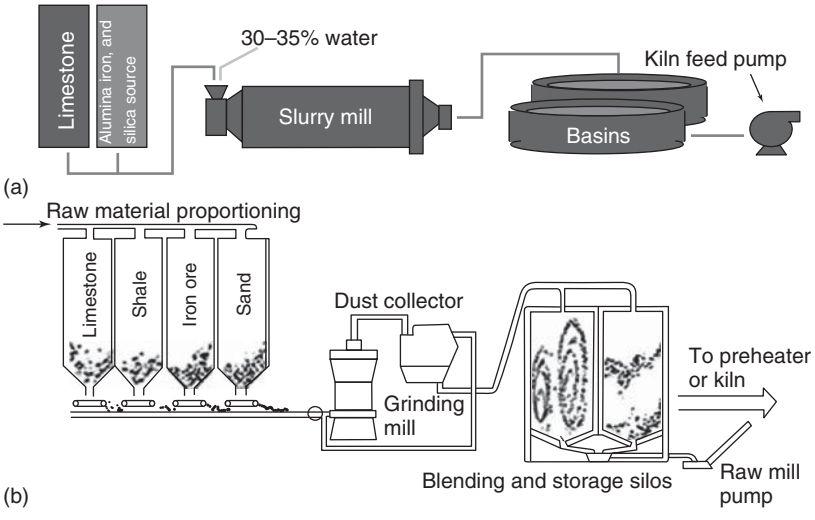

Figure 9.1 Schematic of raw meal preparation for (a) wet kiln and (b) dry kiln.

long dry process, the preheater process, and the most recent technology – a preheater/precalciner system. Each type of system is further described below.

For use in the wet process, the raw materials are mixed and ground with water (~30–35 wt%) to produce slurry, which simplifies the blending of the kiln feed to produce a uniform chemical composition. The dry process involves mixing a calculated proportion of raw materials, drying, and grinding the mixture to a powdered form, blending the materials together in silos, and feeding the raw meal to the kiln in a dry state. For the preheater and preheater/precalciner processes, heat to dry the raw material may be recovered from the kiln system and utilized in an in-line raw mill system. For a continuous operation, the raw mill must grind more raw materials than can be used in the kiln system in a given time frame; otherwise, sufficient kiln feed would not be available on a consistent basis as the raw mills require more down time for maintenance and repair than the kiln. Normally, raw mill systems are designed to grind enough material such that they can be taken off-line once a week for repair and maintenance. Under most circumstances, raw mills are designed to operate about 85–90% of the kiln operational time. For the in-line raw mill design, this phenomenon is known as *raw mill on* and *raw mill off* operating conditions.

The kiln system is where the key process step occurs, where a specific combination of minerals is heated to a temperature of about 1500° C in a large, cylindrical, rotating, refractory-lined kiln, and associated equipment, depending on the type of kiln system. The raw materials are fed counter-current to the gases from burning fuel in the combustion zone of the kiln and undergo the chemical and physical reactions required to produce quality cement. Inside the kiln, the minerals are partially fused at high temperatures, resulting in the formation of clinker nodules, which is the intermediate product of cement. Cement kiln dust (CKD) is generated during raw materials processing inside the kiln system. CKD includes thermally changed and unchanged raw feed that becomes entrained in the counter-current gas flow through the kiln system. Gases that exit the cement kiln system are vented to an air pollution control device (APCD) where the CKD is removed, followed by the exhaust stack. Traditionally, an electrostatic precipitator (ESP) or baghouse is used as the APCD in the cement industry. New APCD technologies are beginning to be studied and tested as regulations are becoming increasingly stringent for additional pollutants.

Large amounts of fuel are necessary to drive the pyroprocessing that occurs in the kiln system. Typical fuels used in cement kilns are coal, petroleum coke, natural gas, oil, and/or alternative materials used for energy recovery, such as used tires, plastics, and oil. The most significant quantity of traditional fuel continues to be solid fuel, including coal and coke. In a typical kiln, ~2–6 million British thermal units of heat value are required to produce a ton of clinker [1]. Fuels fired in the hot end generally need to have a relatively high heat value as fired to maintain the high flame temperature required at the front of the kiln. Fuel fired at the hot end of the kiln also must be finely atomized to promote rapid combustion, which is important to clinker quality. The most important factor for fuel is the consistency. If each load has a different consistency, maintaining stable kiln

operations, maximum kiln production, and product quality is challenging. Also, an accurate control of energy input is required for the critical clinkering step. Insufficient energy input in the kiln will not allow necessary chemical reactions to occur during the clinkering process, which may result in unreacted lime in the clinker, thereby producing poor quality cement. Too much energy input will shorten the life of the kiln refractory lining, which may damage the kiln shell. It can also cause molten clinker to drop into the clinker cooler, causing significant damage and shutting down the system.

The clinker exits the hot end of the kiln, and is cooled from ~1500 to 90° C in the clinker cooler where ambient air is forced through a slowly moving bed of clinker for rapid cooling to stabilize its molecular structure. Typically, the air used to cool the clinker is recovered and used as preheated combustion air in the kiln. The cooled clinker is conveyed to a finishing mill (e.g., ball mill) for grinding. In the finishing mill system, the clinker is interground with a small amount of gypsum ($CaSO_4 \cdot 2H_2O$), an agent that controls the setting time of the concrete, and grinding aid, a material used to make the grinding process more efficient (too varied to describe within the context of this chapter) into the powder known as *portland cement*. At this point, the product is ready for commercial distribution.

Typical portland cement clinker comprises 67% CaO, 22% SiO_2, 5% Al_2O_3, 3% Fe_2O_3, and other minor components such as MgO, K_2O, TiO_2, and Mn_2O_3. Four major phases, including $3CaO \cdot SiO_2$ (50–70%), $2CaO \cdot SiO_2$ (15–30%), $3CaO \cdot Al_2O_3$ (5–10%), $4CaO, Al_2O_3 \cdot Fe_2O_3$ (5–15%), also termed *alite*, *belite*, *aluminate*, and *ferrite*, respectively, are present in clinker [2]. The phases in portland cement clinker are important as they function as a strength development agent in cement when mixed with water. The American Society for Testing and Materials (ASTM) specifies different types of portland cement based on the mineralogical properties of the clinker [3]. Among them, normal portland cement (Type I), modified portland cement (Type II), high-early-strength portland cement (Type III), low-heat portland cement (Type IV), and sulfate-resisting portland cement (Type V) are most common.

9.2.1 Wet Process Kiln

In the wet process, the blended raw feed is introduced to the "cold end" of the rotary kiln and tumbles down the length of the kiln toward the flame in the lower "hot end" of the kiln. In general, a rotary kiln is 400–700 ft in length, and has a 3–4% slope with the horizontal and rotates at 1–2 rev min^{-1} during operation. Figure 9.2 shows the temperature profile of a typical wet kiln [4]. There are essentially four stages to the pyroprocessing – evaporation and preheating, calcining, clinkering (sintering), and cooling. Fuel normally is fired at the hot end of the kiln, although some kilns are equipped with a secondary mid-kiln firing location. Evaporation and preheating remove moisture from the raw feed and raise the feed temperature to about 870° C. At 760° C, calcination of the material takes

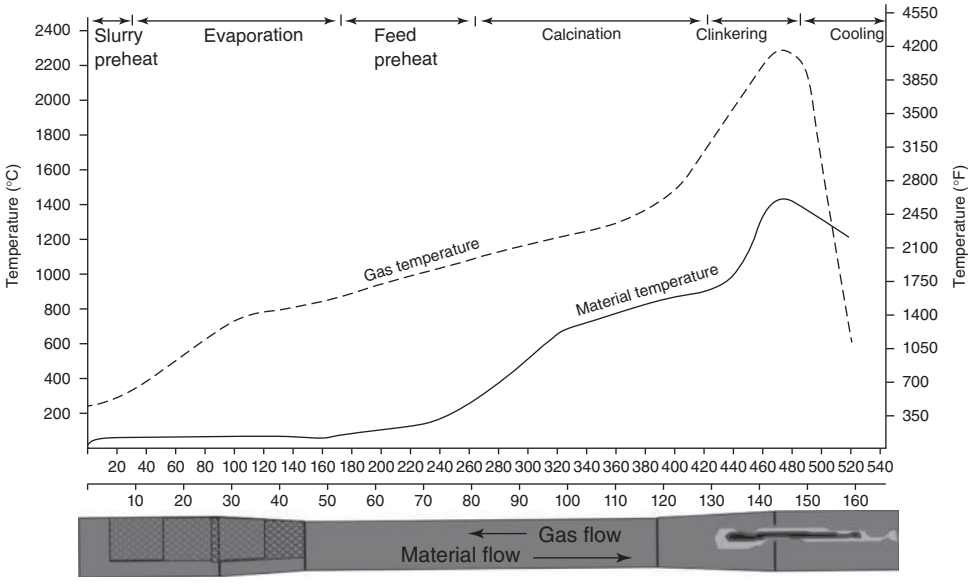

Figure 9.2 Typical temperature profile of wet kiln system in cement industry [4]. (Reproduced from Ref [4] © (1986) with permission from Chemical Publishing Co. Inc.)

place, breaking the calcium carbonate down into calcium oxide and carbon dioxide. At 1500° C, ~20–30% of the load melts and the formation of calcium silicate occurs. At this stage, the material forms the clinker nodules due to gravitational flow and the rotating effect of the kiln. The clinkering process occurs in the hottest zone of the kiln, called the *burning zone*, where the material temperature reaches about 1500° C and in which the material spends ~10–15 min.

Due to the nature of raw feed preparation, the wet process offers more uniform feed blending and generates less dust particles. Wet kilns require more combustion energy per ton of clinker produced than the dry process kiln systems as the water must be evaporated from the slurry feed.

9.2.2
Dry Process Kiln

More than 80% of the U.S. cement industry uses dry process kilns in which raw meal is prepared without adding any water. Dry process kilns are further divided into three types – long dry, preheater, and preheater/precalciner systems, with those built over the last two to three decades typically being the modern preheater/precalciner design. A long dry kiln is similar to a wet kiln with the exception that the raw materials are fed to the kiln as a dry powder, therefore requiring less combustion energy to produce clinker than a wet kiln but more electrical energy to blend the dry raw materials. The preheater kiln system uses dry raw meal that passes through a tower containing one or more cyclone-type vessels that simulate

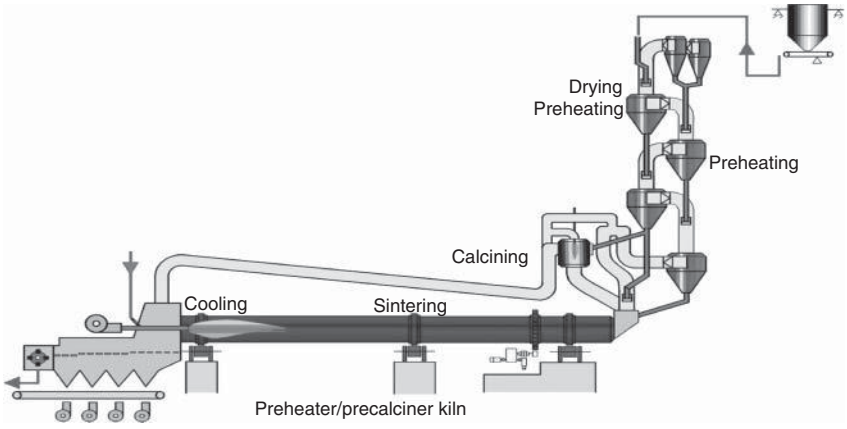

Figure 9.3 Schematic of a typical preheater/precalciner dry kiln in cement industry.

a fluidized bed heat transfer mechanism before entering the rotary kiln. The raw feed is suspended by the hot counter-current kiln gases prior to entering the kiln, and the preheating phase of the process is accomplished in the tower in a few seconds. This allows a rapid and more efficient energy transfer between the hot kiln (flue) gases and raw meal than a typical long dry or wet process kiln.

A preheater/precalciner kiln system has a tower with preheater vessels but also contains a secondary combustion vessel, called a *calciner*, near the lower stages of the preheater tower. (Figure 9.3 shows a typical preheater/precalciner kiln system, and Figure 9.4 documents the temperature profile of a preheater/precalciner kiln.) Fuel is introduced into the calciner and about 90% of the kiln feed is calcined within a few seconds in the hottest zone of that vessel. In this type of process, drying, preheating, and most of the calcining take place before the feed enters the rotary kiln. Preheater and preheater/precalciner systems require shorter rotary kilns, and the process is the most energy-efficient from a fuel standpoint. Approximately 60% of the overall fuel requirements for a precalciner system is at the calciner versus the main burner in the rotary kiln [5]. Therefore, the addition of a precalciner also extends the refractory service life of the kiln by reducing the heat load inside the rotary kiln. A variety of fuels with larger particle sizes and lower heat values can be accommodated in the calciner as the temperature required for calcination is much lower than sintering (clinkering) the raw meal into clinker. Most of the preheater/precalciner kiln systems are equipped with in-line raw mills usually located between the preheater tower and the APCD, allowing the exhaust gas from the preheater to be further used to dry the raw material in the raw mill. The gases exit the raw mill and pass through the APCD before being released from the stack to the atmosphere. APCDs employed for these types of systems are primarily fabric filters, or baghouses; however, some kilns do use ESPs.

Modern large kilns produce 4000–5000 tons of clinker per day or ~1.5 million tons of clinker per year. This requires processing between 6000 and 8000 tons of raw materials daily. Due to the large amounts of fuel and raw materials required to

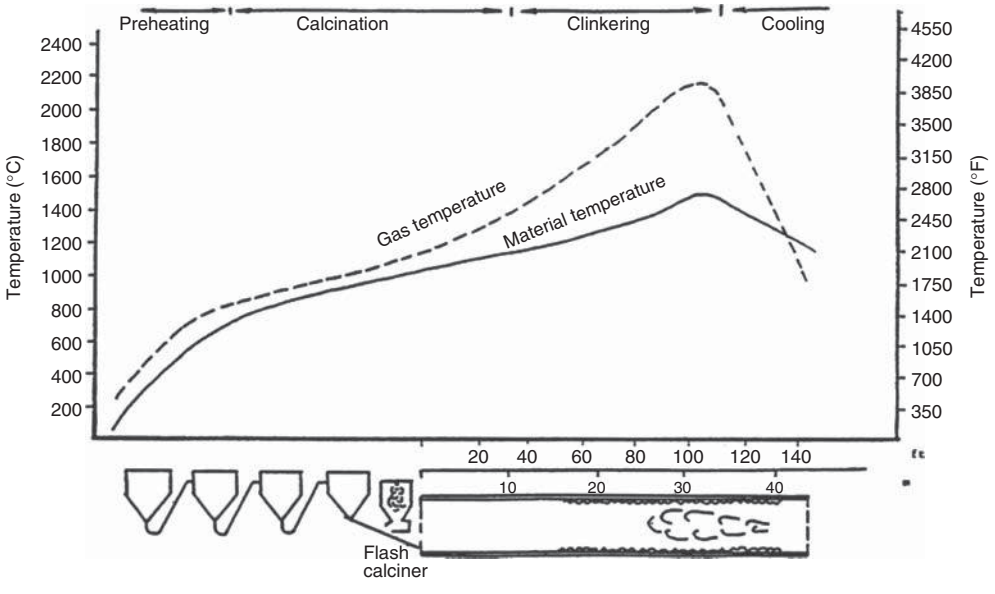

Figure 9.4 Temperature profile of a typical preheater/precalciner dry kiln system [4]. (Reproduced from Ref [4] © (1986) with permission from Chemical Publishing Co. Inc.)

produce cement clinker, there is a production incentive in the cement industry to find alternate fuels and raw materials compatible with the manufacturing process, where cost-effectiveness of the operations can be improved and quarrying of naturally occurring materials can be reduced.

9.3
State of Knowledge on the Source and Behavior of Mercury in the Cement Kiln System

Mercury can enter the kiln system from two sources – the raw material and the fuel – both of which inherently contain trace amounts of mercury as naturally occurring substances and are used in large quantities in manufacturing cement. The mass and chemical composition of the raw material and fuel and the type of pollution abatement technology ultimately determine the quantity of the mercury emissions from a cement kiln system. Studies have been conducted to determine the mercury content of cement manufacturing raw materials and fuels. The studies have revealed mercury concentrations ranging from 0.01 to >1.0 ppm in raw materials [6]. The amount of mercury in the raw feed is highly dependent on the quarry characteristics. The mercury input from fuel can also be significant. The concentration and distribution of mercury content in coal has been documented through U.S. Geological Survey research over the last 20 years. The study results show concentrations ranging from 0.058 to 0.362 ppm [6]. It is also important to note there are several constituents in raw materials that can have an effect on the kiln operations/chemistry and resulting air emissions.

These include sulfur content, alkali content, chlorine content, and other minor constituents (e.g., fluorine). The understanding of the chemistry can also play an important part in the understanding of potential mercury reactions in the cement kiln system and the form of the mercury in the exhaust gas from the kiln.

All mercury and mercury compounds in the fuel or raw material are volatilized and converted completely to the elemental form (Hg^0) at temperatures above 500 °C in the kiln system. The volatilized mercury is subsequently carried through the kiln system toward the raw feed end of the kiln along with combustion gases, where it is subject to cooling from ~1900 °C down to ~200 °C. Generally, once mercury enters a cement kiln system, it has five potential fates [7]:

- It may remain unchanged and exit the kiln as part of the clinker (very small amount).
- It may react with raw materials and exit the kiln as part of the clinker (very small amount).
- It may vaporize in the high temperature zone of the kiln and/or preheater.
- It may condense or react with the CKD and be removed by the APCD.
- It may exit the kiln system in vapor form or be adsorbed to a dust particle as emitted from the stack.

If the primary source of mercury is the raw feed, studies have shown that it is likely to be in the form of mercury sulfate ($HgSO_4$) or mercury sulfide (HgS) in the raw material [7]. If the mercury is primarily from the fuel, then it is most likely in the mercuric chloride ($HgCl_2$) or HgS form, or already existing as mercuric oxide (HgO). Also, during combustion, oxidizing agents that may be present in the fuel, such as chlorine and sulfur, are released. These oxidizing agents play an important role in the speciation of mercury emitted from cement kiln systems.

Mercury is reported to be present in the combustion gas (or flue gas) comprising varying percentages of Hg^0, oxidized (Hg^{2+}), or particle-bound (Hg_p) form [8]. Hg^0 is considered as less reactive, highly volatile, and also insoluble in water. It passes through the entire kiln system and exits the stack in the vapor phase. Hg^0 and a minor proportion of HgO can be present in the flue gas at high temperatures; however, only Hg^0 is stable at the high temperatures. As the flue gas cools, mercury is oxidized through the reaction with compounds from the raw materials and fuel (e.g., chlorinated compounds, oxygen, bromine, etc.). Hg^0 and Hg^{2+} comprise the vapor-phase mercury. Organomercury compounds would be minuscule in comparison to inorganic mercury or not likely to be found in the emissions of a cement kiln as these compounds would be destroyed in the presence of the high temperatures in the kiln system. In the cooler zones of the kiln system, the Hg^{2+} may adsorb or condense onto CKD particles in flue gas to form Hg_p. Much of the dust containing mercury would then be captured by the APCD and, for most kiln systems, returned to the kiln. A portion of the CKD is often removed from the system in order to lower the alkali content of the clinker to meet product specifications. The removal of CKD is a mechanism to bleed the kiln system of alkali salts that build up as they circulate through the system. Mercury adsorbed onto the dust would also be removed in the same way.

A number of complex thermo-chemical gas-phase reactions control the speciation of mercury associated with cement kilns. The presence of hydrogen chloride (HCl) in the exhaust (flue gas with a range of HCl from 1 to 120 ppm or greater), which may accelerate the mercury oxidation reaction in the kiln through the Decon reaction, can result in the formation of $HgCl_2$ [9–12]. The oxidation of mercury occurs when the elemental mercury reacts with chlorine to form $HgCl_2$ below the gas temperature range of 480–590 °C due to a thermo-chemical process [6, 13]. The possible mercury oxidation in the kiln system is reported to be a homogeneous- or heterogeneous-phase reaction [14]. The homogeneous oxidation may occur in the gas phase whereas the heterogeneous oxidation occurs on the interface of solid particles inside the kiln system or APCD. As the flue gas passes through the APCD, temperatures continue to drop below 200 °C, allowing some of the Hg^0 to be adsorbed onto the CKD. Some of the Hg^{2+} compounds also adsorb and condense onto the CKD. The remaining mercury compounds pass through the stack and are emitted. Mercury oxidation reactions in the cement kiln system are as follows:

$$Hg^0 + Cl_2 \rightarrow HgCl_2 \tag{9.1}$$

$$Hg^0 + HCl \rightarrow HgCl_2 \tag{9.2}$$

There has been a limited, but recently increasing amount of sampling and analysis of mercury speciation in U.S. cement kiln stack emissions. Figure 9.5 shows the averages for Hg^0, Hg^{2+}, and Hg_p emissions for wet kilns, long dry kilns, and preheater/precalciner kilns with both raw mill on and off conditions [15]. Due to the limited data, the results shown in Figure 9.5 may not be representative. However, this limited data indicates that wet kilns predominantly emit higher concentrations of Hg^0 compared to long dry and preheater/precalciner kiln systems. This may be explained by kiln system heat profile differences between wet kilns and long dry or preheater/precalciner kilns. More data are needed to be more definitive on mercury speciation from different kiln systems.

In a long wet or dry kiln, the raw materials are introduced through the kiln feed end where they encounter gas temperatures of ~200–300 °C. In the long kiln, the evaporation of water from the slurry (wet kiln) or kiln feed (dry kiln) must first occur, with the raw meal being maintained in the 50–100° C range, with gas temperatures being as high as 300 °C (Figure 9.2). Hg^0 that may form during drying and subsequent calcination of raw meal will reach the APCD with a very limited interaction with CKD. For long dry kilns, as there is little water to evaporate, the temperature profile may be sufficiently different compared to the long wet kiln that oxidation may be more pronounced. In consideration of the limited data and knowledge of other influencing factors that may be present, additional long-term data are necessary to confirm the assumed mechanisms of formation.

In contrast, in a preheater/precalciner kiln system, the raw meal passes through the preheater cyclones and calciner before entering the rotary kiln. The heat profile of this system, as shown in Figure 9.4, allows sufficient time and temperature for the oxidation of mercury to occur in the presence of an oxidizing agent (e.g., chlorine, sulfur, and oxygen). In the preheater/precalciner system, the formation of

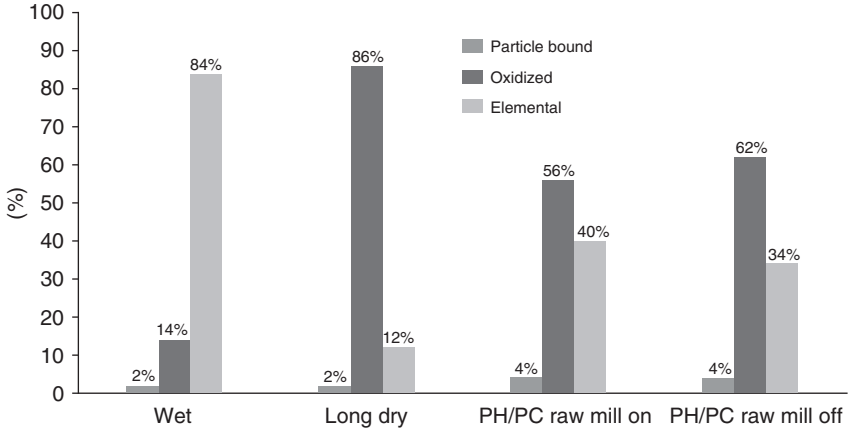

Figure 9.5 Mercury speciation percentages – averages for all kiln types [15]. (Reproduced from Ref [15] © (2009) with permission from Portland Cement Association.)

Hg^0 occurs when the temperature of the raw meal reaches in excess of 500 °C as it descends through the preheater tower.

Figures 9.5 and 9.6 show mercury speciation data for all kiln types and for preheater/precalciner systems with the raw mill on-line and off-line conditions. The data for preheater/precalciner systems is derived from tests on seven different kiln systems. The studies have shown that, during the raw mill off-condition, the gas stream delivered directly to the system's APCD is found to have a higher concentration of mercury as compared to the raw mill on-condition [16]. When the mill is on-line, exhaust gas exits the top of the preheater tower and is introduced into the raw mill to dry the raw meal. The temperature of the mercury-laden hot flue gas exiting the preheater tower prior to entering the in-line raw mill ranges from 315 to 398 °C. The preheater tower exit gas typically contains ~100–150 g nm^{-3} of fine

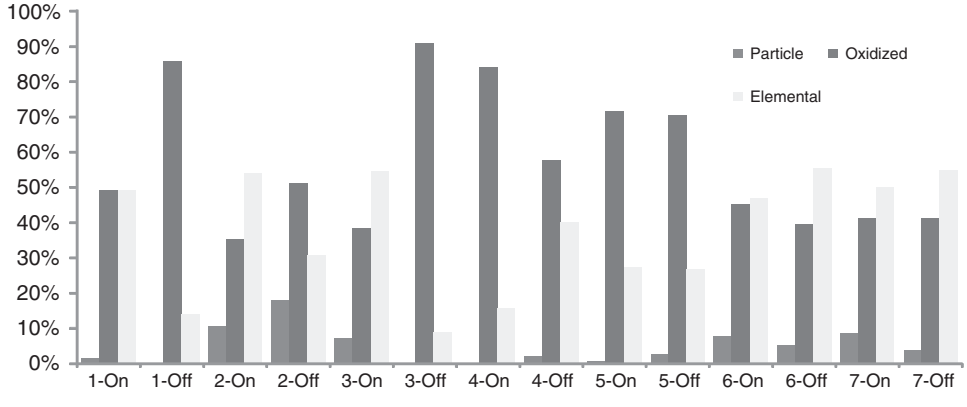

Figure 9.6 Mercury speciation percentages – raw mill on and raw mill off [15]. (Reproduced from Ref [15] © (2009) with permission from Portland Cement Association.)

dust particles [15] containing volatilized Hg^0. In this scenario, the operating raw mill acts as both a dry scrubber and condenser. The gas temperature is reduced through heat exchange in the raw mill to the exit temperature of 90–120 °C. The larger surface area of the finer dust particles in the gases allows adsorption of condensed material containing mercury to occur at the lower temperatures.

The gas stream exiting the raw mill with mercury-laden fine particles is ducted to cyclones in most system designs prior to the APCD, thus removing 85–90% of the coarser particles (10–50 μm range) from the gas stream. The finer particulate (0–5 μm) is carried to the APCD where further gas/particulate separation occurs. In essence, with the raw mill operating, mercury-laden particulate is captured by both the raw mill system and the APCD and is transported to the blend silos where it is re-blended into the raw meal and used as kiln feed, creating the opportunity for a significant mercury recycle loop. The cleaned gas stream is exhausted out the stack. When the re-blended raw meal reaches temperatures in the preheater cyclones of ~400 °C, the captured mercury is again volatilized and returned in the gas stream to the raw mill, only to be recaptured in the particulate. The repeated volatilization and adsorption of mercury in the preheater tower, raw mill, and APCD create an enriching mercury loop in the kiln system during the raw mill on operating condition.

For illustrative purposes, Figure 9.7 shows a mercury loop in a cement kiln for the raw mill off and on conditions. When the mill is off, the kiln flue gas stream continues to be cleaned by the APCD. This stream has particulates, in the form of CKD, with elevated levels of mercury. In general, the mercury-laden CKD

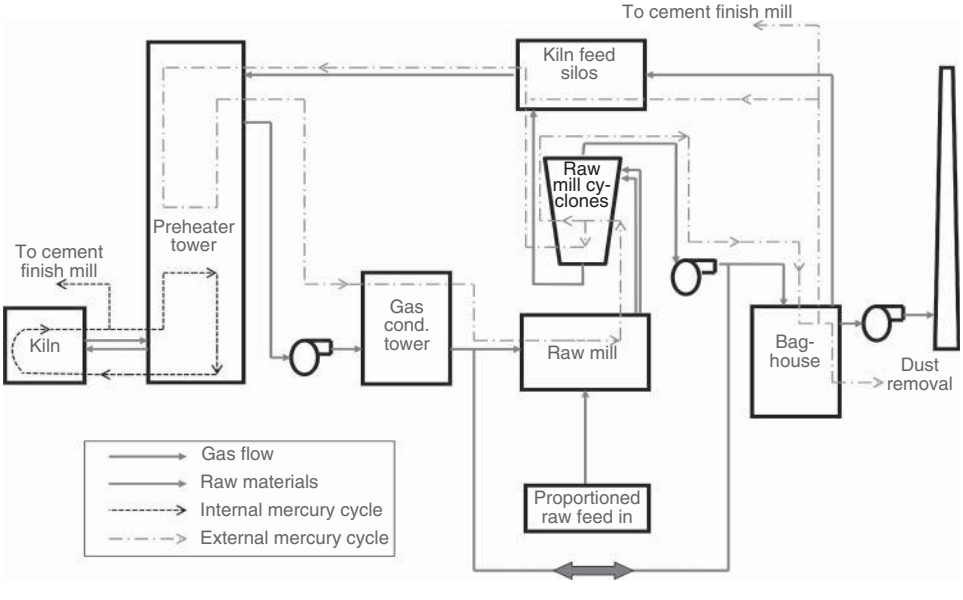

Figure 9.7 Possible internal mercury pathways in cement kiln system and external cycle during raw mill off and on condition.

captured by the APCD would be returned to the kiln. As the CKD is returned to the system, a circulation of mercury will be created through the preheater, raw mill, and APCD. Depending on the APCD inlet temperature, some of the mercury may be in the gaseous state due to higher operating temperatures in the mill off condition, will not be attached to the CKD, and will be released to the environment. The net effect of raw mill on and off is simply accumulation of mercury in the kiln system. Eventually, the mercury will be released to the environment over time [17].

The release and form of mercury in cement kiln systems is not completely understood. In general, the form of mercury in the system will be dependent on the cooling rate, temperature, and opportunities for the oxidation/chemical reaction to occur. These conditions correspond to the gas-phase chemistry relevant to the specific kiln characteristics, which are driven by the raw materials, gas conditions, and operating conditions. For example, the concentration of chlorine in the flue gas depends on a complex series of gas-phase reactions involving oxygen, water vapor, hydrocarbons, chlorine, and sulfur compounds present in the flue gas in the kiln system [18, 19].

Without significant data on mercury speciation in cement kilns, it is difficult to make definitive statements about the types of mercury compounds. However, the gas-phase equilibrium studies for coal-based flue gas suggest that $HgCl_2$ is the dominant oxidized species in flue gas at temperatures below 480–590 °C [19, 20]. The equilibrium of the oxidation reaction also depends on the concentration of chlorine and the degree of flue gas cooling [19]. It is generally assumed that the oxidation of mercury may have a similar pattern in the cement kiln system. Therefore, the degree of oxidation of mercury in the cement kiln system would be expected to decrease with increased flue gas cooling rates. As the flue gas temperatures continue to cool to the mercury boiling point (~357 °C), some of the mercury reacts to form HgO, which may further react with chlorine to form $HgCl_2$. However, the gas-phase homogeneous oxidation of Hg^0 is kinetically limited because of the short residence time [10], on the order of ~2 s. At gas temperatures below ~325 °C, some of the mercury may react with sulfur dioxide (SO_2) to form $HgSO_4$ and its subsequent reaction with gaseous HCl produces volatile dichloride which remains within the flue gas [21]. Therefore, the presence of SO_2 compounds in the flue gas may limit the concentration of chlorine and subsequent conversion of Hg^0 to $HgCl_2$.

The formation of complex silicates in a kiln system is also possible due to the high silica content in typical raw feed (13–15% by weight) and sufficient residence time for reactions to take place as vaporized mercury cycles through a kiln system. Owens *et al.* [22] stated that the formation of mercury silicates is possible based on the estimated thermodynamic data at temperatures ranging between 225 and 325 °C. However, the formation of mercury silicate may be inhibited by the presence of chlorine and sulfur. Additional research and alternative laboratory methods for clinker analysis will be required to confirm that mercury silicates are stable above temperatures of 325° C. As the flue gas passes through the APCD, the temperature continues to drop below 200° C, allowing some of the Hg^0 to adsorb

Table 9.1 Potential mercury transformation within cement kiln systems [15]. (Reproduced from Ref [15] © (2009) with permission from Portland Cement Association.)

System temperature (°C)	Chemical species influencing reactions	Resulting mercury compounds
2200	—	Hg (elemental, vapor)
<480–590	Chlorine	$HgCl_2$
<350	Oxygen, chlorine	HgO, $HgCl_2$
<325	Sulfur	$HgSO_4$
225–325	Silica	$HgSiO_3$

onto CKD particles. Also, some of the Hg^{2+} compounds (i.e., $HgCl_2$, HgO, $HgSO_4$) adsorb onto the CKD particles as mentioned already. It is evident that a lower flue gas temperature would produce more Hg_p, which would be efficiently removed by the APCD [23] with the remaining mercury compounds exiting the stack. The mercury reactions that can take place at different temperatures in a cement kiln system are summarized in Table 9.1.

It is postulated that nearly all forms of mercury exiting the kiln system will be gaseous or condensed on the fine particulate that exits with the gas stream. However, there is some very limited data that shows the presence of low but detectable levels of mercury in cement clinker. As cement manufacturing is a large industrial process that involves complicating factors such as raw mill on versus raw mill off and accumulation of mercury in the feed silo or accumulation at different parts of the system, it is important to note that a short-term stack emission test is not necessarily representative of actual annual emissions.

9.4
Mercury Emissions Control Solutions in the Cement Industry

U.S. Environmental Protection Agency (EPA) recently set a new limit for maximum mercury emissions from U.S. cement kiln stacks at 55 lb MM ton^{-1} clinker for an existing kiln, and 21 lb MM ton^{-1} clinker for a new kiln [24]. Therefore, reductions of mercury from cement kiln stacks will need to be further accomplished in the near future, in addition to those reductions already being implemented.

As described earlier, the source of mercury emissions from cement kiln systems are trace amounts of mercury in the raw materials and fuel that are inherently introduced into the kiln system as a part of the cement manufacturing process. The behavior of mercury in cement kiln systems is very complex as mercury can exist in various forms depending on the type of system and the chemical reactions that occur in that specific system. The following possible approaches can be considered for mercury control, which are based on the current state of mercury

control knowledge as applied to the cement process. Further study is ongoing and may provide additional approaches or variations to the following.

Option 1: The mass of mercury entering the kiln system can be reduced by using different raw materials or different fuels containing smaller trace amounts of mercury, although this option is limited.

Option 2: Some of the CKD captured in the APCD that contains elevated mercury concentrations can be removed from the system and wasted, treated, or mixed with clinker.

Option 3: The gas stream can be treated to remove the mercury before it is exhausted out the kiln stack.

Each of these options is further described in the following paragraphs.

Option 1: Although this option may sound the most practical, reducing mercury emissions by reducing mercury concentrations in the raw materials may be difficult to accomplish without profound economic consequences. Cement plants are located in areas where raw materials are readily available. Therefore, changing sources of raw materials, if possible, could impose a huge economic burden on a cement plant. In a situation where the fuel is found to contain relatively high trace levels of mercury, the economics, and practicality of reducing mercury inputs may also be difficult. Transportation costs for fuel can be very significant and the location of a potential alternate source of fuel with lower mercury content may significantly increase costs of fuel acquisition.

Option 2: In cement kiln operations, a portion of the CKD is often removed from the system in order to lower the alkali content of the clinker to meet U.S. product specifications. This mode of operation is also known in the cement industry as wasting CKD. This practice is minimized as much as possible to keep from wasting material that has already been partially calcined, thus continuing to have economic value as a partially processed raw material. As a matter of fact, the U.S. cement industry has made significant reductions in dust wastage rates over the last few decades. The removal of CKD is a mechanism to bleed the kiln system of alkali salts that build up as they circulate through the system in a pattern similar to mercury. If a portion of the dust from the APCD is not wasted, the mercury remains in the system and is recirculated, with the concentration of mercury in the external loop of a preheater/precalciner system (shown in Figure 9.7) increasing over a period of time. If the raw mill exhaust is equipped with cyclones to separate coarse dust particles that are transported to the blending silo, then the mercury concentration in the APCD may not be significantly different between raw mill off versus raw mill on operating modes. If the raw mill exhaust is not equipped with cyclones, then diverting APCD dust with the raw mill on will not be as efficient for removing mercury from the system because of the dilution effect of the large mass of dust captured by the APCD. The amount of CKD generated in a typical kiln system when the raw mill is off can be

significant at 8–15 ton h^{-1}. Wasting all the CKD would not be economically viable due to its value as a raw material to the process.

A patent-pending, mercury-laden, kiln CKD roasting technology has been identified as a possible mercury removal mechanism for the cement industry [25]. In the roasting system, the mercury-laden CKD is heated above the boiling point of mercury. While mercury is in the gas phase, an ESP is used to separate the dust from the gas-phase mercury, which can then be removed by various techniques such as activated carbon injection (ACI). The cleaned dust is taken back to the blending silo to be used as kiln feed.

Another practice possible for cement plants is called *dust shuttling*. This practice is utilized currently at some facilities, and is being considered by others as a potentially viable option to remove mercury from the kiln system by shuttling dust from the APCD. For this practice, the facility maintains a specific mix chemistry to allow incorporating a small quantity (3–5% of product) of CKD in the finish mill, intermixing the CKD with cement [25–27].

For those cement kilns that do not waste or shuttle CKD, it is reasonable to assume that essentially all the mercury in the raw material and fuel will end up as stack emissions over the course of a year. However, if a portion of the dust is shuttled, this will lower mercury stack emissions, as some of the mercury becomes bound up in the cement product matrix. This is a viable mercury reduction option to the extent the CKD can be interground with the clinker while still maintaining a quality product. Since only a portion of the collected CKD from the APCD can be diverted, the mercury reduction capability is limited. It is reported that the efficiency of mercury removal of APCD dust is dependent on site-specific conditions, including the flue gas composition, operating temperature at the inlet of APCD, and dust loading in the systems [25]. Thus, dust shuttling is expected to have a limited impact on mercury emission reductions. However, in the event, as the shuttled CKD has a high mercury content, dust shuttling may present an effective method of removing mercury from the system, subsequently being a significant mercury control option.

Option 3: When considering cement industry options for treating the gas stream for mercury removal before exhausting the gas through the kiln stack, the majority of the controls require tailpipe treatment after the existing APCD. In fact, as described below, control technologies being currently considered would require an additional APCD between the existing APCD and the stack.

Mercury control technologies currently being considered as options for cement kiln system emissions include

- Activated carbon injection (ACI)
- Wet scrubbing
- Selective catalytic reduction (SCR) and wet scrubbing.

9.4.1 Activated Carbon Injection (ACI)

Activated carbon is a widely used adsorbent in several industries due to its unique physical and chemical properties. The large surface area, pore volume, and pore size distribution of activated carbon make it a potential adsorbent to accomplish mercury removal from the cement kiln flue gas. ACI applications have been used historically for mercury control in municipal waste incinerators, hazardous waste incinerators, and power plant applications. However, there are some factors that make direct transfer of this technology to the cement industry less effective. For example, the variable SO_2 and HCl concentrations along with a high dust loading of calcium and alkali materials may interfere with the absorption sites on the activated carbon. The percent mercury removal using ACI in the cement industry will be dependent on the temperature and composition of kiln flue gas and the amount and type of activated carbon used. Cement kiln APCD operating temperatures are usually at the high end of absorption temperatures of activated carbon, being effective up to 204 °C. It has been found that typical mercury reduction ranges from 20% to 90% using ACI rates of 2 – 10 lb $MMacf^{-1}$. It is reported that the mercury adsorbed onto activated carbon is stable. It does not readily desorb, nor is it leachable (based on toxicity characteristic leaching procedure (TCLP) results) [28, 29]. This becomes an important factor as the carbon and CKD captured in the APCD must be appropriately managed for final disposal.

There are at least two cement kilns in the United States currently using ACI technology for mercury control. However, there are additional issues to study and resolve as described in the following paragraphs.

The new EPA MACT (maximum achievable control technology) standard for HCl in an existing cement kiln is 3 ppm [24]. When facilities comply with the HCl standard concurrently with the Hg standard, there may be an impact on the effectiveness of mercury control technologies. This correlation needs to be taken into account for determining the final control mechanism for a particular kiln. Moreover, chlorine in the cement kiln may combine with the alkalis (sodium and potassium) prevalent in the raw materials, resulting in insufficient chlorine to convert Hg^0 to Hg^{2+}. In addition, the presence of SO_2 in the flue gas may interfere with the carbon absorption efficiency [30].

In employing ACI technology to a cement kiln system, an additional APCD may be required to be constructed between the existing APCD and the kiln stack for further polishing. Activated carbon would be injected into the gas stream between the first and second APCDs. By capturing the remaining mercury from the flue gas in the second APCD before it is exhausted through the stack, mercury can be effectively removed from the system, as the mercury-laden activated carbon is separated from the kiln flue gas stream prior to the gases being released to the environment through the stack. This activated carbon can be wasted typically to a sanitary landfill as non-hazardous solid waste, which would effectively remove mercury from the kiln system.

Another approach to collecting and removing mercury from a cement kiln would be to use the absorption capacity of the kiln system, which could also be enhanced by using activated carbon. In a current kiln system configuration, the CKD is typically recycled to the maximum extent possible back to the kiln as part of the kiln feed, with most of the Hg_p being absorbed by the dust recycled back to the kiln. However, in some kiln systems, activated carbon could be injected into the main baghouse, depending upon the mercury carbon absorption properties of the collected dust. Some of this collected dust could be shuttled to the finished mill, with the remainder sent to the blend silos. This would work where the dust shuttled material would be small enough not to impact product quality. The material from the blend silos would re-enter the kiln system, destroying the carbon, and releasing the mercury to be once again collected on new carbon that is injected into the baghouse. This would have the effect of increasing the mercury concentration of the baghouse dust, which would make the removal of that dust a more efficient mechanism for mercury removal from the kiln system.

For an in-line raw mill system, ACI might be a mercury control option when the raw mill is off-line. However, the adsorption of mercury onto activated carbon is temperature-dependent. It is reported that ACI can work effectively only at temperatures below 160 °C [31]. This may be a problematic temperature for some existing systems as the flue gas temperature is comparatively high when the raw mill is not operating. Some halogenated powdered activated carbon (PAC) is reported to reduce mercury emission by more than 70% at APCD inlet temperatures up to 343 °C, but further investigation is needed to test the PAC performance for a longer period of time at various cement plants. As an example of potential issues, the brominated PACs could cause operational issues in a kiln system if they are reintroduced, causing an imbalance in the alkali–halogen ratio in the kiln.

As described above, both temperature and mercury concentrations in the flue gas may be issues that render the use of ACI technology less effective in the cement kiln system environment. Moreover, the baghouse dust with activated carbon may be problematic when used in clinker grinding or dust shuttling, but this issue will be site-specific. Activated carbon negatively impacts the air entrainment capabilities of the final cement product [25, 32]. Although ACI has the potential for mercury control in a cement kiln system, the industry still faces the significant economic issues of an additional large capital cost to construct a second APCD and to deal with disposal of the mercury-laden carbon material.

9.4.2 Wet Scrubbing

Wet scrubbing has been used in several industrial processes such as the electric power generation industry to reduce the SO_2 content of flue gases. In this process, a slurry of limestone or lime is sprayed into the gas stream, usually after the APCD, and the acidic SO_2 content of the gas reacts with the basic lime content to form gypsum. Therefore, the soluble components within the gas stream are removed in the scrubber, and a clean gas stream results. The solid residue that is

formed is removed and discarded. Wet scrubbers have not been used extensively in the cement industry historically due to lime inherently being in the kiln system. This creates a natural dry scrubbing process that removes much of the SO_2 content from gaseous effluents, nullifying the need for additional SO_2 control. It is reported that wet scrubbers have the capability of capturing soluble forms of mercury [33]. The oxidized mercuric compounds such as $HgCl_2$ are generally soluble in water, whereas Hg^0 is not soluble in water. EPA has reported that the electric power generation industry has had some success in mercury removal in wet scrubbers, especially in plants burning medium to high sulfur bituminous coals that tend to produce a larger amount of the Hg^{2+} species.

A limited number of cement kiln systems in the United States (five known installations to date) have installed wet scrubbers primarily for SO_2 and acid gas control. It is reported that the wet scrubber can capture more than 80% of SO_2 and $HgCl_2$ from the cement kiln flue gases [25]. However, there are several problems in transferring the process from electric power generation to the cement industry for mercury control. The effectiveness of wet scrubbing is highly dependent on the temperature of the gas stream, and the scrubber is normally located after the APCD. In many cases, the cement kiln gas stream exiting the APCD is >204 °C when the raw mill is off-line. Wet scrubbers have been shown to be effective in capturing up to 90% of the Hg^{2+} in the kiln flue gases. Hg_p not captured in the APCD will likely be captured in the wet scrubbers. However, Hg^0 is not removed from the flue gases due to its non-solubility.

As described, the effectiveness of wet scrubbers for mercury removal mainly depends on the mercury species present in the flue gas. In addition, the reemission of mercury may occur with wet scrubbers. Reemission is a result of mercury reduction chemistry in wet scrubbers, where Hg^{2+} is reduced to insoluble Hg^0. Thus, the overall effectiveness of wet scrubbing for cement kiln emissions is unclear [34]. Studies based on the coal-fired power plant flue gases have shown that the amount of mercury retained in the scrubber solids may range from 40% to 85% [35]. The primary reported factor affecting mercury retention by a wet scrubber is the liquid to gas ratio, which may limit the mass transfer of pollutants. In addition, the scrubber solids must be properly managed and the water chemistry must be controlled to prevent reemission of the captured mercury.

9.4.3 Selective Catalytic Reduction (SCR) and Wet Scrubbing

SCR has been developed to remove NO_x emissions from flue gas. In an SCR system, the reducing agent of ammonia or urea is injected into the flue gas at the upstream side of the catalyst bed. The flue gas is passed through the catalyst bed containing oxides of vanadium or titanium where NO_x is reduced to form elemental nitrogen and water vapor. The SCR system is generally installed before the primary APCD in a cement plant for NO_x control as temperatures in the

range of 288–460 °C are required for the catalyst to be effective. A wet scrubber is installed after the APCD to control SO_2 emissions. A co-benefit of the SCR process is reported to be its ability to convert Hg^0 to Hg^{2+}, primarily $HgCl_2$ [36]. As described earlier, $HgCl_2$ is water soluble and can be captured in a wet scrubber along with SO_2. EPA has reported data from its Mercury Information Collection Request (ICR) showing that some electric power generation facilities use a combination of SCR and wet scrubber technologies to control the oxides of nitrogen and sulfur, which is also very effective in removing mercury from flue gases. The oxidation of mercury by the SCR process appears to be dependent on the type of coal combusted, furnace conditions, and physical and chemical properties of the catalyst [37, 38].

The catalyst used in an SCR system has the potential to catalyze the formation of sulfur trioxide (SO_3) from SO_2 and gas-phase chlorine (Cl_2) from HCl that are present in the flue gas [37]. Cl_2 in the flue gas will affect the overall conversion of Hg^0 to $HgCl_2$. Bituminous coal typically contains higher Cl_2 and sulfur than the low-ranking sub-bituminous and lignite coals that are abundant with high calcium [37–40]. Higher quantities of Cl_2 result in greater conversion of Hg^0 to Hg^{2+} in an SCR system and subsequently increase the removal of mercury in the wet scrubber. Conversely, the flue gas from the combustion of sub-bituminous and lignite coal appears to reduce the effectiveness of the SCR in converting mercury. This is due to the Cl_2 in the power plant flue gas from coal combustion tending to react with the alkaline materials in ash resulting in little, if any, Cl_2 being available for the oxidation of mercury. In a power plant SCR application, ~80–90% Hg^0 in the flue gases from bituminous coal use is reported to be oxidized to $HgCl_2$. When the gas stream passes through the wet scrubber, the soluble $HgCl_2$ is dissolved in the solution sprayed into the wet scrubber. Therefore, the wet scrubber would then be expected to remove ~90% of the soluble mercury. The reduction of mercury from the flue gases of a power plant utilizing sub-bituminous and lignite coals is found to be only 20% with or without SCR [40]. However, the use of an SCR system at a cement plant will be dependent on site-specific conditions. The SCR catalyst bed must be located in an area where the flue gas temperature is in the appropriate range. There may be catalyst poisons such as alkali metals and calcium oxide in the cement kiln flue gas that will deactivate the catalyst by reacting with active sites. The catalyst may also become plugged in the high dust installations associated with preheater/precalciner kiln systems.

9.5 Conclusions

The cement manufacturing industry is a raw material-driven industry with demanding combustion conditions a part of the pyroprocessing portion of the process. As such, the study of mercury sources, forms, and emissions are unique in this industry. With the wide range of temperatures existing within a kiln system, mercury can be present in several chemical forms at different locations within the system. It can pass through the system as Hg^0 or a volatile mercury

compound. It can condense or adsorb onto CKD in cooler parts of the system, such as in the APCD or raw mill (for preheater/precalciner kilns), when the temperature falls below 200° C. It has been shown that there are mercury recycle loops within the kiln system. CKD generated during processing of raw meal is recycled back to the kiln as kiln feed, with some systems being designed to continuously bleed some portion of the CKD from the APCD to maintain cement quality. This process inherently helps break the mercury accumulation cycle in the kiln, subsequently reducing the mercury load in the system and therefore reducing annual emissions.

As increased regulatory controls have just been put in place, and corresponding control of mercury emissions is currently being evaluated for future installations, the status of proven mercury control technologies used in cement kiln systems to treat the kiln exit gas stream is not yet clearly established. There are several technologies, including the use of ACI, a wet scrubber, and SCR; all of which are currently used to control mercury from flue gases in the electric power generation industry and for municipal and hazardous waste incinerators. These technologies may potentially be transferable to a cement kiln system, although the gas streams that exit the kiln are different than those industries currently using these technologies for mercury control. Current mercury control technologies used in other industries and transferred to cement kilns would require the installation of an additional APCD for an ACI installation or wet scrubber for particulate control downstream of the existing APCD. Another mercury control solution may be through wasting or shuttling some of the mercury-enriched CKD collected in the APCD when the raw mill of a preheater/precalciner kiln is off-line.

Regardless of the control system(s) used for mercury in a cement plant, additional data collection on the variation of mercury emissions over time needs to be conducted. This is especially true of emissions under the raw mill on/off scenarios of a preheater/precalciner kiln. Additional data collection is also needed to determine the speciation of mercury emissions from cement kiln stacks and within the kiln process. As described in this chapter, and throughout this book, many of the control technologies are dependent on the exact form of mercury. There are limited definitive studies on the speciation of mercury in a cement kiln system, and there is yet much to learn on mercury control for this industry. It is anticipated that much knowledge will be gained over the next few years and that additional control technologies currently being developed and tested will become additional solutions for the industry.

10.1
Introduction

The U.S. Department of Energy's (DOE's) National Energy Technology Laboratory (NETL) managed a comprehensive, collaborative program from the mid-1990s to 2008 that focused on the research, development, and demonstration (RD&D) of cost-effective mercury (Hg) control technologies, including investigating the potential impact of Hg control on the use and disposal of coal combustion byproducts. The overall goal of the program was to significantly lower the cost and increase the capture efficiency of advanced systems to remove Hg from coal combustion flue gas, should coal-fired power plants be regulated. NETL achieved this ambitious goal and ultimately was successful in bringing Hg control technology from what was only a concept in the early 1990s to a commercial product. As of 2010, pollution control equipment vendors have sold nearly 150 full-scale activated carbon injection (ACI) systems, a signature technology of the NETL program, to U.S. coal-fired power generators. These sales represent more than 56 GW of coal-fired electric generating capacity. The U.S. Environmental Protection Agency (EPA) projects that 146 GW of ACI will be installed on U.S. power plants by 2015 in order to comply with proposed Federal Hg emission control regulations [1]. The Hg control systems developed under the NETL program that are currently being deployed by the electric-utility industry have the potential to achieve 80–90% or more Hg reduction at a cost that can dip below $10 000 per pound of Hg removed, compared to baseline costs of $50 000–70 000 per pound of Hg.

10.2
Background

Coal is one of the United States' most abundant and secure energy resources and coal-based power systems generated ~45% of the nation's electricity in 2009 [2]. Coal is projected to continue to be an important component of the U.S. energy

Mercury Control: for Coal-Derived Gas Streams, First Edition.

portfolio well into the twenty-first century. While coal-based power plants have made significant strides since the early 1970s in substantially reducing emissions of particulate matter (PM), sulfur dioxide (SO_2), and nitrogen oxide (NO_x), environmental challenges still exist. One of those challenges is Hg. Mercury is found in trace amounts in coal, and much of it escapes capture by technologies designed to remove PM, SO_2, and NO_x. Today, coal-fired utility boilers represent the largest source of anthropogenic Hg emissions in the United States, accounting for about 50% of all man-made emissions [1].

Mercury is present in dilute concentrations in power plant flue gases. Liquid at room temperature and pressure, Hg, when heated, is volatile and easily vaporized. Depending on the type or mix of coal being burned and the downstream emissions control systems being employed by a power plant, Hg is released to the atmosphere in varying percentages in two primary gaseous forms – elemental Hg and oxidized Hg. It can also be emitted as particulate-bound Hg.

As part of the 1990 Clean Air Act Amendments (CAAAs), Congress mandated that EPA assess the potential health impacts of Hg and other hazardous air pollutants and, if necessary, set standards that would reduce these impacts. In 2000, EPA determined that there was sufficient evidence of a link between Hg emitted from stationary sources and certain adverse health effects and began crafting regulations. In March 2011, EPA proposed new Federal Hg standards (known as *Maximum Achievable Control Technology* (*MACT*)) that would reduce Hg emissions from coal- and oil-fired power plants by more than 90%. The new proposed rule will replace the vacated Clean Air Mercury Rule (CAMR) that was issued by EPA in March 2005. The proposed MACT standards would establish plant-specific numerical emission limits for Hg, PM (a surrogate for toxic, non-Hg metals), and hydrochloric acid (a toxic acid gas). The final MACT rule was promulgated in November 2011. Due in part to EPA's delay in setting Federal Hg emission standards, state regulatory agencies began implementing Hg standards. As of February 2011, at least 14 states had laws or regulations requiring Hg emission reductions at coal-fired power plants [3].

10.2.1 NETL's Hg Control Technology R&D

Paralleling EPA's assessment of the health effects of Hg, NETL initiated an ambitious Hg control technology research and development (R&D) program in the mid-1990s [4]. The program was driven by concerns that cost-effective Hg capture technology did not exist should EPA conclude that Hg emissions from coal-fired power plants and other stationary sources needed to be regulated. Under DOE's Office of Fossil Energy's (FEs) Innovations for Existing Plants (IEP) Program, NETL worked collaboratively with EPA, the Electric Power Research Institute (EPRI), the University of North Dakota Energy and Environmental Research Center (UNDEERC), power plant operators, and state and local agencies, as well as a host of research organizations, technology developers, and academic institutions, to bring to commercial readiness both reliable techniques for measuring the

different chemical forms of Hg in coal-based flue gas and cost-effective technologies and approaches for reducing Hg emissions from power plants.

More than $120 million in Federally funded extramural and in-house research was conducted under the IEP Hg Program – including more than $30 million in private-sector cost sharing – directed at five interrelated research areas:

- Emissions characterization.
- Development and testing of measurement devices.
- Speciation research.
- Development and field testing of control technologies.
- Coal utilization byproducts (CUBs) characterization.

The overall short-term goal of the NETL Hg R&D Program was to develop Hg control technologies that would be ready for commercial demonstration by 2007 and that could achieve 50–70% Hg capture at 50–75% of the cost of state-of-the-art ACI estimated to be between $50 000 and $70 000 per pound of Hg removed. The NETL Hg R&D Program had a longer-term goal of developing advanced Hg control technologies that could achieve 90% or greater capture at 50–75% of the cost of state-of-the-art ACI technology for commercial demonstration by 2010. However, in 2008, it was determined that DOE had successfully achieved its goal of bringing efficient, cost-effective Hg control technologies to commercial readiness and that further development and refinement of Hg control systems should be carried out by the private sector.

10.2.2 Mercury Speciation

Analysis of flue gas samples conducted early in the NETL program revealed that the trace amount of Hg present in coal is volatilized during combustion and converted to gaseous elemental mercury (Hg^0). Subsequent cooling of the coal combustion flue gas and interaction of the gaseous Hg^0 with other flue gas constituents, such as chlorine (Cl) and unburned carbon (UBC), result in a portion of the Hg^0 being converted to gaseous oxidized forms of mercury (Hg^{2+}) and particulate-bound mercury (Hg_P) [5].

The initial research conducted by NETL and other organizations, such as EPRI and UNDEERC, further showed that the varying percentages of Hg_P, Hg^{2+}, and Hg^0 had a profound effect on the Hg capture efficiency of existing air pollution control devices (APCDs) designed to control PM, SO_2, and NO_x emissions, ranging from 0% to more than 90% removal [6]. The Hg_P fraction typically was captured by a power plant's particulate control system, such as an electrostatic precipitator (ESP) or fabric filter (FF). The Hg^{2+} portion is water-soluble, and therefore a relatively high percentage was shown to be removed in a plant's wet flue gas desulfurization (FGD) unit designed to remove SO_2. The Hg^0 fraction is generally not captured by any existing APCD. In addition, operation of a selective catalytic reduction (SCR) system for control of NO_x emissions was shown to promote Hg^0 oxidation and enhance Hg capture across a downstream FGD [7].

In summary, NETL's Hg speciation research revealed that (i) several key factors influence Hg speciation in coal combustion flue gas; (ii) Hg speciation impacts the level of Hg control achieved by existing APCD configurations; and (iii) Hg capture across existing APCD configurations could be enhanced.

10.2.3 Mercury Control Technologies

The Hg speciation research set the stage for the development of a suite of Hg control technologies that would be needed for the diverse fleet of U.S. coal-fired power plants. The research was directed at two general approaches for controlling Hg: (i) Hg^0 oxidation concepts that maximize co-benefit removal of Hg^{2+} in wet FGD systems and (ii) Hg-specific control technology, such as ACI. In a typical ACI configuration, powdered activated carbon (PAC) is injected downstream of the power plant's air heater and upstream of the particulate control device – either an ESP or FF (Figure 10.1). The PAC adsorbs the Hg from the combustion flue gas and is subsequently captured along with the fly ash in the ESP or FF.

In 2000, following laboratory-through pilot-scale development of these approaches, NETL launched a three-phase field testing program. The program called for full-scale and slip-stream testing of Hg control technologies over a limited test period at operating coal-fired power plants. The initial field testing (Phase I) focused on both slip-stream and larger-scale testing of conventional (untreated) PAC and on improving the capture of Hg across wet FGD systems. Phase II, which began in 2003, included longer duration, full-scale field testing of chemically treated ACI, sorbent enhancement additives (SEAs), and sorbent-based technologies designed to preserve fly ash quality. Phase II also included evaluations of chemical additives and Hg^0 oxidation catalysts to enhance FGD Hg capture. The goal of Phase I and Phase II was to develop Hg control technologies that could achieve 50–70% Hg capture at costs 25–50% less than

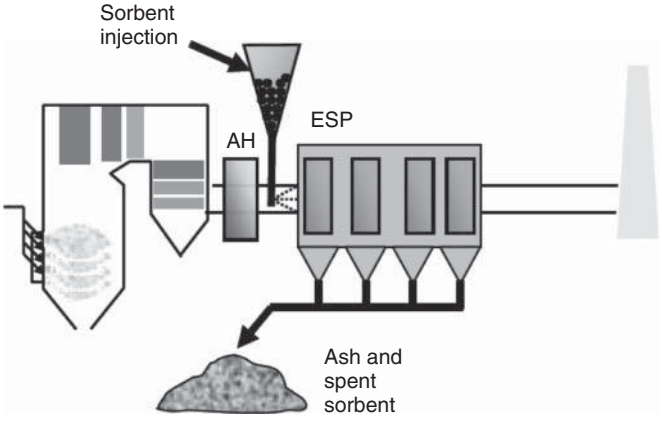

Figure 10.1 Activated carbon injection technology schematic.

the baseline (1999) estimate of about $60 000 per pound of Hg removed ($/lb Hg removed).

While the 30-day-long tests conducted in Phase II yielded significant information on the performance of the advanced Hg control technologies, the testing period was not always sufficient to answer all of the questions about the impact these systems might have on power plant operations. To better understand potential balance-of-plant impacts and to further push the capture effectiveness of the Hg control technologies, NETL initiated nine new projects in 2006 to conduct longer duration field tests. The Phase III projects supported the NETL Hg R&D Program's longer-term goal of developing advanced Hg control technologies that could achieve at least 90% Hg capture and be available for commercial demonstration by 2010.

10.2.4
Results from Field Testing Program

Between 2000 and 2008, the NETL Hg R&D Program managed full-scale field tests of Hg control technologies at nearly 50 U.S. coal-fired power generation facilities. The flexibility of the Hg R&D Program allowed NETL to quickly incorporate insights and lessons learned into the development of advanced Hg control technologies tailored to specific areas of need. For instance, a determination that Cl released during coal combustion promotes Hg oxidation in flue gas led to field testing of technologies designed to provide a halogen "boost" for coals such as subbituminous and lignite. NETL had observed a step-change improvement in both the cost and performance of Hg control during full-scale field tests of coal treatment with an aqueous calcium bromide ($CaBr_2$) solution at plants equipped with a wet FGD system, and during tests using chemically treated (or brominated) ACI upstream of a particulate control device.

10.2.5
Oxidation Enhancements

Oxidation of flue gas Hg^0 followed by absorption of Hg^{2+} across a wet FGD system has the potential to be a reliable and cost-effective Hg control strategy for some coal-fired power plants. To optimize Hg capture across FGD systems, NETL funded field tests of technologies, such as chemical additives and Hg^0 oxidation catalysts that promote Hg^0 oxidation in coal combustion flue gas. The impacts of combustion modification, such as coal reburn, on flue gas Hg^0 oxidation were also examined under the NETL Hg R&D Program [8]. In addition, NETL evaluated FGD additives designed to suppress Hg^0 reemissions across an FGD system. Originally thought to be a sampling artifact, Hg^0 reemissions were observed at several coal-fired units to occur when Hg^{2+} captured by a wet FGD is chemically reduced within the vessel and reemitted as Hg^0.

10.2.6 Chemical Additives

The ability of chemical additives, sprayed onto the coal as an aqueous salt solution, to promote flue gas Hg^0 oxidation and enhance FGD Hg capture was evaluated during a full-scale field test at Luminant Power's Monticello Station Unit 3 [9]. During a 2-week trial conducted at Monticello Station, which burns a 50 : 50 blend of Powder River Basin (PRB) subbituminous and Texas lignite (TxL) coals, total Hg capture across the ESP/FGD configuration averaged 86% with a $CaBr_2$ injection rate equivalent to 113 ppm Br in the dry coal. Greater than 90% total Hg capture was observed during a short-term test with a $CaBr_2$ injection rate equivalent to 330 ppm Br in the coal.

NETL also conducted pilot- and full-scale field tests of wet FGD additives designed to limit Hg^0 reemissions through the formation of insoluble salts with Hg^{2+} [10]. The effectiveness of Degussa Corporation's TMT-15 additive in suppressing Hg^0 reemissions was also evaluated at the Monticello Station and at Southern Company's bituminous-fired Plant Yates. The results were inconclusive due to (i) the absence of reemissions, even without chemical addition, at Monticello Station and (ii) Hg measurement issues at Plant Yates. However, TMT-15 had the anticipated impact on FGD byproducts as the FGD liquor Hg concentrations were significantly reduced during both tests. During a full-scale field test at Indianapolis Power and Light's Petersburg Station, which burns high-sulfur bituminous coal, a modest decline in Hg^0 reemissions was observed during an 8-day TMT-15 injection test, but the additive did not impact the partitioning of Hg in FGD byproducts at this site. Meanwhile, full-scale results obtained during a 30-day evaluation of Nalco Company's 8034 additive at Plant Yates were confounded by low baseline Hg^0 reemission levels. A third wet FGD additive to reduce Hg reemission, Babcock and Wilcox's Absorption Plus (Hg)™, was evaluated at E.ON America's high-sulfur bituminous-fired Mill Creek Station after parametric trials revealed that untreated ACI had little, if any, impact on Hg removal [11]. During long-term testing, total Hg removal averaged about 92% with the addition of Absorption Plus (Hg). Note that more than 80% of total Hg removal was observed under baseline conditions.

10.2.7 Catalysts

The ability of fixed-bed catalysts to promote flue gas Hg^0 oxidation was evaluated at pilot-scale, and a full-scale field test of a gold-based catalyst was conducted in 2008/2009 at Lower Colorado River Authority's Fayette Unit 3 [12]. The catalysts were designed for installation downstream of an ESP or FF to (i) minimize fly ash deposition on the catalysts; (ii) prevent or minimize catalyst erosion; and (iii) ensure a low flue gas temperature and flow rate, which reduces the catalyst space velocity and minimizes the length of catalyst required. The full-scale catalyst test was planned for 24 months to provide catalyst life data. However, the test

was terminated after 17 months because of continual increases in pressure drop across the catalyst. The adverse effects of the fly ash buildup on oxidation catalyst performance, along with variable Hg reemissions across the Unit 3 wet FGD absorbers, led to an increase in Hg removal averaging only 27–30% during the demonstration.

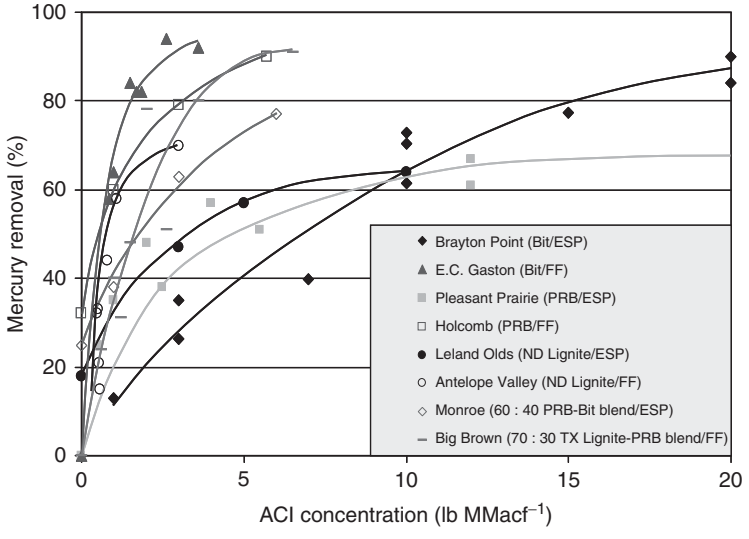
During pilot-scale testing at Great River Energy's (GREs) North Dakota lignite-fired Coal Creek Station, about 67% Hg^0 oxidation was measured across a palladium-based (Pd#1) catalyst after 20 months of operation. Following thermal regeneration, Hg^0 oxidation across the Pd#1 catalyst increased from 67% to 88% (near the 95% activity of the fresh catalyst). Meanwhile, nearly 80% total Hg capture was observed across the pilot-scale wet FGD, with 84% Hg^{2+} at the FGD inlet. At Luminant Power's Monticello Station, severe fly ash buildup was observed on the catalyst surfaces, likely caused by frequent pilot unit outages during the test campaign. Following catalyst cleaning, Hg^0 oxidation was ~72% across the regenerated Pd#1 catalyst (transferred from Coal Creek) and 66% across a gold-based catalyst after about 20 months of pilot-scale operation. Total Hg capture across a pilot-scale wet FGD ranged from 76% to 87%, compared with only 36% removal under baseline conditions. This equates to about 70% incremental Hg capture due to the catalysts.

10.2.8 Activated Carbon Injection

DOE/NETL's portfolio of full-scale field testing projects encompassed several variations of sorbent injection technology: untreated PAC, untreated PAC with chemical additives, chemically treated PAC, EPRI's toxic emissions control (TOXECON™) configuration, TOXECON II™, and non-carbon and "concrete-friendly" PAC sorbents. The development, and subsequent field testing, of ACI with chemically treated PAC and chemical additives, in conjunction with untreated PAC, represented a concerted effort to enhance Hg capture at units firing low-rank coal after Phase I results at the PRB-fired Pleasant Prairie Unit 2 showed total Hg removal via untreated PAC was limited to about 65%. These advanced, Hg-specific control technologies were designed to introduce excess halogens into the Cl-deficient flue gas emitted from low-rank coals to promote Hg^0 oxidation and adsorption. Meanwhile, minimizing the impact of ACI on fly ash utilization was the driving force behind field testing of the TOXECON configurations and non-carbon/"concrete-friendly" sorbent injection.

10.2.8.1 Untreated PAC

NETL's initial field testing using ACI with untreated PAC was conducted by ADA-ES at four coal-fired power plants (E.C. Gaston, Pleasant Prairie, Brayton Point, and Salem Harbor) in 2001–2002 [13]. Testing included parametric tests using several commercially available PAC products at various feed rates and operating



* All data generated using NORIT Americas' DARCO® Hg.

Figure 10.2 Test results for untreated activated carbon injection.

conditions, followed by a 1–2 week short-term test with a PAC selected from the parametric testing. Test results for E.C. Gaston, Pleasant Prairie, and Brayton Point are shown in Figure 10.2. The ACI test results at Salem Harbor were inconclusive because average Hg capture was already at 90% during baseline testing without PAC injection. The high baseline Hg removal was attributed to high levels of UBC and low flue gas temperature.

Untreated PAC was also evaluated during two 30-day long-term tests at Plant Yates Unit 1 during subsequent field testing during Phase II of NETL's R&D Program. URS selected RWE Rhinebraun's Super HOK sorbent and total Hg capture varied from 50–86%, with injection rates ranging from 4.5 to 9.5 lb MMacf^{-1} [14]. Plant Yates was selected for long-term testing, in part, to gain a better understanding of the effect of ACI on small specific collection area (SCA) ESP (173 SCA) and wet FGD operation. URS observed an increase in the ESP arcing rate during continuous ACI, particularly at high load. While the 30-day long-term injection test caused no visible physical damage to the ESP, it was unclear what effect the increased arcing rate would have on ESP performance over longer time periods.

ADA-ES chose DARCO® Hg PAC for the 30-day long-term test conducted at DTE Energy's Monroe Station Unit 4, which burns a 60% PRB and 40% bituminous coal blend and is equipped with an SCR and cold-side-electrostatic precipitator (CS-ESP) [15]. Total Hg removal averaged 78% with DARCO Hg injection at 4.9 lb MMacf^{-1}. The performance of untreated DARCO Hg during select full-scale field tests is presented in Figure 10.2.

10.2.8.2 Chemically Treated PAC

The limited Hg removal achieved by untreated ACI at Pleasant Prairie spurred the development and full-scale field testing of alternatives, such as PAC chemically treated with Br. Two brominated PACs – NORIT Americas' DARCO Hg-LH and Sorbent Technologies' B-PAC™ – were consistently top performers at field testing units burning lower-rank coals. In fact, the outstanding performance (see Figure 10.3) of these brominated sorbents accelerated the commercialization of Hg-specific control technologies and drastically reduced the estimated cost of Hg control due to a reduction in the ACI rate required to achieve a given level of control, which offsets the higher cost of these sorbents.

ADA-ES selected brominated DARCO Hg-LH for 30-day long-term field tests at two PRB-fired units: Sunflower Electric's Holcomb Station Unit 1 and AmerenUE's Meramec Station Unit 2. At Meramec, 93% average total Hg removal was achieved across the CS-ESP with DARCO Hg-LH injection at 3.3 lb $MMacf^{-1}$ [16]. Total Hg capture averaged 93% across the spray dryer absorber (SDA)/FF configuration at Holcomb with DARCO Hg-LH injection at 1.2 lb $MMacf^{-1}$ [17]. UNDEERC also conducted a 30-day evaluation of DARCO Hg-LH at GRE's North Dakota lignite-fired Stanton Station Unit 10. With DARCO Hg-LH injection at 0.7 lb $MMacf^{-1}$, total Hg capture across the SDA/FF configuration averaged 59% [18]. However, >90% Hg capture was achieved at this unit during parametric trials with both DARCO Hg-LH and B-PAC injection at 1.5 lb $MMacf^{-1}$.

The brominated B-PAC sorbent was also selected for 30-day long-term trials at three of NETL's field testing sites. At GRE's PRB-fired Stanton Station Unit 1, URS observed 85% average total Hg removal across the CS-ESP with B-PAC injection at 1.7 lb $MMacf^{-1}$ [19]. Sorbent Technologies conducted long-term field tests with B-PAC at DTE Energy's St. Clair Station Unit 1 that burned an 85% PRB and 15% bituminous coal blend, and at Progress Energy's bituminous-fired Lee Station

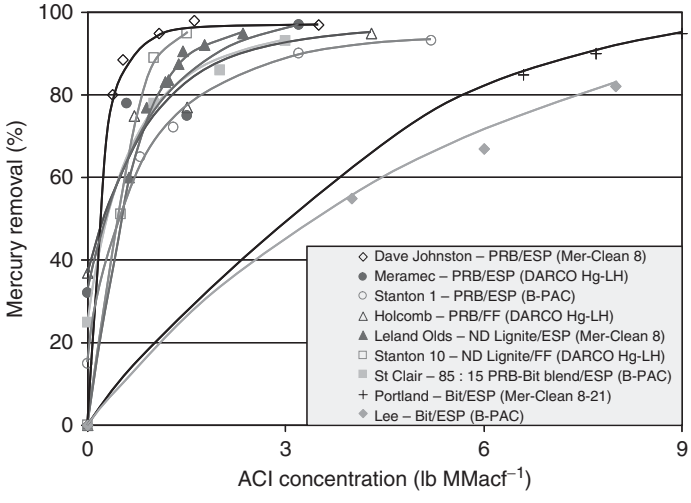


Figure 10.3 Test results for treated activated carbon injection.

Unit 1. At St. Clair, 94% average total Hg removal was achieved across the CS-ESP with B-PAC injection at 3 lb MMacf^{-1} [20]. Total Hg capture averaged 85% across the CS-ESP at Lee with B-PAC injection at 8 lb MMacf^{-1} [19]. Note that the 30-day long-term test at Lee was conducted with the sulfur trioxide (SO_3) flue gas conditioning (FGC) system idled and opacity levels remained acceptable.

ADA-ES conducted field testing at Rocky Mountain Power's PRB-fired Hardin Generating Station to evaluate the Hg removal performance, long-term emissions variability, and associated operating and maintenance costs of PAC injection for >90% Hg control during a year-long, full-scale demonstration. Baseline Hg capture at Hardin ranged from 20–30% across the SCR and SDA/FF configuration [21]. During parametric testing, an injection rate of about 1 lb MMacf^{-1} was required to attain slightly more than 90% total Hg removal with DARCO Hg-LH and Calgon Carbon's brominated FLUEPAC™-MC Plus. In addition, injection of a DARCO Hg and FLUEPAC-MC Plus mixture achieved 90% total Hg at 0.14 lb MMacf^{-1}, with a low KNX™ additive rate.

URS conducted field testing at NRG Texas Power LLC's Limestone Electric Generating Station Unit 1 that fired a 70 : 30 blend of TxL and PRB coals and was equipped with a CS-ESP and wet FGD. Baseline Hg removal was highly variable, ranging from about 5–50%. Since this unit markets its fly ash for reuse, two Hg control technologies designed to preserve ash quality were evaluated during parametric tests: low-ash impact sorbent injection and TOXECON II [22]. During injection upstream of the ESP, the brominated B-PAC and DARCO Hg-LH sorbents performed similarly, with about 90% ACI Hg removal at 2–3 lb MMacf^{-1}. Untreated DARCO Hg also achieved 90% ACI Hg removal with injection at slightly <6 lb MMacf^{-1}. Injection of the "concrete-friendly" C-PAC™ sorbent at about 1.5 lb MMacf^{-1} resulted in ~73% ACI Hg removal. During parametric trials with the TOXECON II configuration, ACI Hg removal was limited to about 60% with DARCO Hg and DARCO Hg-LH injection at about 5–6 lb MMacf^{-1}. Note that DARCO Hg-LH injection into the TOXECON II configuration took place with the unit firing 100% PRB coal. A 2-month continuous injection test was completed with DARCO Hg-LH injection at 2 lb MMacf^{-1}, and results indicated that the project goal of 50–70% ACI Hg removal across the ESP was achieved. In addition, URS was confident that the low DARCO Hg-LH injection rate would not prohibit fly ash reuse.

Another chemically treated ACI technology tested under the NETL Hg Program, ALSTOM Power, Inc.–U.S. Power Plant Laboratories' (ALSTOM–PPLs) Mer-Cure™ process, is unique in that injection takes place in the high-temperature region upstream of the air preheater (APH) and the process employs a proprietary "processor" to prevent chemically treated Mer-Clean™ sorbent agglomeration and to ensure uniform sorbent dispersion [23]. Three 30-day long-term field tests of Mer-Cure were completed at sites equipped with a CS-ESP: (i) PacifiCorp's PRB-fired Dave Johnston Unit 3; (ii) Leland Olds Unit 1; and (iii) Reliant Energy's medium-sulfur (2%) bituminous-fired Portland Station Unit 1. Chemically treated Mer-Clean eight injection rates of 0.63 and 1.4 lb MMacf^{-1} achieved average total Hg removals of 92% and 90% at Dave

Johnston and Leland Olds, respectively. At Portland, about 95% average total Hg capture was observed with chemically treated Mer-Clean 8–21 injection at 8.5 lb $MMacf^{-1}$. The reduced efficiency of the Mer-Clean sorbents at Portland might have been caused by elevated levels of flue gas SO_3, resulting from the combustion of medium-sulfur bituminous coal.

An evaluation of Mer-Cure was completed at LCRA's Fayette Unit 3 in April 2007 [24]. Baseline Hg capture was ~50% across the CS-ESP and wet FGD. ALSTOM–PPL evaluated three sorbents (eSorb™ 11, eSorb™ 13, and eSorb™ 18) designed to preserve fly ash quality, along with Mer-Clean 8, during parametric testing. Excluding eSorb 18, 80% ACI Hg capture was achieved with injection at 0.4–0.5 lb $MMacf^{-1}$. At an injection at about 0.8 lb $MMacf^{-1}$, eSorb 11, and Mer-Clean 8 attained 90% ACI Hg capture. Test results indicate that fly ash remains marketable with eSorb 13 at about 0.5 lb $MMacf^{-1}$ (85% ACI Hg capture).

10.2.8.3 Conventional PAC with Chemical Additives

As an alternative to using chemically treated PAC, NETL also sponsored field tests using conventional PAC supplemented with chemical additives – known as *sorbent enhancement additives* (*SEA*) – applied to the coal and/or flue gas to overcome the poor performance of conventional PAC in low-rank coal applications. Through funding provided by NETL, UNDEERC conducted two 30-day long-term field tests at full-scale units firing North Dakota lignite coal to determine whether SEA coal treatment enhances the performance of untreated ACI at units burning lower-rank coals [18]. Indeed, SEA coal treatment improved the Hg capture efficiency of untreated ACI at both of these field testing sites. During the 30-day trial at Basin Electric's Leland Olds Station Unit 1, 58% average total Hg capture was observed across the CS-ESP with DARCO Hg injection at 2.7 lb $MMacf^{-1}$, coupled with the addition of an aqueous $CaCl_2$ solution to the North Dakota lignite coal at a rate of 2.9 lb $MMacf^{-1}$. UNDEERC also evaluated this advanced, Hg-specific control technology at Basin Electric's Antelope Valley Station Unit 1. Total Hg removal averaged 92% across the SDA/FF configuration with the addition of SEA2 to the North Dakota lignite coal at a rate of 0.033 lb $MMacf^{-1}$ and DARCO Hg injection at 0.81 lb $MMacf^{-1}$.

UNDEERC conducted additional field testing at Montana-Dakota Utilities Company's Montana lignite-fired Lewis and Clark Station that was equipped with a mechanical collector and wet venturi scrubber. Parametric tests evaluated the Hg capture efficiency of SEA1 and SEA2 addition to the coal with and without ACI upstream of the wet venturi scrubber [25]. With SEA1 injection at 600 ppm coal equivalent, about 90% Hg removal was achieved with untreated DARCO Hg injection at 3 lb $MMacf^{-1}$. Slight improvements in performance were observed with higher SEA1 and DARCO Hg injection rates. Ninety percent Hg removal was also observed with SEA2 injection at 100 ppm coal equivalent and DARCO Hg injection at 1 lb $MMacf^{-1}$. Note that in the absence of PAC injection, Hg removal was limited to about 55% with SEA2 injection at 100 ppm coal equivalent.

UNDEERC evaluated PAC and SEA injection, as well as the SEA2 technique 2 (SEA2 T2) technology that involves co-injection of the proprietary SEA2 additive and PAC upstream of the particulate control device. Full-scale field testing was conducted at Kansas City Power & Light's Hawthorn Unit 5 that burns PRB coal and was equipped with an SCR and SDA/FF configuration. During parametric testing at Hawthorne, >90% total Hg capture was achieved with SEA1 added to the coal at 1200 ppm and DARCO Hg-LH injection at 3 lb $MMacf^{-1}$ [26]. With the SEA2 T2 technology, the co-injection of DARCO Hg at 2.8 lb $MMacf^{-1}$ and SEA2 at 0.14 lb/lb of PAC resulted in about 85% total Hg removal.

10.2.8.4 ACI Upstream of a Hot-Side ESP

NETL also evaluated Hg control technologies designed specifically for hot-side electrostatic precipitator (HS-ESP) applications where the elevated flue gas temperature limits the Hg capture efficiency of ACI. A 4-day trial conducted at Duke Energy's low-sulfur bituminous coal-fired Buck Plant achieved ~70% total Hg removal with the injection of Sorbent Technologies' chemically treated H-PAC™ at 10 lb $MMacf^{-1}$ [20]. Sorbent Technologies conducted additional field testing at Midwestern Generation's PRB-fired Will County Unit 3. A high-temperature version of the brominated, "concrete-friendly" C-PAC sorbent was evaluated as fly ash from this unit is marketed for reuse. Using a newly developed X-a-Lance distributing lance design, 73% Hg removal was achieved during a parametric trial with C-PAC injection at 5 lb $MMacf^{-1}$ [27]. During a 6-day continuous test, Hg removal ranged from about 60–73% with C-PAC injection at 5 lb $MMacf^{-1}$.

Under a separate project, ADA-ES evaluated the impact of adding high-temperature liquid sorbents to the pre-combusted coal and/or upstream of the HS-ESP on Hg control at MidAmerican's PRB-fired Louisa Station Unit 1 [28]. While Alstom's brominated KNX coal additive promoted Hg^0 oxidation, the lack of a downstream FGD at this unit led to no increase in Hg removal.

10.2.9 Remaining Technical Issues

Although the development of chemically treated ACI, oxidation additives, and catalysts under NETL's R&D Program has significantly improved the cost and performance of Hg control for coal-based power plants, two primary technical issues remain – impacts on fly ash and sulfur trioxide interference.

10.2.9.1 Impacts on Fly Ash

The typical ACI system is located upstream of a particulate control device to enable simultaneous capture of the spent sorbent and fly ash. This Hg control strategy leads to commingling of the sorbent and fly ash that can prohibit certain fly ash recycling efforts. In 2009, U.S. power plants generated 63 million tons of fly ash, with nearly 25 million tons put to beneficial use. One of the highest-value reuse applications for fly ash is as a substitute for Portland cement in concrete

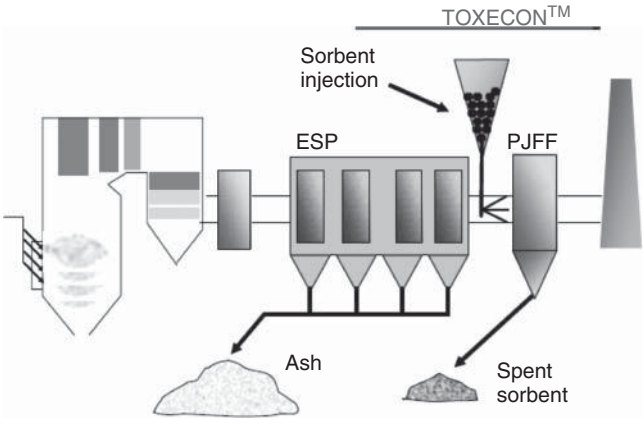

Figure 10.4 EPRI's TOXECON™ process configuration.

production [29]. The utilization of fly ash in concrete production is particularly sensitive to carbon content as well as the surface area of the carbon present in the fly ash.

NETL's Hg control technology portfolio included alternative sorbent injection technologies designed to minimize fly ash carbon contamination caused by ACI upstream of a particulate control device. The TOXECON configuration, developed by EPRI, is designed not to impact fly ash utilization because the ash is removed by an ESP upstream of the sorbent injection location, whereas the spent sorbent is captured by a downstream FF (Figure 10.4). EPRI's TOXECON II technology injects sorbents directly into the downstream collecting field(s) of an ESP. Because the majority of fly ash (~90%) is collected in the upstream ESP fields, only a small portion of the total collected ash contains spent sorbent. During full-scale TOXECON II testing at Entergy's PRB-fired Independence Station Unit 1, DARCO Hg-LH injection at 5.5 lb $MMacf^{-1}$ achieved 90% total Hg removal [30]. A remaining concern with any Hg control strategy involving sorbent injection, particularly the TOXECON II configuration that limits ESP residence time, is the potential for inefficiencies in the existing particulate control system that could trigger New Source Review.

Activated carbon passivated during production can potentially allow coal-fired power generators to continue marketing fly ash commingled with the spent sorbent as a suitable replacement for Portland cement in concrete. Sorbent Technologies conducted a 30-day evaluation of their brominated, "concrete-friendly" C-PAC sorbent at Midwest Generation's PRB-fired Crawford Station Unit 7 [31]. Total Hg removal averaged 81% with C-PAC injection upstream of the ESP at about 4.6 lb $MMacf^{-1}$. A high-temperature version of C-PAC was tested at Midwest Generation's PRB-fired Will County Unit 3 that is equipped with an HS-ESP [32]. During a 6-day continuous test, Hg removal ranged from about 60–73% with C-PAC injection at 5 lb $MMacf^{-1}$. Most importantly, test results indicated that fly

ash collected during C-PAC injection at these sites remained suitable for reuse in concrete production.

During testing at Lower Colorado River Authority's PRB-fired Fayette Unit 3, Alstom evaluated three sorbents (eSorb 11, eSorb 13, and eSorb 18) designed by Envergex to preserve fly ash quality [33]. Results indicated that fly ash remains marketable with eSorb 13 at about 0.5 lb MMacf^{-1} (~85% ACI Hg capture).

10.2.9.2 Sulfur Trioxide Interference

Field testing showed that SO_3 in the flue gas, even at low concentrations, can impede the performance of ACI. It appears that SO_3 competes with Hg for adsorption sites on the sorbent surface, thereby limiting its performance [34]. During field testing at American Electric Power's (AEP's) high-sulfur (3–4%) bituminous-fired Conesville Station Unit 6, total Hg removal was limited to ~30% with chemically treated ACI at 12 lb MMacf^{-1} [35]. Consequently, a long-term field test was not conducted at this unit; instead, NETL evaluated the impact of SO_3 FGC on ACI performance at AmerenUE's PRB-fired Labadie Station Unit 2 [36]. As shown in Figure 10.5, turning the SO_3 FGC system off at Labadie increased total Hg removal from about 50–80% with DARCO Hg-LH injection at 8 lb MMacf^{-1}. Greater than 90% Hg removal was observed with no SO_3 injection and DARCO Hg-LH injection upstream of the APH at about 5 lb MMacf^{-1}. The performance of brominated B-PAC was also impacted by SO_3 FGC at Progress Energy's Lee Station Unit 1 [37]. With B-PAC injection at 8 lb MMacf^{-1}, Hg capture increased from 32% to 82% when SO_3 FGC was idled.

One possible solution to the SO_3 issue that was considered was dual injection of Hg sorbents and alkaline materials. This approach was explored during a field test

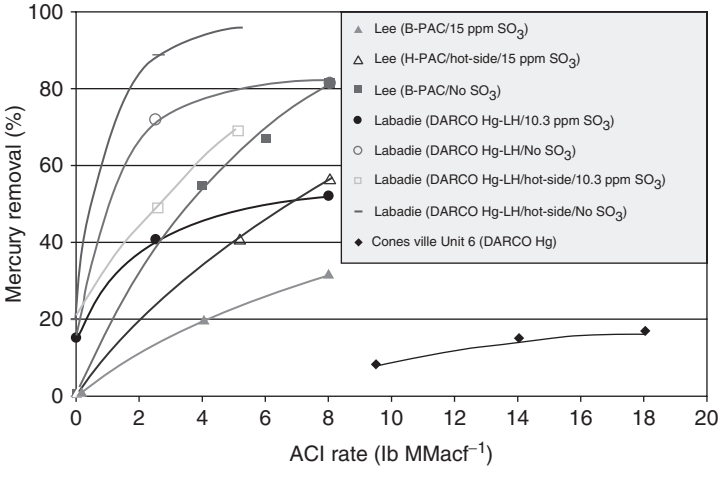

Figure 10.5 Impact of flue gas SO_3 on ACI performance.

at Public Service of New Hampshire Company's Merrimack Station Unit 2 that utilized a cyclone-fired boiler to burn a blend of bituminous coals (~1% sulfur) and is equipped with an SCR system followed by two ESPs in series [38]. During parametric testing, several Hg sorbents were evaluated both with and without the injection of two potential SO_3 mitigation additives – magnesium oxide (MgO) and sodium sesquicarbonate (trona). Results indicated that trona injection enhanced ACI performance to a greater degree than MgO; however, the sodium content of trona could limit fly ash recycling opportunities. Without SO_3 mitigation, Hg removal was limited to about 22% with brominated DARCO Hg-LH injection between the two ESPs at 8 lb $MMacf^{-1}$. During a continuous injection test completed in March 2008, 50% Hg removal was achieved with trona injection upstream of the APH at 500 lb h^{-1} and DARCO Hg-LH injection between the two ESPs at about 4 lb $MMacf^{-1}$.

10.2.10 NETL In-House Development of Novel Control Technologies

In addition to the technologies developed in partnership with private sector companies, researchers from NETL's Office of Research and Development (ORD) also developed and patented technologies for capturing and detecting mercury from coal-based power systems. In one case, ultraviolet light near the wavelength of 254 nm was found to oxidize elemental mercury [39]. The oxidized form of mercury is much more readily removed by the more traditional capture techniques than elemental mercury. This method was unique not only because the photochemical technique enhances the capture of mercury, but also because, as a spinoff, it can be used as the basis for mercury detection. Another patented technique that had been developed uses a lance or "thief" to extract a partially combusted coal from the combustion section of a pulverized coal-fired combustor [40]. This material acts very similarly to that of activated carbon and will remove mercury when injected into the flue gas ductwork. Not only can the thief process be used to capture mercury, the carbon-based material itself, and a few other materials were also found able to catalytically convert elemental mercury to the oxidized form.

Recognizing the need for a low-cost technique to remove Hg from coal-based integrated gasification combined cycle (IGCC) power plants, ORD researchers invented a new palladium (Pd)-based sorbent that works on fuel gas at elevated temperatures [41]. IGCC plants will be affected by the new mercury regulation. Although electricity in the United States is primarily a product of combusting coal, IGCC may be the power generation method in the future if mitigation of the greenhouse gas carbon dioxide is imposed on the power industry. Unlike conventional sorbents such as activated carbon, which operate at a lower temperature, high-temperature Pd sorbents remove Hg and arsenic at temperatures above 500 °F, resulting in a major improvement in overall thermal energy efficiency of the IGCC power process.

10.2.11 Hg Control Technology Commercial Demonstrations

A key component of the overall success of NETL's Hg Program was the full-scale commercial demonstration of Hg control technology under DOE's Clean Coal Power Initiative (CCPI). CCPI was part of DOE's Major Demonstration Program directed at accelerating advanced coal technology adoption, thus rapidly moving promising new concepts to a point where private-sector decisions on deployment could be made.

In the first project, EPRI's TOXECON was selected for demonstration on a 270-MW slipstream at We Energies' Presque Isle Power Plant in Marquette, Michigan. During initial operation in 2006, the TOXECON configuration maintained >90% total Hg removal for 48 consecutive days. Sorbent injection rates of about 1.7 and 1.2 lb $MMacf^{-1}$ were required to achieve at least 90% total Hg removal with untreated DARCO Hg and brominated DARCO Hg-LH, respectively [42]. Over a 3-year demonstration period (2006–2009), We Energies consistently demonstrated more than 90% Hg removal based on monthly averages while maintaining acceptable baghouse pressure drops of 5–6 in. of water and providing significant opacity improvements. The TOXECON installation at Presque Isle cost $128 per kilowatt (kW) and increased the cost of electricity by about 0.3–0.5 cents kWh^{-1} [43].

In the second project, NeuCo, Inc., a developer of power plant control and optimization technologies, demonstrated the capability to optimize Hg speciation and control Hg emissions from an existing power plant. This demonstration took place at an 890 MW utility boiler in Jewett, Texas, that was completed in 2010 and is owned by NRG Energy. NeuCo utilized state-of-the-art sensors and neural, network-based optimization and control technologies to maximize the proportion of Hg^{2+} species in order to increase the rate of co-benefit Hg capture. Artificial intelligence and simulation technologies were used to control and optimize appropriate operational parameters. Critical sensing devices were added to the unit to monitor inputs and emissions from the plant. Data from these sensors was analyzed by the neural network to optimize plant operations, while simultaneously minimizing Hg emissions [44].

10.2.12 Mercury Control Cost Estimates

NETL has conducted in-depth economic analyses for both ACI and wet FGD enhancement technologies for Hg control, based on the results of its field testing program. The increase in cost resulting from Hg control via ACI is primarily determined by annual PAC consumption costs that are dependent on the required ACI rate, delivered PAC price, and the volume of flue gas being treated. Chemical composition also affects PAC price since manufacturers charge a higher price for chemically treated PAC to offset the additional production costs required to alter the sorbent's molecular structure. The ACI rate required to achieve a given level

of Hg control can be impacted by a host of plant-specific dynamics, including, but not limited to, Cl and sulfur contents of the coal being burned, APCD configuration, flue gas temperature, boiler efficiency, UBC content of the fly ash, and ductwork geometry in proximity to the ACI location.

10.2.12.1 Economic Analyses for ACI

In 2003, NETL prepared an economic assessment of ACI with untreated PAC based on the results of its Phase I field testing program [45]. The report developed "study-level" costs for Hg control using ACI at representative 500 MW bituminous- and subbituminous-fired power plant units equipped with an existing CS-ESP. Costs were estimated for ACI into an existing CS-ESP, as well as a TOXECON configuration. The cost estimates were developed for equipment designed to achieve Hg control at low (50%), mid-range (60–70%), and high (90%) levels. It is important to note that the costs developed here were based on the current state of knowledge and understanding of ACI technology at three of the Phase I field test sites. The incremental cost of Hg control for this analysis, excluding impact to fly ash sales and disposal practices, was estimated to range from $33 000/lb Hg removed to $131 000/lb Hg removed for the bituminous-fired unit, and from ~$18 000/lb Hg removed to $55 000/lb Hg removed for the subbituminous-fired unit.

A follow-up NETL economic analysis released in May 2007 indicated that the high Hg capture efficiency of chemically treated sorbents drastically reduced the estimated cost of Hg control due to the lower injection rate required to achieve a given level of control that offsets the higher cost of these treated sorbents [46]. As shown in Figure 10.6, the 20-year levelized incremental cost of 90% ACI Hg control ranged from about $30 000 to <10 000/lb Hg removed (without considering impacts on CUBs) for seven of NETL's field testing sites where chemically treated ACI was evaluated. The May 2007 report provides "study-level," plant-specific cost estimates and gives NETL a gage to measure its success in achieving the target of reducing the baseline Hg control cost estimate of $60 000/lb Hg removed by 25–50%.

10.2.12.2 Economic Analyses for Wet FGD Enhancement

In May 2008, NETL released a report that provided cost estimates for technologies developed to enhance co-benefit Hg capture for wet FGD systems [47]. The report provides "study-level" cost estimates for two such technologies: fixed-bed Hg^0 oxidation catalysts, and coal treatment with a $CaBr_2$ solution. The economics were developed for an average Hg control level of 73% at "representative" 500 MW units burning three types of low-rank coal: North Dakota lignite, PRB subbituminous, and a blend of 50% TxL and 50% PRB subbituminous coals. The report estimated an incremental cost of control <$17 000 per pound of Hg removed ($/lb Hg removed) using the Hg^0 oxidation catalysts. Addition of $CaBr_2$ solution at an injection rate of about 5.90 lb h^{-1} was required to achieve 73% total Hg removal at the "representative" PRB-fired unit equipped with an SCR, resulting in a cost of $2200/lb Hg removed. Without an SCR in-service, a $CaBr_2$ injection rate of

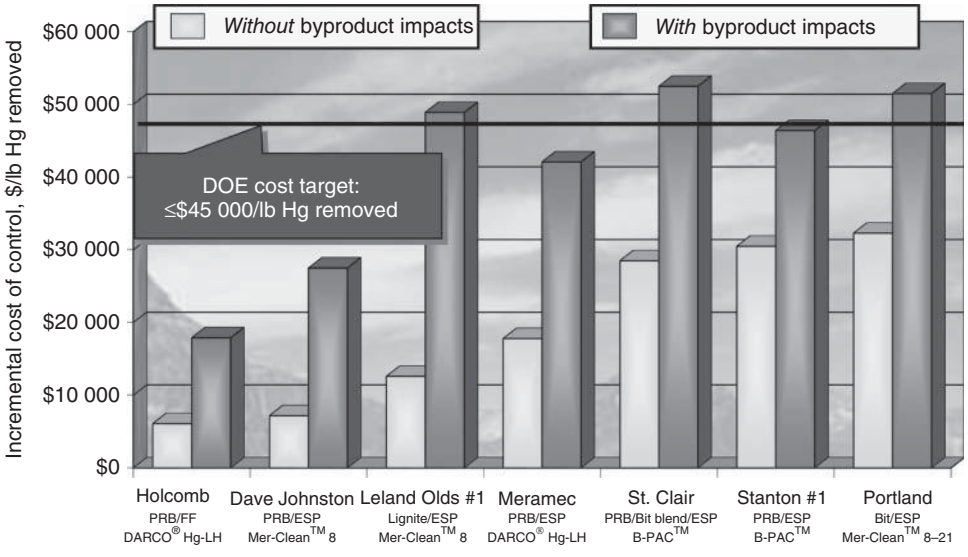

Figure 10.6 Six-year levelized incremental cost of 90% Hg control with chemically treated ACI.

322 lb h^{-1} was required to achieve the same level of control and the levelized costs rise to $21 200/lb Hg removed.

10.2.13 Coal Utilization Byproducts (CUB) R&D Program

In addition to developing cost-effective control technologies for coal-fired power plants, NETL's program also investigated the potential implication of Hg control on the use and disposal of CUB [48, 49]. CUB are the solid materials resulting from the combustion of coal and the removal of air pollutants from coal-based flue gas that include bottom ash, fly ash, boiler slag, and FGD gypsum. U.S. power plants produced 134.7 million tons of CUB in 2009, with nearly 42% put to beneficial use in applications such as concrete, flowable fill, road base, snow and ice control, blasting grit, fertilizer, and wallboard [29]. Put another way, this was 56 million tons of material that did not have to be landfilled or placed in an impoundment.

The CUB research was directed at better understanding the transfer and ultimate fate of Hg and other trace metals from the flue gas to the power plant's solid and liquid effluent streams as a result of implementing Hg control systems. Although the NETL CUB program was ended in 2008, it was determined that DOE had successfully achieved its goal of bringing efficient, cost-effective Hg control technologies to commercial readiness and that further research into the fate of Hg and other trace metals in fly ash, scrubber solids, and other byproducts should be carried out by the private sector.

ACI Hg control leads to commingling of the PAC and fly ash that can prohibit certain fly ash recycling efforts. As part of the economic analyses noted above

[42, 43], NETL evaluated the 20-year levelized costs of Hg control both with and without the inclusion of byproduct impacts. The analyses assumed that for units equipped with a CS-ESP, the utility was able to sell all fly ash collected in the ESP hoppers for $18/ton prior to ACI. Following installation of an ACI system, it was assumed that the fly ash could no longer be sold; instead, the utility must pay $17/ton for non-hazardous fly ash disposal. For an SDA/FF system, it was assumed that solids that were given away prior to ACI would have to be disposed of at a price of $17/ton (non-hazardous). Using these assumptions, NETL estimated that the cost for Hg control, with chemically treated ACI and accounting for the cost of byproduct disposal, ranged from $52 500/lb Hg removed to $17 900/lb Hg removed for seven of NETL's field testing sites, as shown in Figure 10.6.

While CUB were, and still are, regulated as non-hazardous under the Resource Conservation and Recovery Act, EPA is considering alternative regulatory approaches for CUB, including a hazardous designation due in part to concerns over the partitioning of Hg to these materials. Such a designation would significantly increase the cost of Hg control because the cost of hazardous waste disposal can be more than five times more expensive than non-hazardous disposal. Therefore, it was extremely important to evaluate the potential for leaching and volatilization of Hg and other trace metals from CUB to the environment as part of the NETL Hg Program.

10.2.14 Determining the Fate of Hg in FGD Byproducts

NETL's ORD conducted research directed at determining the fate of Hg in FGD materials [50]. This activity focused on Hg stability during FGD gypsum drying, Hg stability during wallboard production using FGD gypsum, Hg leachability from FGD gypsum, and the Hg-binding phase in FGD gypsum. The stability of Hg during FGD gypsum drying was studied by collecting samples before and after natural gas-fired heating that reduces the moisture content of the FGD solids for ease of handling during the wallboard manufacturing process. Results indicated that within analytical precision, no Hg desorbed during the drying process.

The stability of Hg in FGD gypsum during wallboard production was also analyzed by collecting samples of FGD gypsum feedstock and the corresponding wallboard products from five wallboard manufacturing plants. The Hg present in the unprocessed FGD gypsum and the finished wallboard product ranged from 0.04 to 1.5 ppm on a dry basis. The quantity of Hg retained in the finished wallboard product varied, with three samples showing nearly complete Hg retention during the wallboard manufacturing process. For the other two samples, Hg losses were 12% and 58%, suggesting that the quantity and thermal stability of Hg in FGD gypsum and wallboard depends on the origin of the gypsum and/or the nature of processing.

Research was also performed using FGD slurry samples in an attempt to isolate the Hg-binding phase from bulk gypsum. During settling, Hg partitioned almost exclusively to the top, slower-settling layer of the FGD slurry. Analysis of this

residue revealed that both Hg and iron (Fe) were enriched in the top layer by factors of about 20 and 10, respectively. Meanwhile, Hg was not mobilized during FGD slurry leaching experiments using a continuous, stirred-tank extractor. This is indicative of a strong chemisorption rather than physical adsorption of Hg. As a result, it is believed that Hg sequestered in FGD gypsum is primarily bound to an iron-rich phase, such as iron-coated clay materials or iron oxide/hydroxide particles, probably introduced with the limestone used as the FGD reagent. Additional research [51] also showed that some Hg retained in FGD gypsum requires hydrogen peroxide oxidation for release, such as a phase containing sulfides or carbonaceous materials.

Leach testing was also used to evaluate the impacts of pH and oxidation–reduction potential (ORP) on Hg mobility in FGD byproducts. Leaching of six FGD materials to pH > 2 under aerobic conditions failed to mobilize appreciable amounts of Hg. While no Hg was released to the leachate during experiments with pH > 4 and ORP > 100 mV, dissolution of the major immobilized form of Hg was complete with pH < 1 and an ORP of ~350 mV. Consequently, ORD researchers concluded that the Hg-retaining phase will immobilize Hg in many reuse applications, with one possible exception being placement in mine-land reclamation areas where the FGD byproducts could be exposed to acidic, anaerobic conditions.

As part of NETL's CUB research, the Tennessee Valley Authority (TVA) evaluated Hg retention in FGD gypsum from three sources: an Hg-amended commercial calcium sulfate, a laboratory-scale wet FGD system, and a full-scale wet FGD system [52]. TVA researchers concluded that no Hg would evolve from disposed FGD byproducts up to a maximum temperature of 140 °F, although thermal desorption of Hg from FGD gypsum did occur at ~400 °F.

USG Corporation provided data on the extent and location of Hg loss during the wallboard production process, and also provided information on the potential for Hg leaching at the end of the wallboard life cycle, when it is disposed in municipal landfills [53]. FGD gypsum evaluation tests from six different power plant/FGD feedstock variations were completed to investigate the impact of different configurations on the stability of Hg during wallboard production. Testing included the use of FGD gypsum produced during TMT-15 injection into a power plant scrubber. Test results indicated that use of fines blowdown in wet FGD systems significantly reduced Hg content in the FGD gypsum. For FGD gypsum generated without fines blowdown, Hg loss amounted to <8%, while tests using FGD gypsum from power plants employing fines blowdown indicated Hg loss of 46–55%.

10.2.15 Determining the Fate of Hg in Fly Ash

NETL awarded a contract to Frontier Geosciences, Inc. (Frontier) to conduct independent laboratory analysis of CUB generated during NETL's Phase II full-scale Hg control technology field testing program [54]. The purpose of the independent

laboratory analysis was to ensure accurate and consistent laboratory procedures were used to determine the environmental fate of Hg in CUB. NETL's ORD also conducted in-house leaching experiments with fly ash collected from ACI field testing sites.

The Frontier work included leaching studies using the Synthetic Precipitation Leaching Procedure (SPLP, EPA Method 1312); low-temperature (40 °C for 30 days), medium-temperature (190 °C for 1 h), and high-temperature (900–1200 °C for 5 min) Hg volatility tests; microbial methylation experiments; and halide analysis. The SPLP results indicated that little to no Hg would be released under normal disposal conditions. In addition, Hg bound to PAC sorbents, particularly those that were chemically treated, appeared to be more stable than the UBC-bound Hg. During the low-temperature volatility tests, essentially no Hg was emitted from the fly ash samples. Thermal desorption of Hg was observed during the medium- and high-temperature volatility tests conducted by Frontier.

A pure culture of sulfate-reducing bacteria known to methylate Hg or produce methyl-mercury, was monitored over a 30-day period to assess the methylation potential of Hg present in CUB. Results from this "worst-case-scenario" microbial mobilization study indicated an increase in methyl-mercury production. However, microbial activity also stabilized a number of target metals.

NETL's ORD researchers also conducted leaching experiments on the Phase II byproducts using the modified SPLP, the NETL Serial Batch Leaching Procedure (SBLP), and NETL Column Leaching on a select number of sample pairs. During a 5-month continuous column experiment using four leachants, water (pH = 5.7), dilute sulfuric acid (pH = 1.2), dilute acetic acid (pH = 2.9), and sodium carbonate (pH = 11.1) [55], the PAC/ash mixtures were generally found to effectively immobilize the captured Hg over a range of laboratory conditions. Overall, very little of the Hg (always below 0.5% and often under 0.1%) contained in the ash samples was solubilized during leaching. Neither the pH nor the nature of the anion had a noticeable effect on the leachate Hg.

Not only have the Hg control technologies demonstrated capture of Hg that would otherwise be released into the environment, but the Hg has generally been shown to be retained in the control technology byproducts under conditions of laboratory leaching tests. For some of these materials, the tests performed show these control technology byproducts, in spite of their higher Hg content, to be environmentally more stable with respect to Hg release than the corresponding baseline ashes of lower Hg content [56].

10.3 Summary

Working closely with key stakeholders, NETL's Hg RD&D program successfully brought Hg control technology from what was a concept in the early 1990s to a commercial product by 2008. As of June 2010, nearly 150 full-scale ACI systems,

a signature technology of the NETL Hg R&D Program, have been ordered by U.S. coal-fired power generators [57]. These contracts represent more than 56 GW of coal-fired electric generating capacity. This includes ~43 GW of existing capacity (almost 15% of total U.S. coal-fired capacity) that will be retrofit with ACI systems to control Hg emissions. EPA projects that 146 GW of ACI will be installed on U.S. power plants by 2015 in order to comply with proposed Federal Hg regulations [1].

The ACI systems have the potential to remove up to 90% or more of the Hg in many, but not all, applications based on results from NETL's field testing program, at a cost estimated to be as low as $10 000/lb Hg removed in some situations. However, although the results achieved during NETL's field tests met or exceeded the program goals, only through experience gained during long-term continuous operation of these advanced technologies in a range of full-scale commercial applications will their actual costs and performance be determined.

U.S. EPA Research Program

Nick Hutson

11.1
Introduction

The U.S. Environmental Protection Agency (EPA) has maintained a broad research program examining the emissions and control of hazardous air pollutants (HAPs), including mercury, from stationary sources. The EPA has also maintained research programs studying the fate and transport of mercury and the resulting impacts, including health impacts, on the environment. There is considerable documentation of the studies of the fate and transport and the resulting effects of mercury on the environment. This section focuses exclusively on the EPA research program dealing with emissions of mercury from coal combustion. This work includes studies that were mandated by Congress to evaluate the emissions and hazards of mercury emissions from fossil-fuel-fired electricity generating units. It also includes fundamental work focused on development and evaluation of control technologies for mercury control. The EPA has also conducted considerable and significant work on the fate of mercury and other toxic metals in coal combustion residuals (CCRs) and other process effluents. That work is summarized in full in another section. The EPA has also played a leading role in the development and testing of technologies and techniques for continuous measurement and monitoring of mercury emissions in the very low concentrations (parts per trillion) and in the harsh environments that are seen in typical coal combustion flue gas streams. That work is also summarized in another section and is thus not covered here.

11.2
Congressionally Mandated Studies

In the 1990 Clean Air Act (CAA) amendments, Congress established a specific structure for determining whether to regulate HAP emissions from electric generating units (EGUs). Congress required that various reports concerning HAP emissions from EGUs be completed.

Mercury Control: for Coal-Derived Gas Streams, First Edition.
Edited by Evan J. Granite, Henry W. Pennline and Constance Senior.

The first report, the Utility Study, required the EPA to evaluate the hazards to public health reasonably anticipated to occur as the result of HAP emissions from EGUs after imposition of the requirements of the CAA. The EPA issued the Utility Study, which included numerous analyses, in February 1998. The EPA first collected HAP emissions test data from 52 EGUs, including a range of coal-, oil-, and natural-gas-fired units. The test data along with facility specific information were used to estimate HAP emissions from all 684 utility facilities. The EPA determined that 67 HAPs were potentially emitted from fossil-fuel-fired EGUs.

The EPA evaluated exposures, hazards, and risks due to HAP emissions from coal-, oil-, and natural-gas-fired EGUs. The EPA conducted a screening-level assessment of all 67 of the potentially emitted HAPs to prioritize the pollutants for further analysis. A total of 14 were identified as priority HAPs that would be further assessed. Twelve HAPs (arsenic (As), beryllium (Be), cadmium (Cd), chromium (Cr), manganese (Mn), nickel (Ni), hydrochloric acid (HCl), hydrofluoric acid (HF), acrolein, dioxins, formaldehyde, and radionuclides) were identified as priority pollutants for further assessment based on inhalation exposure and risk. Six HAPs (Hg, radionuclides, As, Cd, Pb, and dioxins) were considered a priority for multipathway assessment of exposure and risk. On the basis of the multipathway assessments, the EPA determined that Hg from coal-fired EGUs was the HAP of greatest potential concern.

The second report directed the EPA to "conduct a study of mercury emissions from EGUs, municipal waste combustion units, and other sources, including area sources." This is referred to as the *Mercury Study*. In conducting the Mercury Study, Congress directed the EPA to "consider the rate and mass of emissions, the health and environmental effects of such emissions, technologies which are available to control such emissions, and the costs of such technologies." The EPA issued the Mercury Study in December 1997. The Mercury Study assessed the magnitude of U.S. Hg emissions by source, the health and environmental implications of those emissions, and the availability and cost of control technologies.

The last required report was to be completed by the National Institute of Environmental Health Sciences (NIEHS). Congress directed NIEHS to conduct "a study to determine the threshold level of Hg exposure below which adverse human health effects are not expected to occur." In conducting this study, NIEHS was to determine "a threshold for mercury concentrations in the tissue of fish which may be consumed (including consumption by sensitive populations) without adverse effects to public health." In addition, Congress, in the conference report language associated with EPA's fiscal year 1999 appropriations, directed the EPA to fund the National Academy of Sciences (NAS) to perform an independent evaluation of the available data related to the health impacts of methyl mercury (MeHg). Specifically, NAS was tasked with advising the EPA as to the appropriate reference dose (RfD) for MeHg, which is the amount of a chemical which, when ingested daily over a lifetime, is anticipated to be without adverse health effects to humans, including sensitive subpopulations.

The EPA completed the Mercury Study and the Utility Study by 1998. The NIEHS study was completed in 1995, and the NAS study was completed in 2000.

In December 2000, after considering public input, the results of the required studies described and other relevant information, including Hg emission data from EGUs, EPA determined that it was appropriate and necessary to regulate EGUs under CAA Section 11.2.

11.3 Control Technology from Work on Municipal Waste Combustors (MWCs)

There has been significant public and scientific concern over the risks of air pollution emissions from municipal waste combustors (MWCs). Historically, the primary pollutants of concern have been dioxins/furans (e.g., polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs)), and mercury (Hg). The potential emissions of each of these toxic pollutants can vary considerably depending on the composition of the waste and the control technologies used. The EPA conducted work in the mid-1990s to examine the effectiveness of typical air pollution control (APC) technologies for mitigation of emissions of PCDDs/PCDFs and Hg from MWC [1]. Much of this knowledge was later applied to the initial development and testing of similar controls for mercury emissions from coal-fired electricity generating units. EPA researchers noted that powdered activated carbon (PAC) can be injected into MWC flue gas to reduce Hg emissions from SD/FF (spray dryer/fabric filter) and SD/ESP (electrostatic precipitator) systems and that it can also be used to improve PCDD/PCDF capture in these systems. The researchers also identified fundamental Hg properties that affect capture in flue gas cleaning equipment.

EPA researchers also conducted bench-scale experiments under conditions simulating MWCs and coal-fired units to study Hg capture by dry sorbents, including PAC [2]. The focus of the work was specifically to evaluate the effects of reaction temperature on the capture of different Hg species (Hg^0 and Hg^{2+}) by various types of dry sorbents.

Ghorishi *et al.* [3] followed with tests designed to better understand the transformation of mercury species (elemental and oxidized forms) in stationary waste combustion sources. Elemental mercury (Hg^0) poses a challenging flue gas control issue, and oxidized forms of mercury (Hg^{2+}) are of concern because of the potential for local deposition. Gas-phase studies indicated that homogeneous oxidation of Hg^0 in the presence of hydrogen chloride (HCl) is slow, proceeding at measurable rates only at temperatures >700 °C and with HCl concentrations of 100 ppm or more. The effect of fly ash composition on heterogeneous Hg^0 oxidation was investigated using a fixed-bed reactor containing different synthetic model fly ash components such as alumina (Al_2O_3), silica (SiO_2), ferric oxide (Fe_2O_3), copper oxide (CuO), and calcium oxide (CaO). The transition metal oxides, CuO and Fe_2O_3, exhibited significant catalytic activity in the surface-mediated oxidation of Hg^0 in the presence of HCl. This was suggested to be possibly caused by the Deacon process in which chlorine gas (Cl_2) is produced via catalytic oxidation of HCl over these two oxides. The researchers also studied the effect of the sulfur dioxide

to HCl ratio (SO_2 : HCl) on Hg^0 oxidation. The addition of SO_2 to the moist flue gas at high SO_2 : HCl ratios (from 10 : 1 to 4 : 1) caused a notable decrease in oxidation of Hg^0. This was attributed to a scavenging effect of SO_2 and H_2O on Cl_2. Addition of CaO to the synthetic fly ashes also caused a drop in Hg^0 oxidation – likely due to the neutralization of HCl by reaction with CaO.

11.4 Mercury Chemistry, Adsorption, and Sorbent Development

Most of the larger scale mercury control demonstration projects have been sponsored or cosponsored by the Department of Energy (DOE), by the Electric Power Research Institute (EPRI), and by the electric utilities. By contrast, the EPA focused its research efforts on smaller scale experimental work with the goal of better understanding the fundamental aspects of mercury control.

Much of the early work originated from results obtained from studies aimed at controlling organic emissions and mercury from MWCs (as just described). Other work looked at sorbent injection technology to reduce emissions of trace air toxic metals (including Hg) from coal combustion facilities. Gullett and Raghunathan [4] conducted pilot-scale tests of high-temperature furnace injection using hydrated lime, limestone, kaolinite, and bauxite sorbents. They found that the impact of sorbent injection on trace metal emissions is a function of metal type, sorbent type, and injection mode. Reductions in submicron concentrations of antimony, arsenic, mercury, and selenium were observed when hydrated lime and limestone were injected.

Krishnan *et al.* [5] studied the mechanisms and rate of elemental mercury (Hg^0) capture by activated carbons using a bench-scale apparatus. Three types of activated carbons were chosen to study the effects of surface area, sorption temperature (from room temperature to 140 °C), and varying Hg^0 concentration. The results suggested the sorption mechanism to be a combination of physisorption and chemisorption at lower temperature and primarily via chemisorption at 140 °C.

Additional bench-scale experiments were conducted in a flow reactor to simulate entrained-flow capture of elemental mercury (Hg^0) by activated carbon [6, 7]. Mercury adsorption by several commercial activated carbons was examined at different carbon-to-Hg mass ratios, particle sizes, Hg^0 concentrations, and temperatures (from room temperature to 250 °C). Increasing the carbon-to-Hg mass ratio increased mercury removal in some cases and capture increased with a decrease in the particle size of the sorbent.

Efforts were made to use detailed chemical models to better understand and explain mercury reaction and control mechanisms in a coal combustion flue gas environment. Mercury speciation in combustion-generated flue gas was modeled using a detailed chemical mechanism consisting of 60 reactions and 21 species [8]. The model confirmed a strong sensitivity to reaction temperature. Starting

with pure HCl, at higher reactor temperatures (more than 630 °C), model predictions were in good agreement with experimental data. But, at lower reactor temperatures, the model tended to underpredict Hg chlorination compared with experimental data, indicating that Hg oxidation at lower temperatures is dominated by heterogeneous mechanisms.

EPA researchers also conducted considerable bench-scale work to understand binding mechanisms of mercury on activated carbon sorbents. Li *et al.* [9] conducted experiments to examine the effect of surface moisture on low-temperature Hg adsorption on activated carbons. A bituminous coal-based activated carbon and an activated carbon fiber were tested for Hg^0 adsorption capacity. Tests showed that Hg^0 adsorption decreased considerably when the sorbent moisture was removed by heating at 110 °C before the adsorption experiments. These observations suggested that moisture contained in activated carbons may play an important role in retaining Hg^0 under these conditions. This effect of moisture on Hg adsorption was observed for both carbon sorbents, despite extreme differences in their ash contents. Temperature programmed desorption (TPD) experiments performed on the two mercury-containing carbons indicated that chemisorption of Hg is the predominant process over physisorption for the moisture-containing samples. The nature of the mercury binding on the carbon surface was examined by X-ray absorption fine structure (XAFS) spectroscopy. XAFS results provided evidence that mercury binding on the carbon surface was associated with oxygen. The results of the study suggested that surface oxygen complexes provide the active sites for mercury binding. The adsorbed H_2O is closely associated with surface oxygen complexes and the removal of the H_2O from the carbon surface by low-temperature heat treatment reduces the number of active sites that can chemically bind Hg^0 or eliminates the reactive surface conditions that favor Hg^0 adsorption.

Li *et al.* [10] studied the effect of varying physical and chemical properties of activated carbons on adsorption of elemental mercury (Hg^0) by treating two activated carbons to modify their surface functional groups and pore structures. Heat treatment (to 927 °C) in nitrogen (N_2), air oxidation (at 420 °C), and nitric acid treatment (6 N HNO_3) of two activated carbons were conducted to vary their surface oxygen functional groups. Adsorption experiments of Hg^0 by the activated carbons were conducted using a fixed-bed reactor at a temperature of 125 °C and under a N_2 atmosphere. The pore structures of the samples were characterized by N_2 and carbon dioxide (CO_2) adsorption. TPD and acid–base titration experiments were conducted to determine the chemical characteristics of the carbon samples. Characterization of the physical and chemical properties of activated carbons in relation to their Hg^0 adsorption capacity can provide important mechanistic information on Hg^0 adsorption. The results suggested that oxygen surface complexes, possibly lactone and carbonyl groups, are the active sites for Hg^0 capture. The carbons having a lower carbon monoxide (CO)/CO_2 ratio and a low phenol group concentration tended to have a higher Hg^0 adsorption capacity, suggesting that phenol groups may inhibit Hg^0 adsorption. The high Hg^0 adsorption capacity of one carbon sample was also found to be associated with a low ratio of

the phenol/carbonyl groups. The EPA concluded that a possible Hg^0 adsorption mechanism may involve an electron-transfer process in which the carbon surfaces act as an electrode for Hg^0 oxidation.

11.4.1 Halogenated Activated Carbon Sorbents

Ghorishi *et al.* [11] conducted studies in an effort to discern the role of an activated carbon's surface functional groups on the adsorption of Hg^0 vapor and gaseous mercuric chloride ($HgCl_2$). The results demonstrated that chlorine (Cl) impregnation of a virgin activated carbon using dilute solutions of HCl leads to increased (by a factor of 2–3) fixed-bed capture of these mercury species. A commercially available activated carbon was Cl impregnated and tested for entrained flow, short-time-scale capture of Hg^0. In the entrained-flow reactor, the chlorine-impregnated powdered activated carbon (Cl-PAC) was introduced in Hg^0-laden synthetic flue gases (containing 86 ppb of Hg^0) of varying compositions with gas/solid contact times of about 3–4 s. The results indicated significant Hg^0 removal (80–90%), compared to virgin activated carbon (10–15% Hg removal). These levels of Hg^0 removal were observed across a wide range of very low carbon-to-Hg weight ratios. Variation of the natural gas combustion flue gas composition, by doping with nitrogen oxides and sulfur dioxide, and the flow reactor temperature (ranging from 100 to 200 °C) had minimal effect on Hg^0 removal by the Cl-PAC in the studied carbon-to-Hg weight ratios. The results demonstrated significant enhancement of activated carbon reactivity with minimal halogen treatment.

Brominated powdered activated carbon (Br-PAC) sorbents have been shown to be quite effective for Hg capture when injected into the flue gas duct at coal-fired power plants and are especially useful when burning western subbituminous and other low-chlorine coals. Hutson *et al.* [12] used X-ray absorption spectroscopy (XAS) and X-ray photoelectron spectroscopy (XPS) to determine information about the speciation and binding of Hg on two commercially available brominated activated carbons. The results were compared with similar analysis of a conventional (nonhalogenated) and chlorinated activated carbon. Both the XAS and XPS results indicated that the Hg, although introduced as elemental vapor, was consistently bound on the carbon in an oxidized form. The conventional and chlorinated activated carbons appeared to contain mercury bound to chlorinated sites and possibly to sulfate species that have been incorporated onto the carbon from adsorbed SO_2. The Hg-containing brominated sorbents appeared to contain Hg bound primarily at bromination sites. The researchers concluded that the mechanism of capture for the sorbents likely consists of surface-enhanced oxidation of the Hg^0 vapor via interaction with surface-bound halide species with subsequent binding by surface halide or sulfate species.

With the use of halogenated PACs, concerns were raised about the potential for these PACs to assist in the formation and emission of brominated and/or chlorinated dioxins and furans. To evaluate this, Hutson *et al.* [13] conducted

sampling campaigns at two U.S. DOE demonstration sites where Br-PAC was being injected for control of mercury emissions. The results of the studies showed that injection of the Br-PAC upstream of the ESP did not increase the emissions of total and Toxic EQuivalent (TEQ) chlorinated and brominated dioxin compounds. Rather, the data suggested that the sorbent may capture these compounds and reduce their concentration in the flue gas stream. This effect, when seen, was small, and independent of the type of plant emission controls, temperature at the point of injection, or fuel-chlorine content. The addition of the brominated-PAC sorbent resulted in slight increases in the total content of chlorinated dioxins and furan in the particulate matter (ash) collected in the ESP, but did not increase its overall toxicity.

11.4.2 Non-Carbonaceous Sorbents

Efforts to develop multipollutant control strategies have demonstrated that adding certain oxidants to different classes of Ca-based sorbents leads to a significant improvement in elemental Hg vapor (Hg^0), SO_2, and NO_x removal from simulated flue gases. Ghorishi *et al.* [14] studied the multipollutant capacity of two classes of Ca-based sorbents (hydrated limes and silicate compounds). A number of oxidizing additives at different concentrations were used in the Ca-based sorbent production process. The Hg^0, SO_2, and NO_x capture capacities of the oxidant-enriched sorbents were evaluated and compared to those of a commercially available activated carbon in bench-scale fixed- and fluidized-bed experimental systems. Calcium-based sorbents prepared with two unspecified oxidants exhibited Hg^0 sorption capacities ($-100\,\mu g\,g^{-1}$) comparable to that of the activated carbon; and they showed far superior SO_2 and NO_x sorption capacities.

Meyer *et al.* [15] studied the use of copper-doped Fe nanoaggregates silanized with organic sulfur as bis-(triethoxy silyl propyl)tetrasulfide for the capture of Hg^0 vapor for potential power plant applications. Silanization procedures resulted in 70% deposition of the targeted sulfur level, with particles containing ~4 wt% S. The addition of copper was found to increase the fixed-bed (total) capacity of the sorbent from $170 \pm 20\,\mu g$ Hg/g-sorbent with no copper doping to $2730 \pm 80\,\mu g$ Hg/g-sorbent at 1.2 wt% Cu loading. When no S was deposited, the capacity of Fe/Cu nanoaggregates was only 180 μg Hg/g-sorbent. The findings suggested that a combined Cu–S mechanism is responsible for Hg capture using these sorbents. Moving-bed (injection) testing of the Fe-based sorbents in a simulated flue gas stream showed that the 1.2 wt% Cu sample was able to achieve significant removal of Hg.

Meyer *et al.* [16] conducted additional work to examine the use of Cu–S sites for Hg capture from the gas phase for a silica-based platform using an S4 organic polysulfane and copper sulfate. The maximum fixed-bed equilibrium capacity achieved when using these materials was for a sorbent material with 2.5 wt% Cu and 6 wt% S. When compared to two other platforms, commercially available brominated-PAC and the previously tested Fe–Cu–S4 nanoaggregates, the Si-1

material performed the best in fixed-bed testing. During entrained-flow testing, the performance of Si-1 was only diminished 10% when exposed to 20 ppm SO_3, an encouraging result for flue gas applications where SO_3 levels range from 1 to 40 ppm.

Hutson and Attwood [17] studied Hg capture using adsorbent material derived from the bauxite residue (red mud) from two North American aluminum refineries. The red mud, a seawater-neutralized red mud, and an acid-treated red mud were evaluated for their mercury adsorption capacity and compared with other, more conventional sorbent materials. Two different seawater-neutralized red mud samples were treated with HCl and HBr in an effort to increase the mercury sorption capacity. In all cases, the acid treatment resulted in a significant increase in the total surface area and an increase in the total pore volume. The fixed-bed mercury capture experimental results showed that the HBr activation treatment was effective in increasing the mercury capture performance of both sorbent samples. The HCl treatment, however, had no effect on the mercury capture performance; and entrained-flow experiments revealed that the bromine-containing red mud sorbent was much less effective for in-flight mercury capture.

11.4.3 Mercury Control in a Wet-FGD Scrubber

Experimental data from a laboratory-scale wet scrubber simulator confirmed that oxidized mercury, Hg^{2+}, can be reduced by aqueous S(IV) (sulfite and/or bisulfite) species and result in elemental mercury (Hg^0) emissions under typical wet flue gas desulfurization (FGD) scrubber conditions [18]. The S(IV)-induced Hg^{2+} reduction and Hg^0 emission mechanism was described by a model which assumed that only a fraction of the Hg^{2+} can be reduced, and that the rate-controlling step of the overall process is a first-order reaction involving the Hg–S(IV) complexes. Experimental data and model simulations predicted that Hg^{2+} in the flue gas can cause a rapid increase of Hg^0 concentration in the flue gas across a wet-FGD scrubber. The researchers also noted that forced oxidation enhanced Hg^{2+} reduction and Hg^0 emission by decreasing the S(IV) concentration in the scrubbing liquor. The model predictions also indicated that flue gas Hg^0 increases across a wet-FGD scrubber can be reduced by decreasing the pH, increasing the S(IV) concentration in the scrubber liquor, and lowering the temperature.

Chang and Zhao [19] discussed additional observations of elemental mercury (Hg^0) reemissions from a pilot-scale limestone wet scrubber. In those studies, simulated flue gas was generated by burning natural gas in a down-fired furnace and doped with 2000 ppm of SO_2. A solution of mercuric chloride ($HgCl_2$) was delivered to the scrubber at a controlled rate to simulate the absorption of ionized mercury (Hg^{2+}). The testing results indicated that, after Hg^{2+} was injected, elevated Hg concentrations were soon detected both in the flue gas exiting the scrubber and in the hold tank air, indicating the occurrence of Hg^0 reemissions in both places. When the $HgCl_2$ feed was stopped, the Hg^0 reemission continued

for more than 2 h. In addition, a significant Hg^0 reemission was also detected outside the scrubber loop. In an attempt to understand the Hg^0 reemission increase across the wet scrubber system under transient and steady-state conditions and to understand the underlying relationship with the mercury complexes retained in the wet scrubber system, a mercury reemission model was developed. With this model, the researchers determined that the Hg^0 reemission rate under the current testing conditions could be simulated by a first-order reaction, and only a portion of Hg – S(IV) complexes retained in the slurry were participating in the reemission reaction.

Hutson *et al.* [20] and Krzyzynska *et al.* [21, 22] conducted a series of bench- and pilot-scale studies to examine the simultaneous control of SO_2, NO_x, and mercury (both Hg^0 and Hg^{2+}) from a coal combustion flue gas in a multipollutant wet scrubber. The multipollutant capacity of a calcium-carbonate-based wet scrubber was enhanced with the addition of the oxidizing salt, sodium chlorite. The initial bench-scale results showed a maximum scrubbing of 100% for SO_2 and Hg species and near complete NO oxidation with about 60% scrubbing of the resulting NO_x species. The chlorite additive was less effective as an oxidant in the absence of SO_2 and NO in the flue gas. Oxidation of NO and mercury were only about 50% and 80%, respectively, when no SO_2 was present in the simulated flue gas. The mercury oxidation was similarly affected by the absence of NO in the flue gas.

Parametric studies investigating the effects of flue gas components, temperature, and oxidant addition rate were completed with the bench- and pilot-scale experimental facilities. Various process configurations were examined to optimize the addition of sodium chlorite. Additional studies by Krzyzynska and Hutson [23] showed that the location of the sodium chlorite application (before, in, or after the wet scrubber) greatly influences which pollutants are removed and the amount removed. This effect is related to the chemical conditions (pH, absence/presence of particular gases) that are present at different positions throughout the flue gas cleaning system profile. The results indicated that there is a potential to achieve very high SO_2, NO_x, and Hg removals from the flue gas when sodium chlorite was applied before the wet limestone scrubber. However, applying the oxidizer after the wet limestone scrubber was the most effective configuration for Hg and NO_x control for extremely low chlorite concentrations (below 0.002 M) and therefore appears to be the best configuration for Hg control or as an additional step for NO_x polishing (after other NO_x control technologies).

Krzyzynska and Hutson [24] further examined the role of slurry pH on the multipollutant capacity of the oxidant-enhanced wet scrubber. The results showed that the slurry strongly influenced the chemical mechanism in the scrubber and, therefore, affected pollutant removal. Different NO_x removal efficiencies and mechanisms were found in acidic and alkaline slurry in the multipollutant scrubber. The acidic solution was favorable for NO and Hg^0 oxidation, while increasing the slurry pH above 7.0 was disadvantageous for NO and Hg oxidation/removal.

11.4.4 Effect of SCR on Mercury Oxidation/Capture

Selective catalytic reduction (SCR) technology is increasingly being applied for controlling emissions of nitrogen oxides (NO_x) from coal-fired boilers. Field and pilot studies suggested that the operation of SCR could affect the chemical form of mercury in coal combustion flue gases. The speciation of Hg is an important factor influencing the control and environmental fate of Hg emissions from coal combustion. The vanadium and titanium oxides, used commonly in the vanadia–titania SCR catalyst for catalytic NO_x reduction, promote the formation of oxidized mercury (Hg^{2+}).

Lee *et al.* [25] conducted bench-scale experiments to investigate Hg^0 oxidation in the presence of simulated coal combustion flue gases and under SCR reaction conditions. Flue gas mixtures with different concentrations of hydrogen chloride (HCl) and sulfur dioxide (SO_2) for simulating the combustion of bituminous coals and subbituminous coals were tested. The tests showed that HCl is the most critical flue gas component contributing to conversion of Hg^0 to Hg^{2+} under SCR reaction conditions.

Lee *et al.* [26] followed the bench-scale work with pilot-scale studies to investigate the effect of SCR catalyst on mercury (Hg) speciation in bituminous and subbituminous coal combustion flue gases. Three different Illinois Basin bituminous coals (from high to low sulfur and chlorine) and one Powder River Basin (PRB) subbituminous coal with very low sulfur and very low Cl were tested in a pilot-scale combustor equipped with an SCR reactor for controlling nitrogen oxide (NO_x) emissions. The SCR catalyst induced high oxidation of Hg^0, decreasing the percentage of Hg^0 at the outlet of the SCR to values <12% for the three Illinois coal tests. The PRB coal test indicated a low oxidation of Hg^0 by the SCR catalyst, with the percentage of Hg^0 decreasing from similar to 96% at the inlet of the reactor to similar to 80% at the outlet. The low Cl content of the PRB coal and corresponding low level of available flue gas Cl species were believed to be responsible for low SCR Hg oxidation for this coal type. The test results indicated a strong effect of coal type on the extent of Hg oxidation.

Additional studies were conducted in a bench-scale reactor consisting of a natural gas burner and an electrically heated reactor housing an SCR catalyst that was constructed for studying elemental mercury (Hg^0) oxidation under SCR conditions [27]. A subbituminous coal combustion fly ash was injected into the entrained-flow reactor along with SO_2, nitrogen oxides, HCl, and trace Hg^0. Concentrations of Hg^0 and total mercury upstream and downstream of the SCR catalyst were measured using an online Hg monitor. The effects of HCl concentration, SCR operating temperature, catalyst space velocity, and feed rate of PRB fly ash on Hg^0 oxidation were evaluated. It was observed that HCl provides the source of chlorine for Hg^0 oxidation under simulated PRB coal-firing conditions. The decrease in Hg mass balance closure across the catalyst with decreasing HCl concentration suggests that transient Hg capture on the SCR catalyst occurred during the short test exposure periods and that the outlet

speciation observed may not be representative of steady-state operation at longer exposure times. Increasing the space velocity and operating temperature of the SCR led to less oxidized mercury. Introduction of PRB coal fly ash resulted in slightly decreased outlet oxidized mercury as a percentage of total inlet Hg and correspondingly resulted in an incremental increase in Hg capture. The injection of ammonia (NH_3) for NO_x reduction was found to have a strong effect to decrease Hg oxidation. The observations suggest that Hg^0 oxidation may occur near the exit region of commercial SCR reactors. Passage of flue gas through SCR systems without NH_3 injection, such as during the low-ozone season, may also impact Hg speciation and capture in the flue gas.

11.5
Coal Combustion Residues and By-Products

Flue gas from coal combustion contains significant amounts of volatile toxic trace elements such as arsenic (As), selenium (Se), and mercury (Hg). The capture of these elements in the FGD scrubber unit has resulted in generation of a metal-laden residue. With increasing reuse of the FGD residues in beneficial applications, it is important to determine metal speciation and mobility to understand the environmental impact of its reuse. Al-Abed *et al.* [28] reported the solid-phase speciation of As, Se, and Hg in FGD residues using XAS, X-ray fluorescence spectroscopy (XRF), and sequential chemical extraction (SCE) techniques. The SCE results combined with XRF data indicated a strong possibility of As association with iron oxides, whereas Se was distributed among all geochemical phases. The Hg appeared to be mainly distributed in the strong-complexed phase. XRF images also suggested a strong association of Hg with Fe oxide materials within FGD residues. XAS analysis indicated that As existed in its oxidized state (As(V)), whereas Se and Hg were observed in primarily reduced states as selenite (Se(IV)) and Hg(I), respectively. The results from the SCE and variable pH leaching tests indicated that the labile fractions of As, Se, and Hg were fairly low and thus suggestive of their stability in the FGD residues. However, the presence of a fine fraction enriched in metal content in the FGD residue suggested that size fractionation is important in assessing the environmental risks associated with their reuse.

Changes in emissions control at U.S. coal-fired power plants will shift metal content from the flue gas to the APC residues. To determine the potential fate of metals that are captured through use of enhanced APC practices, the leaching behavior of 73 APC residues was characterized following the approach of the Leaching Environmental Assessment Framework [29]. Materials were tested over pH conditions and liquid solid ratios expected during management via land disposal or beneficial use. Leachate concentrations for most metals were highly variable over a range of coal rank, facility configurations, and APC residue types. Liquid–solid partitioning (equilibrium) as a function of pH showed significantly different leaching behavior for similar residue types and facility configurations. Within a facility, the leaching behavior of blended residues was shown to follow

one of four characteristic patterns. Variability in metal leaching was greater than the variability in total concentrations by several orders of magnitude, inferring that total content is not predictive of leaching behavior. The complex leaching behavior and lack of correlation to total contents indicates that release evaluation under likely field conditions is a better descriptor of environmental performance than total content or linear partitioning approaches.

11.6 EPA SBIR Program

With support from EPA's Small Business Innovation Research (SBIR) Program and the U.S. DOE, Albemarle Mercury Control Division (formerly Sorbent Technologies Corporation) developed gas-phase bromination, a proprietary treatment, for PACs that can increase cost effectiveness for mercury control significantly when compared to non-brominated PAC.

With support from EPA's SBIR Program and the EPRI, Apogee Scientific, Inc. developed an advanced dry-catalytic gas sample conditioning system for use in the determination of in-duct mercury concentrations in coal-fired utility boilers. The Apogee Dry Sample Conditioning System (DSCS) represents a breakthrough in real-time mercury measurement technology.

EPA's SBIR Program also supported Advanced Fuel Research, Inc. (AFR) in the development of a technology to address both (i) removal and recovery of mercury from combustion/incineration flue gas and (ii) reprocessing of waste tires into value-added products. AFR's approach is based on mercury adsorption on low-cost, sulfur-rich activated carbons derived from scrap tires. The sulfur added to tire rubber in the process of vulcanization makes the tire-derived sorbents particularly effective in mercury removal. The first step in the waste-tire-processing scheme is pyrolysis, which involves thermal decomposition of tire rubber in an oxygen-free atmosphere. The solid product of pyrolysis (tire char) is subsequently converted into activated carbon. The sulfur content increases during tire processing, which is believed to facilitate mercury-capture efficiency. The cost-performance characteristics of tire-derived carbons are excellent and more favorable than those of the benchmark commercial carbon, Norit FGD.

The Electric Power Research Institute's Program to Control Mercury Emissions from Coal-Fired Power Plants

Ramsay Chang

12.1
Introduction

The Electric Power Research Institute (EPRI) draws on decades of research to help member companies operate electric power plants in an efficient and cost-effective manner, in compliance with state and federal environmental regulations. This chapter describes EPRI's research and development program to control mercury (Hg) emissions from power plants firing different coals under various configurations and operating conditions. EPRI gratefully acknowledges the participation of stakeholders who have made this research possible, and the work of others who have contributed specific information on the many aspects of mercury control.

12.2
Co-Benefits of Installed Controls

At coal-fired electric generating units, mercury control co-benefits occur when installed control equipment, combustion conditions, and mercury pathways offer a baseline level of flue gas mercury removal that does not depend on adding new controls. Using the co-benefits of installed controls for nitrogen oxides (NO_x) and sulfur oxides (SO_x) is the first key, near-term technology for controlling mercury emissions. Co-benefits assume new importance as power plant owners seek all avenues of compliance with the Mercury and Air Toxics Standards (MATS) rule.

12.2.1
Selective Catalytic Reduction/Flue Gas Desulfurization

When flue gas passes through a selective catalytic reduction (SCR) system, the SCR converts elemental mercury to oxidized mercury, the form most easily captured in a downstream wet or dry flue gas desulfurization (FGD) system. The resulting baseline mercury removal is a co-benefit of SCR operation to control NO_x and FGD operation to control SO_x.

Mercury Control: for Coal-Derived Gas Streams, First Edition.

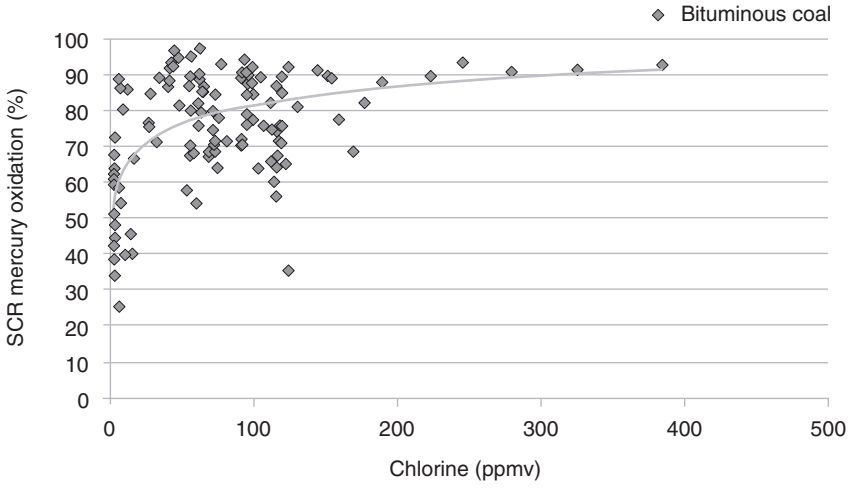

Figure 12.1 SCR mercury oxidation for bituminous coal-fired units.

Some eastern bituminous (EB)-fired units with combined SCR/FGD operation experience baseline mercury removals exceeding 90% [1]. However, many such units fail to achieve 90% control, especially over extended periods of time. For consistent, long-term regulatory compliance, these co-benefit units may require operational adjustments to counter excursions above the 1.2 lb $TBtu^{-1}$ MATS mercury emission limit, and a significant number may require supplemental mercury controls, such as activated carbon injection (ACI) and boiler halogen addition, to meet the limit.

A recent analysis of 240 datasets collected by EPRI at EB-fired co-benefit units shows highly variable mercury oxidation, with an average oxidation of 75% across the SCR; only about one-third of the datasets describe 90% or greater mercury oxidation (Figure 12.1) [2]. In research that will contribute to stable, high mercury removal at these co-benefit units, EPRI is working to enhance mercury oxidation across the SCR by evaluating high-mercury-oxidation SCR catalysts, improving catalyst management, and optimizing flue gas conditions such as halogen (chloride, bromide) content and temperature. EPRI is also pursuing a full characterization and understanding of wet flue gas desulfurization (wFGD) chemistry with the goal of enhancing reliable, continuous mercury removal by managing wFGD processes.

12.2.2 Unburned Carbon

When coal combustion is incomplete, unburned carbon (UBC) particles in fly ash remain available to adsorb flue gas mercury. Capture of the UBC-laden ash in particulate control devices provides a modest level of baseline mercury removal.

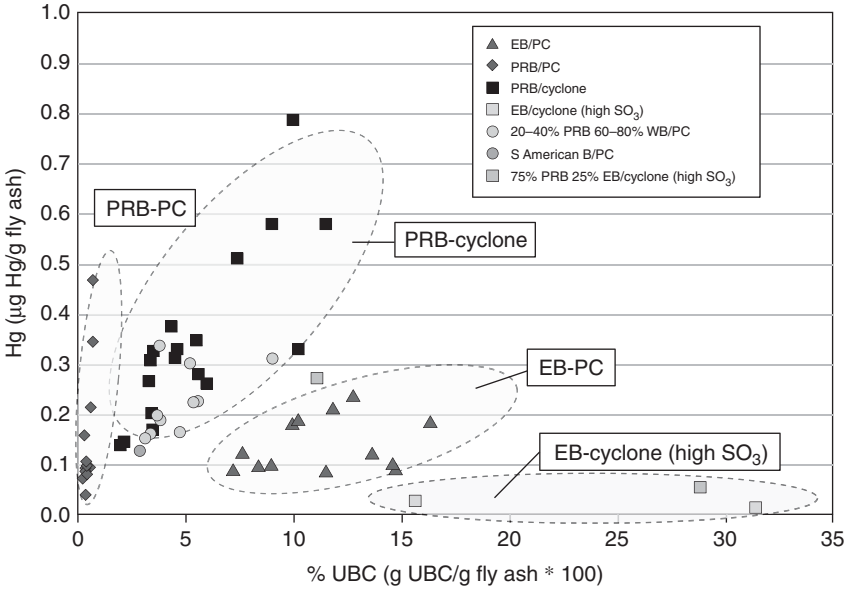

Figure 12.2 Influence of coal type, UBC concentration, and boiler type on fly ash mercury adsorption. (EB, eastern bituminous coal; WB, western bituminous coal; PRB, Powder River Basin coal; and PC, pulverized coal.)

The amount of mercury adsorbed on fly ash depends on coal type, the concentration of UBC in the ash, and boiler type. As shown in Figure 12.2, UBC in fly ash derived from western Powder River Basin (PRB) coal adsorbs much more mercury than does UBC in fly ash derived from high-sulfur eastern bituminous (HSEB) coal [1]. For a given coal, increasing UBC in fly ash enhances mercury capture. Increasing halogen levels in flue gas can enhance UBC affinity for elemental mercury.

12.3 Sorbent Injection

Sorbent injection – in particular, the use of ACI and BACI (brominated activated carbon injection) – is the second key, near-term technology for controlling mercury emissions.

In 2011, EPRI reported that ACI was installed at more than 60 U.S. power plants (more than 100 units) on coal-fired boilers rated from 73 to 1375 MWe [3]. Most of these ACI installations have operated since 2009, in compliance with state regulations and consent decrees. During site visits in 2010–2011, EPRI conducted detailed surveys of 11 ACI installations representing a broad cross section of the industry. EPRI member companies have hosted numerous ACI field studies.

12.3.1 Units Equipped with Electrostatic Precipitators

12.3.1.1 Western Coals

At electrostatic precipitator (ESP)-equipped units firing western coals, ACI removes about 75% of flue gas mercury at an injection rate of 5 lb MMacf^{-1} (Figure 12.3) [1]. This poor performance results from the low halogen content of the flue gas environment created by western coal combustion. Fundamental studies to date show that elemental mercury adsorption is enhanced by halogens that oxidize mercury and form halogen–mercury–carbon bonds. Use of BACI at injection rates similar to those for ACI removes more than 90% of flue gas mercury (Figure 12.3). BACI does not perform significantly better than ACI for EB coals, where a significant fraction of vapor-phase mercury is in the oxidized form [1].

12.3.1.2 Eastern Bituminous Coals and High-Sulfur Flue Gases

At ESP-equipped units firing EB coals, ACI mercury removals vary widely (Figure 12.4) [1]. Although the flue gas environment created by EB coal combustion contains more halogen (chloride) than western coal flue gas, it also contains more sulfur – especially if the coal fired is HSEB (S > 3%). Under these conditions, researchers postulate that sulfur trioxide (SO_3) in the flue gas competes with mercury for active adsorption sites on injected carbon or forms sulfuric acid (H_2SO_4) that blocks carbon pores. High concentrations of SO_3 in flue gas can form during combustion of high-sulfur coal, SCR conversion of sulfur dioxide (SO_2) to SO_3, or the use of SO_3 flue gas conditioning to improve ESP performance.

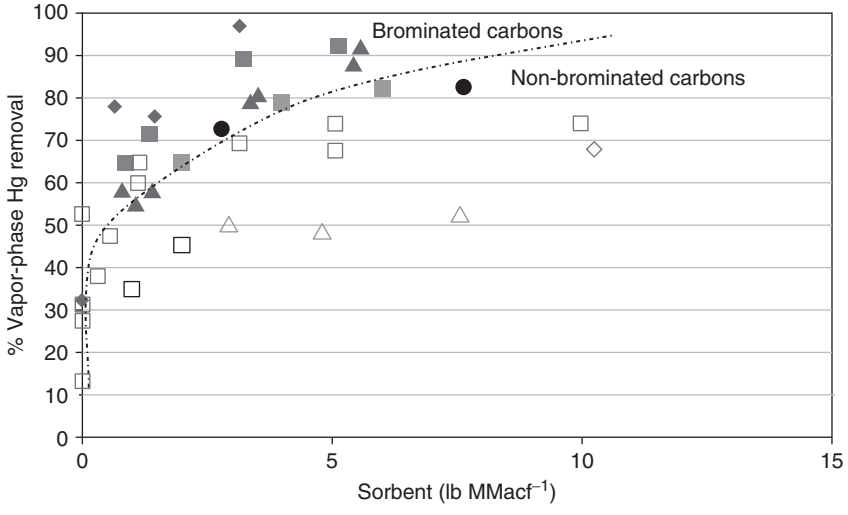

Figure 12.3 ACI mercury removal across ESPs for western coals. (Symbol shapes denote different sorbents, with solids representing BACs and outlines representing ACs.)

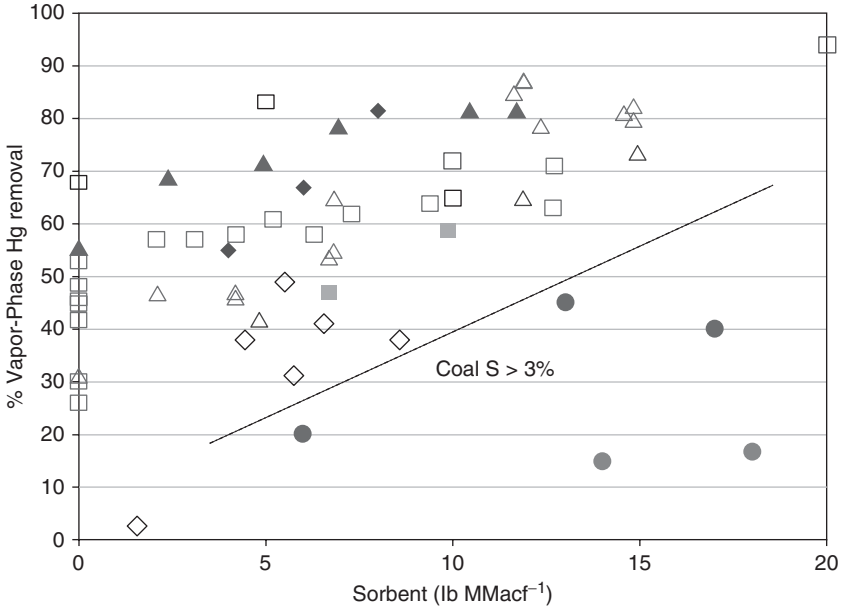

Figure 12.4 ACI mercury removal across ESPs for EB coals. (For LSEB coal (S < 3%), symbol shapes denote different sorbents, with solids representing BACs and outlines representing ACs.

Figures 12.4 and 12.5 illustrate the impact of flue gas SO_3 concentration on mercury removal across an ESP when using ACI for mercury control [1]. EPRI is evaluating various options to mitigate SO_3 impacts, including the use of SO_3-tolerant sorbents, alkali injection to reduce flue gas SO_3 concentrations, and alternate ESP flue gas conditioning agents.

12.3.2 Units Equipped with Fabric Filters or TOXECON®

To date, results show that using ACI or BACI with fabric filters (FFs) – including TOXECON® [4] (an ESP followed by a polishing FF) – can effectively remove mercury from western and low-sulfur eastern bituminous (LSEB) coal flue gases (Figure 12.6) [1]. Few ACI or BACI results are available for HSEB coal flue gas, as very few FFs are installed on HSEB-fired units; most of these units are equipped with an ESP and wFGD. EPRI is investigating whether ACI before an FF can effectively remove mercury from HSEB coal flue gas and whether mercury removals can be enhanced with alkali injection to reduce SO_3 levels.

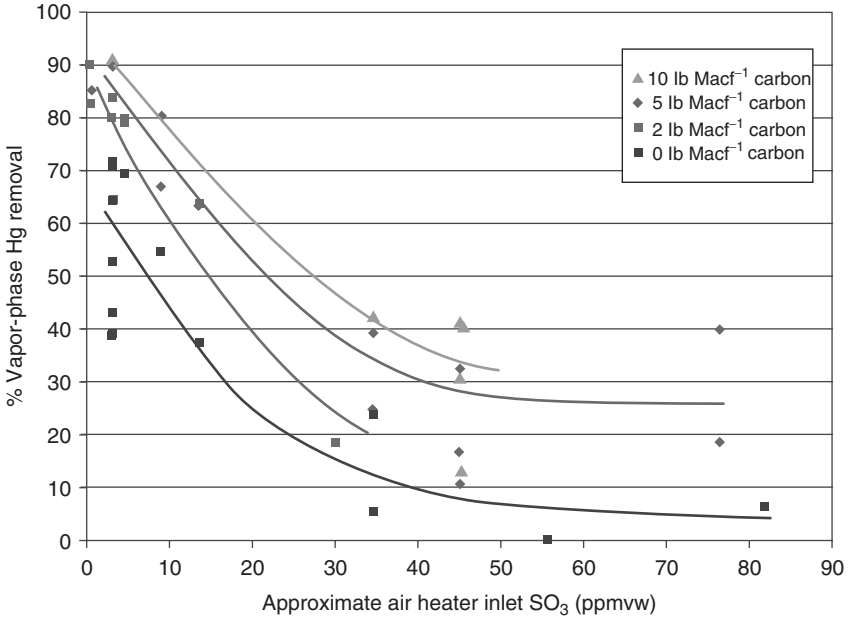

Figure 12.5 Influence of flue gas SO_3 concentration on ACI mercury removal across an ESP.

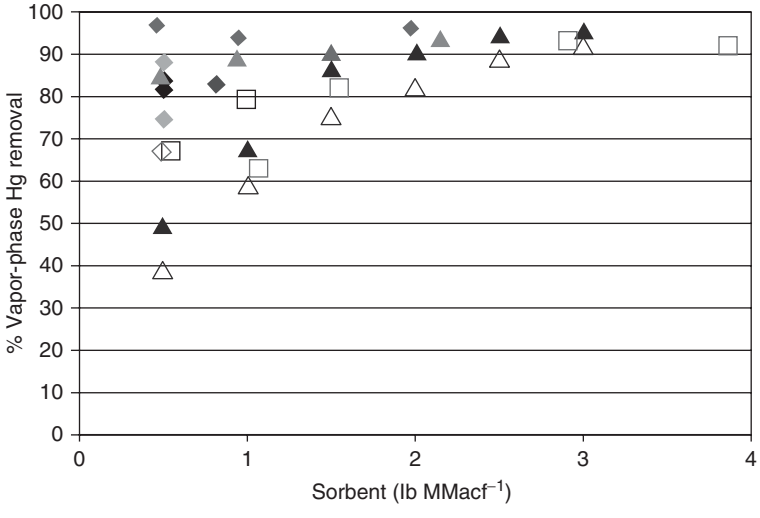

Figure 12.6 ACI mercury removal across FFs for western and LSEB coals. (Symbol shapes denote different carbons, with solids representing brominated and outlines representing non-brominated carbons.)

12.3.3 Challenges and Responses

Potential balance-of-plant impacts associated with ACI and BACI present challenges that must be addressed to contain the cost of regulatory compliance and, hence, the cost of electricity.

12.3.3.1 Preserving Fly Ash Sales

Preserving fly ash sales and avoiding ash disposal costs are important economic goals for many power plants. But these goals are thwarted if ACI or BACI increases the carbon content of fly ash, making it unsuitable for sale as a replacement for Portland cement in concrete.

Even small amounts of activated carbon (AC) in fly ash can adsorb the organic, air-entraining agents (AEAs) that fabricators add to improve concrete expansion and contraction over freeze/thaw cycles. To avoid this problem while continuing to use ACI for mercury control, power plant owners have evaluated mitigation measures such as minimizing the amount of injected AC, treating carbon-laden fly ash with chemicals to block AEA adsorption, injecting specially treated ash compatible carbons or non-carbon sorbents, or installing TOXECON. In EPRI's TOXECON configuration, an initial ESP captures 99% of the fly ash before carbon injection occurs between the ESP and an FF, or secondary particulate collector. Because fly ash collects in the ESP hoppers before it is exposed to AC, the ash remains uncontaminated and suitable for sale.

Some wholesalers purchase fly ash with relatively consistent concentrations of carbon, allowing them to predict the amount of AEA needed for concrete fabrication. Thus, another option to preserve ash sales is to maintain a relatively stable and predictable ratio of AC to fly ash [1].

12.3.3.2 Optimizing Electrostatic Precipitator Performance

- *Particulate matter emissions and opacity*: Although ACI increases the carbon burden in flue gas, EPRI found no significant ACI-related changes in particulate matter (PM) mass emissions or opacity monitored at the stacks of 12 ESP units surveyed in 2010 [5]. With or without ACI, historical data indicate that PM mass emissions from large ESPs and TOXECON units fall below the 0.03 lb $MMBtu^{-1}$ new source performance standard for power plant emissions, which is identical to the MATS limit for filterable PM. However, some small ESPs (specific collection area ~300 ft^2 $kacfm^{-1}$ or lower) do have PM mass emissions above this limit [5]. The electric power industry is evaluating low-cost performance upgrades for these small ESPs.
- *Mercury removal in the presence of flue gas conditioning*: Units firing either EB or western coals may employ both ACI and SO_3 flue gas conditioning to reduce ash resistivity and improve ESP collection efficiency. However, because SO_3 adversely impacts mercury adsorption on AC in flue gas, EPRI has tested the performance of alternative flue gas conditioners.

At a PRB-fired unit equipped with an ESP, researchers replaced SO_3 with an alternative liquid flue gas conditioner (LFGC) in tests of ACI mercury control. The LFGC proved to be as effective as SO_3 conditioning in controlling particulate emissions across the ESP. Furthermore, it did not interfere with mercury removal [3].

12.3.3.3 Optimizing Fabric Filter and TOXECON Performance

- *Optimal ash-to-carbon ratio*: In the TOXECON configuration, if the ESP is too efficient in removing fly ash from flue gas during ACI, PM entering the FF is largely carbon. As observed at one unit, fine carbon particles can clog filter bags – increasing pressure drop and cleaning pulse frequency while decreasing actual mercury removal. To solve this problem, plant operators at the unit detuned the ESP to allow more fly ash to enter the FF [5]. Thus, there may be an optimal ash-to-carbon ratio that must be determined empirically for some TOXECON installations to optimize mercury capture in the FF while maintaining reasonable pressure drop and cleaning frequency.
- *Hopper fires*: The high carbon content of ash in TOXECON FF hoppers also creates the possibility of hopper fires. At one TOXECON installation where fires were reported, researchers modeled combustion of the carbon-rich ash and suggested mitigation measures. These measures included installing temperature sensors and ash level detectors in the hoppers, as well as implementing an aggressive hopper cleaning schedule [6].
- *Influence of flue gas temperature*: AC adsorbs mercury more readily at lower flue gas temperatures. Figure 12.7 illustrates the response of ACI mercury removal to temperature variations from 330 to 360 °F at a PRB-fired unit equipped with an FF. To maintain stable mercury removal at this unit, plant operators must adjust the ACI rate for seasonal variations in temperature from winter to summer months [1].

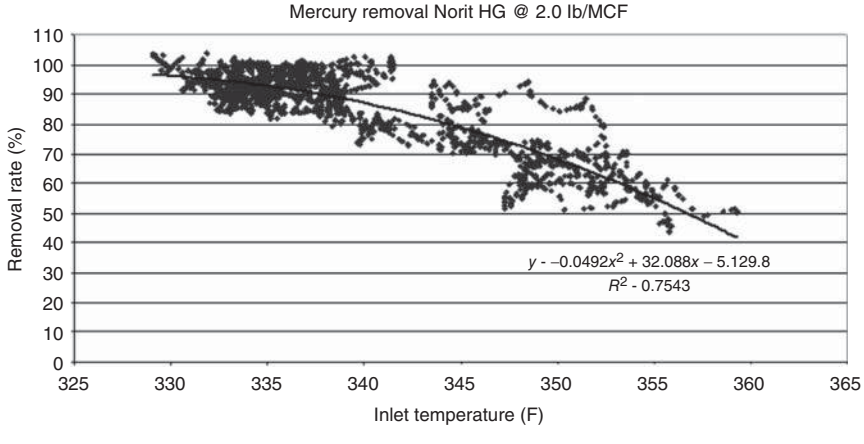

Figure 12.7 Influence of temperature on ACI mercury removal across an FF for PRB coal.

12.4
Boiler Chemical Addition

Boiler chemical addition (BCA) is the third key, near-term technology for controlling mercury emissions. BCA introduces halogens – usually bromide salts, such as calcium bromide (CaBr) – in solid or liquid form to the coal feed [7, 8]. Plant operators may also inject hydrogen bromide (HBr) into flue gas upstream of the air heater. Figure 12.8 shows the locations of these treatments, along with potential bromine balance-of-plant impacts on fly ash, the SO_2 scrubber, and stack emissions.

Since 2004, EPRI has conducted several full-scale demonstrations of boiler bromide addition (BBA) at units firing western coals (PRB and Texas lignite). In these demonstrations, more than 90% of flue gas mercury was oxidized at BBAs equivalent to 25–300 ppm by weight in coal [1]. This oxidizing effect is enhanced at units with SCR. For example, BBA (25 ppm Br) removed 90% of flue gas mercury in a 2-month test at a PRB-fired unit equipped with an SCR, ESP, and a downstream wFGD to capture the bromine-oxidized mercury (Figure 12.9) [9].

In a continuous 12-day test at an EB-fired unit equipped with an ESP and wFGD, BBA failed to achieve more than 90% mercury oxidation and did not improve total mercury removal [3]. At another EB-fired unit, researchers determined that BBA took several weeks to equilibrate in the wFGD; this reduced mercury reemissions and improved total mercury removal (Unpublished EPRI field test data). EPRI continues to study BBA at EB-fired units.

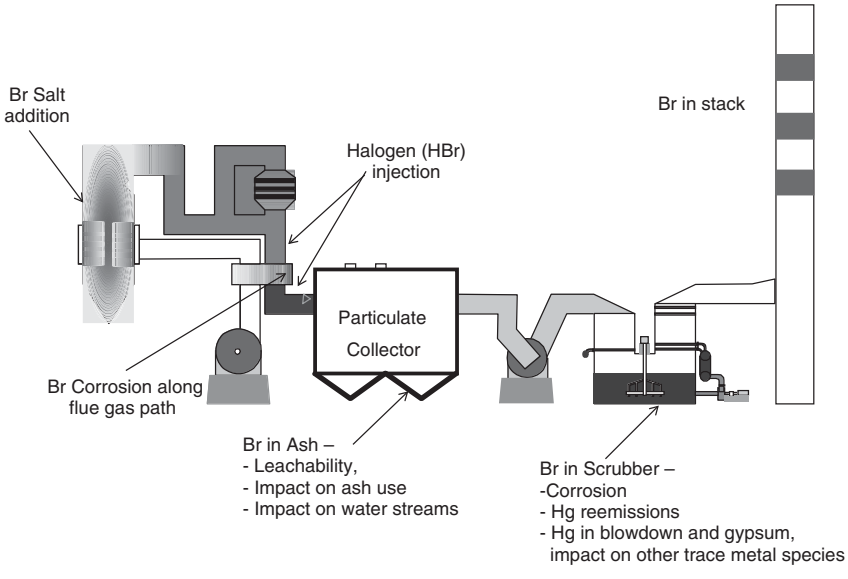

Figure 12.8 BCA options and potential balance-of-plant impacts.

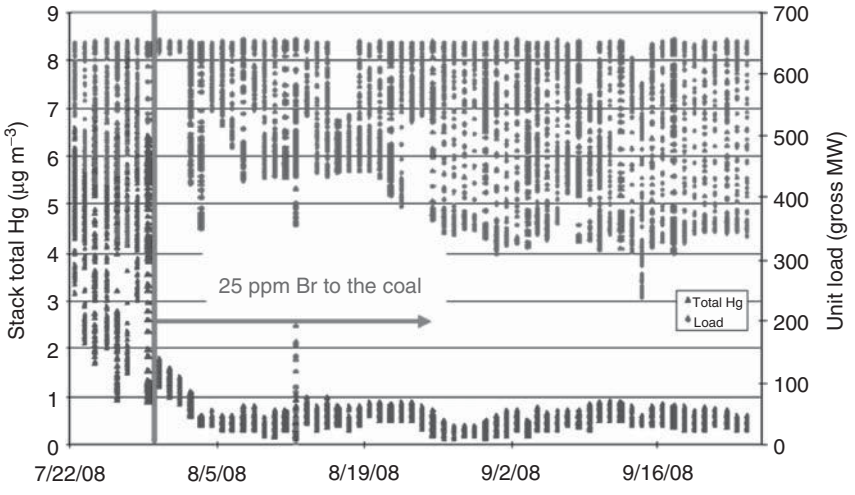

Figure 12.9 BBA promotes SCR mercury oxidation and removal across a wFGD for PRB coal.

12.4.1 Combined Technologies

Recently, several power plants have combined BBA with ACI. Combined technologies may offer an advantage over BACI at western coal-fired units because they reduce the amount of AC needed to achieve a given level of mercury control. At a North Dakota lignite-fired unit equipped with an ESP and wFGD, researchers tested the relative effectiveness of ACI (Norit Darco Hg) and BACI (Norit Darco Hg-LH) used as sole technologies or in combination with varying concentrations of BBA (CaBr). BACI was not as effective as BBA plus ACI in controlling mercury emissions, requiring an injection rate of 2 lb MMacf^{-1} or more to meet the 4.0 lb TBtu^{-1} MATS mercury emission limit for lignite coal-fired units (Figure 12.10). BBA (75 ppm Br) paired with ACI was the most effective treatment, meeting the emission limit at even the lowest sorbent injection rate (Unpublished EPRI field test data). This reduced use of AC can be an important consideration in preserving fly ash sales.

BBA can enhance the mercury removal effectiveness of ACI at units with FFs or TOXECONs, as well as ESPs. In one field test at a TOXECON unit firing PRB coal, the use of BBA (CaBr) alone supported 70–85% mercury removal across the TOXECON FF without ACI. Combining BBA with ACI delivered an average of 90% removal at an ACI rate of about 0.75 lb MMacf^{-1}. On the other hand, several days of continuous BACI offered 90% mercury removal at a rate of 1.26 lb MMacf^{-1} [5]. The decision to use BBA plus ACI versus BACI will depend on cost, including any potential balance-of-plant impacts.

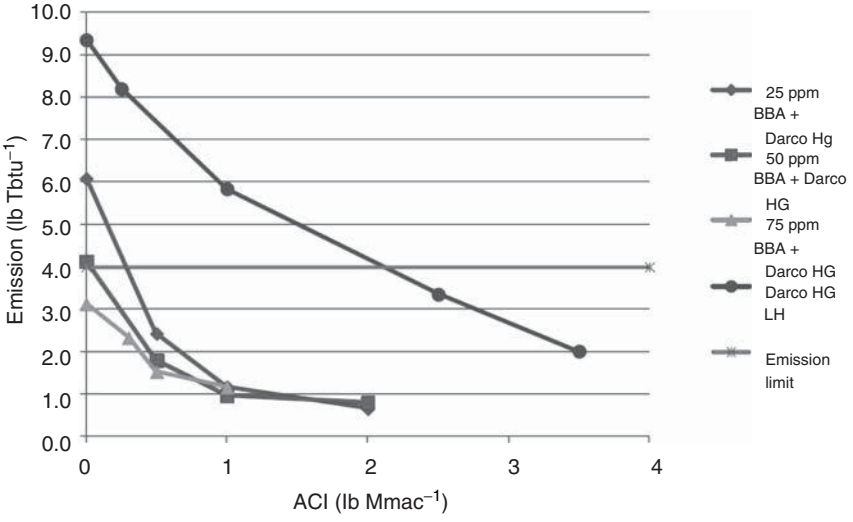

Figure 12.10 Combined BBA and ACI for mercury control.

12.4.2
Challenges and Responses

EPRI pursues a comprehensive research program to clarify potential balance-of-plant impacts associated with BBA to control mercury emissions at coal-fired units (Figure 12.11). This section describes challenges encountered during power plant operation and responses offered by EPRI research.

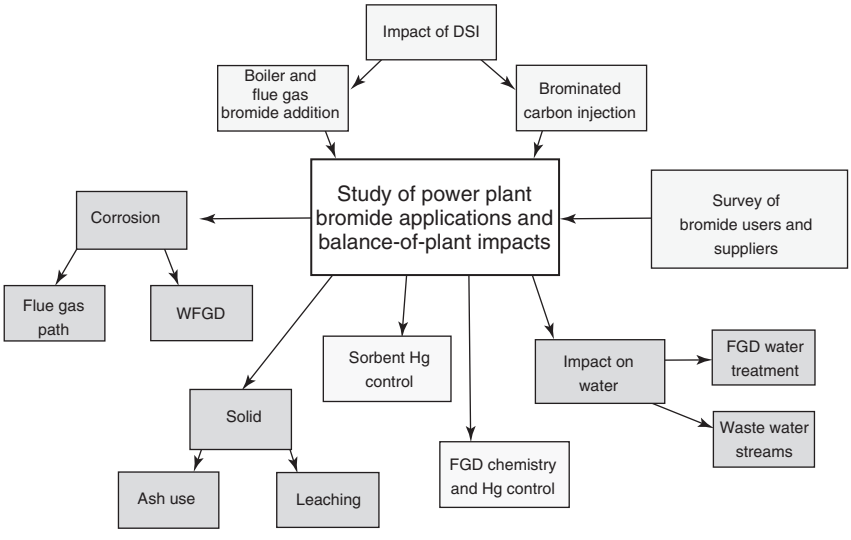

Figure 12.11 EPRI research program to clarify potential balance-of-plant impacts associated with BBA.

12.4.2.1 Wet Flue Gas Desulfurization Chemistry and Mercury Partitioning

Clarity about wFGD chemistry may allow researchers to partition mercury (and other trace metals such as selenium) to the most advantageous liquid or solid waste stream for a given unit. EPRI is conducting fundamental studies of chemical reactions within the scrubber that influence mercury and selenium (Se) partitioning, including mercury reemissions. These reactions involve constituents that concentrate in the FGD, such as limestone ($CaCO_3$) used in forced oxidation scrubbers and the inert materials the limestone contains, ferric chloride ($FeCl_3$) added for water treatment, and trace metals.

In one study at a PRB-fired unit equipped with an SCR, ESP, and wFGD, researchers observed no impact of BBA (CaBr) on mercury reemissions from the FGD. At this unit, most of the scrubbed mercury reported to the FGD solids under baseline conditions and BBA [1].

In contrast, most of the mercury reported to the FGD liquor during BBA at an EB-fired unit equipped with an ESP and wFGD. Under baseline conditions, about 67% of the wFGD mercury partitioned to the liquor. With BBA, these results remained basically unchanged (74%). However, adding AC to the sump liquor decreased wFGD mercury in the liquor to about 5%. This dramatic decrease demonstrated that added carbon was adsorbing mercury from the wFGD liquor. No other trace metals, including selenium, were significantly adsorbed by the added carbon [3].

12.4.2.2 Corrosion along Flue Gas Path and in the wFGD

Bromides formed with BBA are scrubbed and can reach high concentrations (500 to >30 000 ppm) in the wFGD over time, depending on scrubber design and the amount of recirculation that occurs [3]. There is concern that such high bromide concentrations may corrode FGD metal surfaces, especially in conjunction with high chloride levels.

In EPRI-sponsored laboratory studies, researchers exposed various metal alloys to simulated FGD liquors, creating corrosive environments reflecting the operation of a PRB-fired unit equipped with an SCR, ESP, and wFGD. The halogen content of the simulated liquors was based on chlorine already present and BBA rates needed for 90% mercury removal with SCR operation (25 ppm Br) or without SCR operation (100 ppm Br). Under these test conditions, alloys 2205, 317LM, and 316L experienced corrosion at 100 ppm BBA, as shown by the pitting potential in Figure 12.12, where lower voltages indicate greater susceptibility to corrosion [1]. These results suggest that careful selection of FGD construction materials may mitigate corrosion at units employing BBA for mercury control.

In addition to potential corrosion in wFGD scrubbers, corrosion along the flue gas path – for example, in air heater baskets – appears to occur at some full-scale units using BBA [10]. EPRI is conducting field and laboratory studies to determine whether bromide in flue gas causes the observed corrosion, or whether other factors and flue gas constituents are involved.

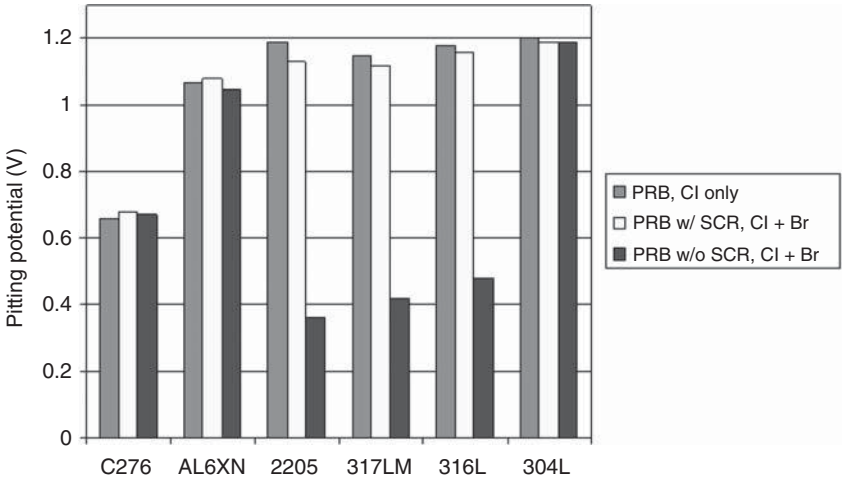

Figure 12.12 Corrosion of alloys in simulated FGD liquor for PRB coals, with and without SCR operation. (Lower pitting potential voltages indicate greater susceptibility to corrosion.)

12.4.2.3 Preserving Fly Ash Sales

At a PRB-fired unit equipped with an SCR, ESP, and FGD, 95% of bromide added to the boiler was scrubbed in the FGD unit. Fly ash adsorbed only 1–2% of the added bromide after 2 weeks of continuous treatment. This bromide concentration in fly ash did not affect physical properties of prepared concrete mixes, such as air content, compressive strength, set time, slump, or unit weight [1].

12.4.2.4 Selenium Partitioning in Wet Flue Gas Desulfurization Systems

Tracking selenium through a unit may alert operators to possible waste disposal issues. EPRI investigated selenium partitioning with BBA at an EB-fired unit equipped with an ESP and wFGD. Under baseline conditions, about 70% of the selenium appeared in the fly ash. BBA displaced this selenium from the fly ash to the FGD liquor, whose selenium concentration increased fourfold – from 151 µg/100 g of liquor at baseline to 590 µg/100 g of liquor at test [3]. This displacement may occur because selenium and bromide react to form selenium bromide (SeBr), a highly volatile compound that is not easily adsorbed on fly ash.

Selenium in the FGD liquor was largely selenate (SeO_4^{2-}), the form most difficult to remove with traditional wastewater treatments. Selenate displacement to the FGD liquor is an undesirable outcome, given the more stringent effluent guidelines proposed by the U.S. Environmental Protection Agency for fluid waste streams from coal-fired power plants.

12.4.2.5 Bromide Leaching from Fly Ash

As reported, 1–2% of bromide added to the boiler was adsorbed by fly ash at a PRB-fired unit equipped with an SCR, ESP, and FGD. In Synthetic Precipitation

Leaching Procedure tests on fly ash samples from the unit, 60–100% of total bromide content leached from the fly ash, confirming bromide's high water solubility [1]. Companies disposing of fly ash in landfills should consult state and local regulations to determine whether specific limits apply to bromide concentrations in landfill leachate.

12.5 Novel Concepts for Mercury Control

Novel concepts address the need to contain capital and operating costs while offering the most effective and efficient controls for mercury and other air pollutants.

12.5.1 TOXECON II®

This adaptation offers many of the advantages of TOXECON, without the expense of installing a compact FF. In the TOXECON II® configuration, sorbent is injected between the fields of an ESP [11]. Most of the fly ash collects in the inlet fields, before carbon injection, and can be sold. About 10% of the remaining fly ash collected in the final fields is contaminated and requires disposal. TOXECON II flue gas mercury removals of about 80% are possible for western coal-fired units without SO_2 scrubbers [1].

12.5.2 Gore® Carbon Polymer Composite Modules

W. L. Gore & Associates, Inc. has developed a carbon polymer composite (CPC) material made of AC granules embedded in a Teflon™ polymer matrix and formed into sheets [12]. When a CPC sheet is placed in the flue gas path, its carbon granules adsorb mercury and oxidize SO_2 to SO_3. Both elemental and oxidized mercury remain bound to the embedded carbon granules, while the SO_3 reacts with flue gas moisture to form sulfuric acid droplets that drain from the surface of the hydrophobic sheet. CPC modules can be placed above the mist eliminator at the top of a wFGD (Figure 12.13) [13]. The goal is to capture residual mercury and SO_2 downstream of the wFGD, where flue gas temperature is low (ensuring maximal mercury adsorption) and moisture is high. Depending on SO_x levels, a CPC reactor could be an alternative to an upgraded or new FGD system.

In 2010, EPRI demonstrated the feasibility of the Gore® CPC concept at an EB-fired unit equipped with an ESP and wFGD. In these tests on slipstream flue gas sampled after a limestone wet scrubber, mercury removal efficiency remained high (80–95%) over the entire 180 days of testing (Figure 12.14), resulting in outlet emissions of <1 lb $TBtu^{-1}$ mercury. About 60% of SO_2 was removed from slipstream flue gas during the same test period [14]. EPRI is conducting further

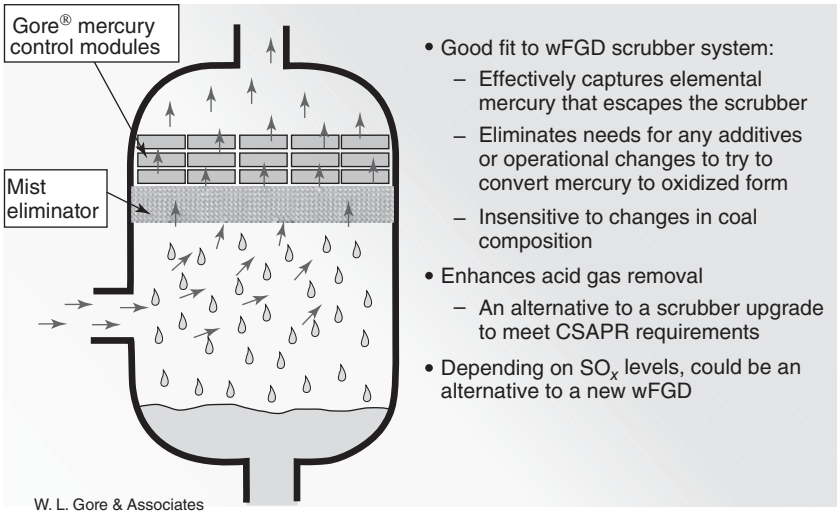

Figure 12.13 CPC modules placed above the mist eliminator in a wFGD.

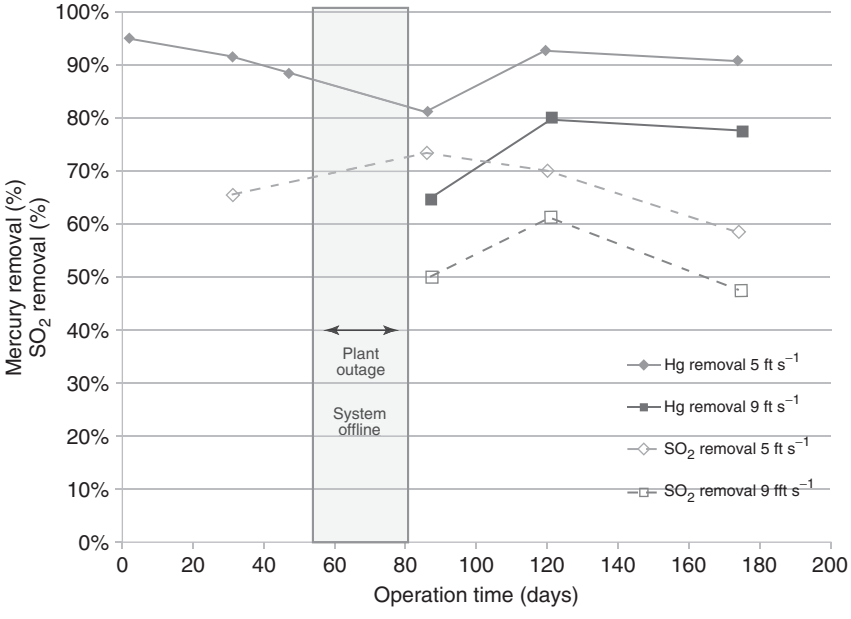

Figure 12.14 Mercury and SO_2 removal by CPC during 180 test days for EB coal.

pilot- and full-scale evaluations at other power plant sites to assess the potential for full-scale applications of CPC technology. Gore has recently renamed the CPC as Gore Mercury Control System (GMCS).

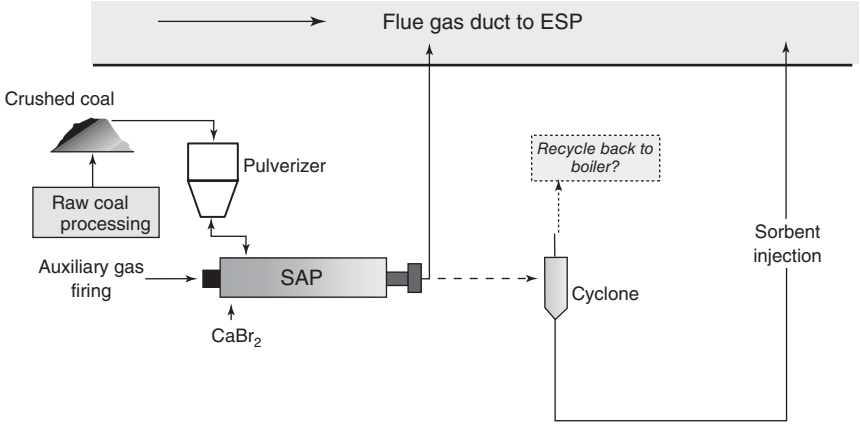

Figure 12.15 SAP process schematic.

12.5.3 Sorbent Activation Process

The Sorbent Activation Process (SAP®) [15, 16] reduces AC cost by more than 50% using on-site feedstocks to produce AC for mercury removal via a much simplified production process. Patented by EPRI and the University of Illinois at Urbana-Champaign, SAP uses a high-temperature reaction chamber to convert pulverized coal feedstock to AC in a matter of seconds (Figure 12.15) [17]. The AC is then injected directly into flue gas before an ESP or other particulate control device. Alternately, SAP flue gas and product AC are separated by a cyclone. The gas is recirculated to the boiler and the AC is injected into the flue gas. SAP uses the coal burned at the power plant site, together with activating agents and other chemicals, to create sorbents with unique surface areas, pore structures, and surface chemistries.

Field tests at a PRB-fired unit and an EB-fired unit confirmed that SAP ACs made from these coals are comparable to commercially available ACs used for mercury control. For example, both a commercial brominated activated carbon (BAC) and an SAP BAC removed about 80% to more than 90% of the mercury from flue gas across an FF (TOXECON configuration) at the PRB-fired unit (Figure 12.16) [17].

Further field tests at the EB-fired unit equipped with an ESP and wFGD offered proof of concept that SAP also can produce lime from limestone co-injected with pulverized coal for acid gas removal [17]. EPRI is demonstrating the cost-effectiveness of SAP at a Texas lignite-fired unit equipped with an ESP and wFGD.

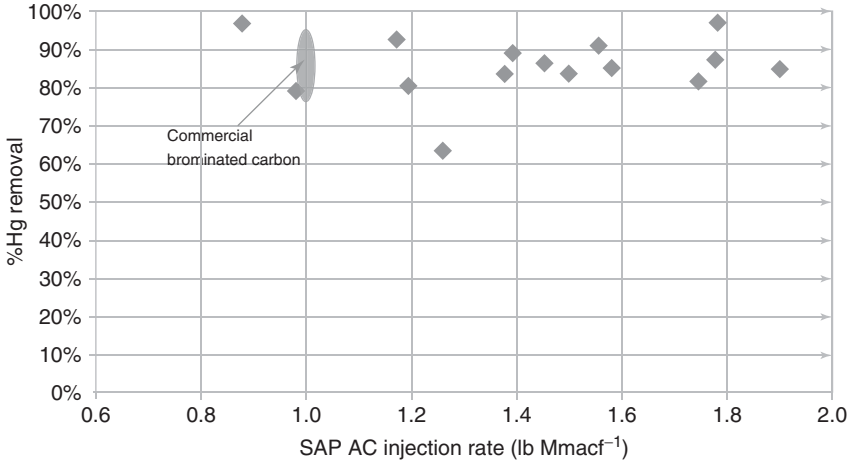

Figure 12.16 Mercury removal for PRB coal using SAP-produced BAC compared to commercial BAC.

12.6
Integration of Controls for Mercury with Controls for Other Air Pollutants

In the era of compliance with strict MATS limits and other pollution control regulations, such as the Cross-State Air Pollution Rule (CSAPR), mercury control technologies must work effectively with other pollution control technologies, such

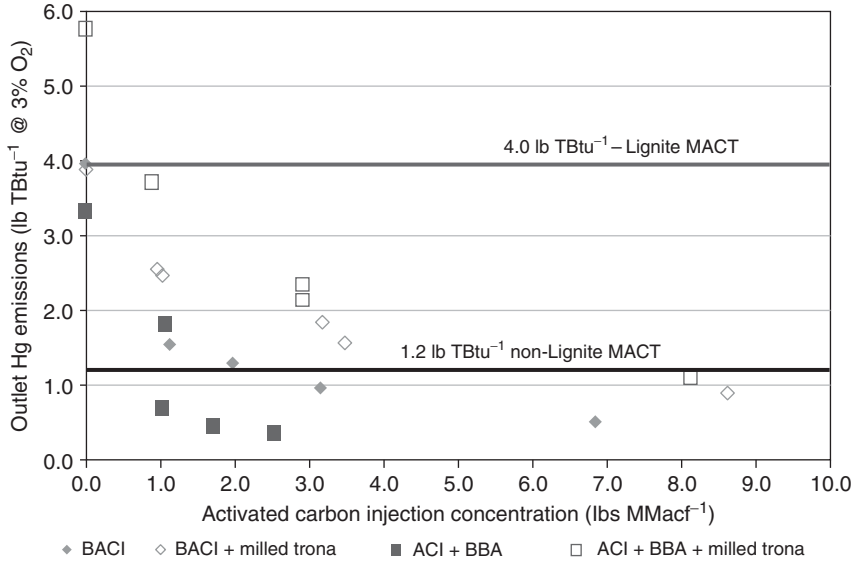

Figure 12.17 DSI (Trona) impact on ACI plus BBA mercury removal across an ESP for PRB coal.

as dry sorbent injection (DSI) for FGD. Many power plants are investigating DSI as a low capital cost, interim solution to meet acid gas control requirements. Tests are being conducted with Trona, sodium bicarbonate, or hydrated lime.

However, evidence suggests that alkali sorbents may reduce the effectiveness of ACI for mercury control. They may interact with BBA for mercury control by removing bromide and other halogens from flue gas. Injection of sodium-based alkali also produces nitrogen dioxide (NO_2), a compound that can reduce ACI mercury removal effectiveness. An example of these interactions is shown in Figure 12.17, where DSI and ACI were tested at a PRB-fired unit equipped with an ESP (Unpublished EPRI field test data). In these tests, milled Trona was simultaneously injected upstream of the air heater with either BAC or AC (paired with BBA in some runs). Co-injecting Trona had a significant, negative impact on mercury control effectiveness with ACI plus BBA.

12.7 Summary

This chapter presents results of EPRI's research and development program to support technologies that offer the most effective flue gas mercury removal at the lowest capital and operating cost. It reviews the achievements, balance-of-plant challenges, and research responses associated with near-term mercury control technologies, and describes novel, longer term concepts.

Mercury Control Using Combustion Modification

Thomas K. Gale

13.1
Mercury Speciation in Coal-Fired Power Plants without Added Catalysts

13.1.1
Mercury is all Liberated and Isolated in the Furnace

The predominant forms of mercury in coal-fired flue gas are elemental (Hg^0) and oxidized ($HgCl_2$) [1–3]. The percentage of oxidized mercury in the stack effluent of a particular power plant depends on the coal type, combustion efficiency, and the pollution control equipment used. Essentially, all of the mercury entering the furnace with the coal is vaporized and exists in the elemental form until the flue gases cool below ~600 °C (~1000 °F) [1–3]. The oxidation of mercury in coal-fired boiler systems is kinetically limited [1–3]. Because the concentration of mercury is exceedingly small at around 1 ppb in flue gas, any favorable mercury-oxidation reaction does not have the ability to promulgate itself. In virtually every conceivable competitive reaction, the competing gas component, much in excess of mercury, dominates. Where the formation of mercuric compounds is thermodynamically favored, the kinetically controlled oxidation requires the oxidant to be in vast abundance compared with mercury.

13.1.2
Chlorine Speciation in Coal-Fired Power Plants

Chlorine (Cl_2) is more reactive for the oxidation of mercury compared to hydrogen chloride (HCl). Chlorine gas (Cl_2) is not thermodynamically promoted at high temperatures. However, below 370 °C (644 K or 700 °F), a significant driving force toward the formation of Cl_2 develops. This driving force begins to dominate over the formation of HCl below 260 °C (533 K or 500 °F). Chlorine speciation is governed by equilibrium in furnace sections of coal-fired boilers and limited by kinetics and residence time downstream. Therefore, several statements can be made relative to chlorine speciation in coal-fired power stations. Chlorine gas

Mercury Control: for Coal-Derived Gas Streams, First Edition.

injection through the burner or entering with the coal will be entirely converted to HCl and Cl^- in the furnace. Any form of chlorine injected through the primary-air line will be converted in the furnace to HCl and a smaller amount of Cl^-, as long as it vaporizes in the flame. The result downstream (~600 °F) will be to increase the total amount of chlorine in the flue gas by the amount injected through the burner. The form of chlorine will be primarily HCl. However, as more total chlorine is injected through the burner, a small but higher concentration of Cl^- may persist a short distance downstream of the furnace. Although a driving force toward the formation of Cl_2 begins to form below 370 °C (644 K or 700 °F), the formation of Cl_2 is expected to be limited by kinetics at this point. Thus, the majority of the HCl is expected to remain in that form for the residence times that exist in full-scale power plants. Furthermore, if Cl_2 gas was injected at a lower temperature location downstream, where the thermodynamic driving force was more favorable to its formation (i.e., after the economizer), then it would remain in the form in which it was injected.

13.1.3 Mechanisms Governing Mercury Speciation

The following mechanism [4] was proposed whereby carbon, in the form of unburned carbon (UBC), activated injected carbon, or other carbon types could oxidize mercury by effectively removing the activation barrier, preventing HCl from directly reacting with elemental mercury atoms in the flue gas:

$$\mathrm{UBC + HCl \Leftrightarrow UBC \cdot Cl + H} \quad \text{and} \quad \mathrm{UBC \cdot Cl + Hg^0 \Leftrightarrow HgCl + UBC} \tag{13.1}$$

Equations 13.2–13.6 describe how UBC can effectively catalyze mercury oxidation by reacting with HCl to form chlorinated carbon sites, which then react with mercury on the surface of the carbon to form adsorbed HgCl, which finally desorbs as oxidized mercury. The oxidized mercury may in turn readsorb onto open UBC sites.

Equation 13.2 describes the formation of chlorinated carbon sites.

$$\mathrm{HCl + C \Leftrightarrow Cl \cdot C + H} \tag{13.2}$$

Equation 13.3 allows for desorption of chlorine, thus providing some moderation of chlorine accumulation on the carbon surface.

$$\mathrm{2Cl \cdot C \Leftrightarrow Cl_2 + C} \tag{13.3}$$

Equation 13.4 describes the capture of elemental mercury by reaction with chlorinated carbon sites located on the surface of ash particles.

$$\mathrm{Cl \cdot C + Hg^0 \Leftrightarrow HgCl \cdot C} \tag{13.4}$$

Equation 13.5 allows for the desorption of oxidized mercury.

$$\mathrm{HgCl \cdot C \Leftrightarrow HgCl + C} \tag{13.5}$$

Various homogeneous pathways can convert HgCl to $HgCl_2$, such as reaction of HgCl with Cl^- or Cl_2. The conversion is assumed to be very fast, and thermochemical equilibrium calculations predict nearly all mercury to be in the $HgCl_2$ form in flue gas downstream of the airheater [1, 5].

Equation 13.6 allows for the readsorption of oxidized mercury onto open carbon sites (as in the dissociative adsorption of mercuric chloride shown here).

$$HgCl_2 + C \Leftrightarrow HgCl \cdot C + Cl^- \tag{13.6}$$

13.2 Role of Unburned Carbon in Mercury Oxidation and Adsorption

13.2.1 UBC is the Only Catalyst with Enough Activity in Coal-Fired Power Plants

Extensive parametric investigations of mercury speciation in coal-fired flue gas and coal-fired power plants *without selective catalytic reductions* (*SCRs*) *installed* (or other catalysts or reagents introduced for the purpose of enhancing mercury oxidation or capture) have shown [1, 5, 6] that variable parameters such as exposed iron-oxide surfaces in the convection pass, flue-gas concentrations of O_2, N_2, H_2O, NO, NO_2, SO_2, CO, and CO_2, or the concentrations of Fe, Al, Si, Na, or derivatives of iron in the flyash have little impact on mercury oxidation or removal under conditions that exist within actual coal-fired power plants. What has been shown to have an impact on mercury oxidation and capture within the flue gas of coal-fired power plants (without SCR or other catalysts or reagents) is the type and extent of carbon in the flyash.

As mentioned earlier, the HCl concentration of the flue gas will have little impact on mercury oxidation if the UBC is low. Figure 13.1, previously published elsewhere [6], compares the relationship between Hg oxidation across a baghouse, HCl concentration in the flue gas, and UBC in the flyash, during a pilot-scale [7] mercury-speciation study. The HCl and UBC concentrations were varied by injecting chlorine gas through the burner while firing Powder River Basin (PRB) coal (a low-chlorine, high-calcium ash, sub-bituminous coal) and by blending PRB with higher chlorine bituminous coals.

A mass balance on coal-mercury suggested that the majority of mercury at the baghouse inlet was in the gas phase for all blend conditions. As shown, chlorine injection alone (i.e., resulting in HCl addition in the back pass) had some impact on mercury oxidation. However, much more mercury oxidation was realized as a result of coal blending, even though there was less chlorine. Adding bituminous coal also yielded more UBC in the ash, which catalytically enhanced mercury oxidation. The chlorine and UBC levels shown in Figure 13.1 are low relative to the levels produced from most eastern bituminous coals. Nevertheless, UBC clearly plays a significant role in catalyzing the oxidation of elemental mercury with hydrochloric acid vapor in the flue gas, and the concentration of UBC in flue

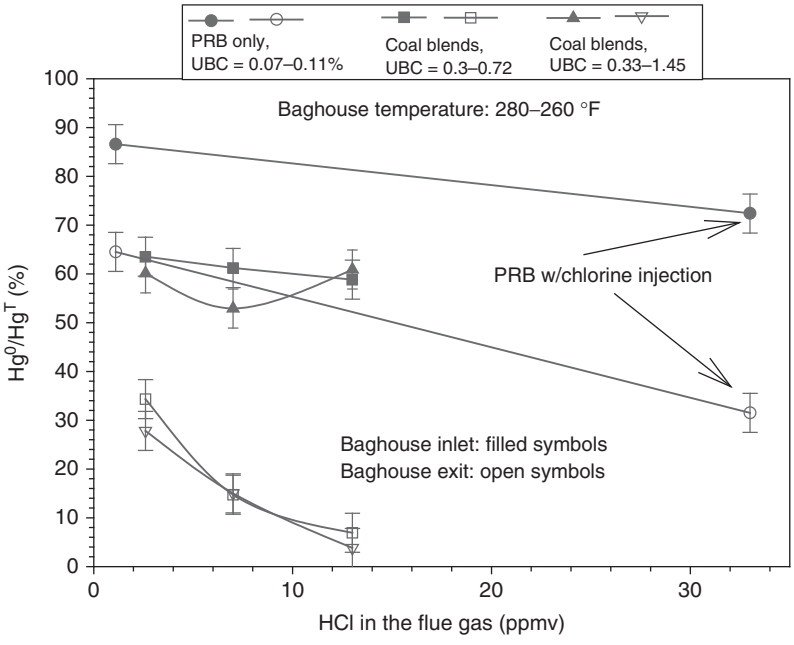

Figure 13.1 Effect of flue-gas– chlorine on mercury oxidation ahead of and across a baghouse [6] (shown as a decrease in the elemental mercury (Hg^0) concentration at the measurement location relative to total mercury (Hg^T) at the baghouse inlet). (Reproduced with permission from Ref [6]. Copyright © 2009, Elsevier Limited.)

gas will be as important, or more important, than the concentration of HCl in the flue gas for many plants relative to mercury oxidation.

13.2.2
UBC can Remove Hg or Oxidize Hg, Depending on the UBC Concentration

It is known [8] that the desorption rate of HgCl from carbon at a given temperature decreases with increasing available carbon sites, as the desorption rate depends primarily on the HgCl concentration deposited on the carbon surface and the concentration of vacant carbon sites per unit mass of carbon. Furthermore, for a given temperature, the adsorption rates of Hg^0 and $HgCl_2$ increase with an increase in the number of sites available for sorption – that is, the UBC sites for activation by HCl and adsorption of $HgCl_2$ (i.e., through the mechanisms described in Equations 13.2 and 13.6, respectively) and the Cl·C sites (see Equation 13.4) for adsorption of Hg^0. Hence, the speciation and removal of mercury by particulate, produced by a given coal and firing condition, depend on the amount (and surface activity) of the carbon (in the flue gas) available to adsorb mercury, keep it adsorbed, and to readsorb oxidized mercury.

With sufficient carbon (i.e., high enough C/Hg ratio), the overall adsorption rate of mercury may be overwhelmingly greater than the overall desorption rate, in

which case significant mercury removal will be observed. On the other hand, if sufficient carbon (activated carbon or UBC) is present to yield significant mercury adsorption on chlorinated carbon sites, but not enough carbon is available to slow the desorption of HgCl and to allow significant readsorption of $HgCl_2$, then extensive mercury oxidation may be observed without significant mercury removal.

13.2.3 Nature of Carbon Type Depends on Parent Coal and Combustion Efficiency
