EPA considered the potential impact of postclosure releases through a sensitivity analysis (see **Appendix K**). This sensitivity analysis modeled closed surface impoundments equivalent to closed landfills, with the full constituent mass still available to leach without replacement. The results of this comparison show that releases from surface impoundments drop dramatically after

closure, even with waste in place. This is because the large hydraulic head present during operation forces leachate into the underlying soils at a faster rate, resulting in higher releases to ground water than can occur postclosure. Based on these findings, EPA concluded that the assumption of clean closure has a negligible effect on modeled risks.

Landfill Leachable Content

It is likely that there may be some insoluble or otherwise unleachable constituent mass that remains bound within any waste. To account for the presence of this recalcitrant fraction, EPA used empirically derived estimates of the leachable mass of each constituent based on data collected using SW-846 Method 1313. However, long-term leachate studies have shown that short-term test methods may underestimate the total mass of constituents that can leach over longer periods of time (U.S. EPA, 2009a). For example, additional mass may become available as the physical matrix of the waste degrades over time.

EPA conducted a sensitivity analysis to provide a bound on the effects that the availability of this additional mass could have on modeled risks. In this sensitivity analysis, the Agency reran EPACMTP for landfills the same as in the full probabilistic analysis, except with the total constituent mass used in place of the leachable mass. This was done for 62 out of 69 CCR wastes sampled with Method 1313 for which data on total constituent mass were available. Since it was the only constituent to exceed any risk criteria in other sensitivity analyses conducted for landfills, arsenic (both III and V) was modeled for this analysis.

The use of total constituent mass resulted in an increase in arsenic III by a factor of less than 2, and an increase in arsenic V by a factor of 3 or less. These increases are not sufficient to push the modeled probabilistic risks above either cancer or noncancer criteria for either species. Furthermore, even if the total mass present in CCR waste were available to leach, it is unlikely that this mass would be released as a continuous pulse or at the same rate as early releases. Therefore, given that this conservative bound on releases modeled with total mass did not appreciably increase risks, the impact of this uncertainty on the modeled risks is negligible.

Closed Landfill Source Term

Landfills were only modeled postclosure because the nonlinear sorption isotherms used by EPACMTP require the infiltration rate to be held constant. The landfill source model assumes that the full footprint of the landfill is filled to capacity at the start of modeling, and that a cap no less permeable than the soil or liner underlying the WMU is present to avoid accumulation of water within the landfill. However, during operation, only a portion of the landfill will actively receive CCR wastes at any given time. The active portion of a landfill would be exposed directly to the elements. While the cap modeled on the closed landfill will limit infiltration, the filled capacity will overestimate the initial loadings into ground water. Because these uncertainties affect the results in opposite directions, the ultimate effect on risks is uncertain.

CCR Compaction

The landfill source model does not consider further compaction of CCR waste that may occur over time as a result of anthropogenic activities, gravity or infiltrating water. This decrease in space

between the particulates can reduce hydraulic conductivity and inhibit water infiltration. However, no data on either the rate or degree to which these processes may occur were identified. As a result, the current full-scale modeling approach will likely overestimate long-term infiltration rates to some degree. However, the magnitude of this overestimation is unknown.

Clay Liner Thickness

Limited data are available on exact liner thickness of clay-lined WMUs. The probabilistic analysis assigned a fixed liner thickness of three feet for all units. There may be a wider range of thicknesses used in practice, with a minimum of two feet specified in Industrial Subtitle D Guidance (U.S. EPA, 2006b). EPA conducted a sensitivity analysis to provide a bound on the effects that different liner thickness may have on modeled risks. In this sensitivity analysis, the Agency reran EPACMTP for clay-lined surface impoundments the same as in the full probabilistic analysis, except with a fixed liner thickness of two feet for all units. Arsenic (both III and V) and boron were modeled in this sensitivity analysis to represent constituents with the highest risks and the fastest travel times, respectively. **Table 5-22** provides a comparison of the modeled risks for clay-lined surface impoundments modeled with a three-foot and two-foot liner.

Table 5-22. Comparison of 90th Percentile Ground Water Ingestion Risks for Clay-Lined Impoundments with Two- and Three-Foot Thick Liners

COPC	3-Foot Liner	2-Foot Liner	Ratio
Cancer Risks			
Arsenic III	6×10^{-6}	2×10^{-5}	3.3
Arsenic V	1×10^{-7}	4×10^{-7}	4.0
Noncancer Risks			
Arsenic III	0.2	0.6	3.0
Arsenic V	< 0.01	0.01	2.5
Boron	0.02	0.06	3.0

Risks from two-foot clay liners were up to four times higher than the risks from three-foot liners. This increase is sufficient to push arsenic III, which was already within the OSWER risk range, slightly above a cancer risk of 1×10^{-5}. Thus, the presence of a thinner liner than modeled in the full probabilistic analysis could lead to increased risks for clay-lined surface impoundments and landfills than modeled in the probabilistic analysis. Conversely, the presence of a thicker liner would result in lower risks than those modeled. The sensitivity analysis results for a two-foot thick liners at all units represents a conservative bound on potential risks. Thus, to the extent that clay-lined units in the field differ from those modeled, there is the potential for higher risks above cancer criteria. Without more detailed information on the actual thickness of liners present each WMU, the ultimate direction and magnitude of this uncertainty is uncertain.

Clay Liner Performance

This risk assessment assumed that compacted clay liners were designed and installed to be three feet thick and achieve a hydraulic conductivity of 1×10^{-7} cm/sec, consistent with the Industrial

Subtitle D Guidance (U.S. EPA, 2006b). Peer reviewers and public commenters noted that clay liners designed to meet a 1×10^{-7} cm/sec hydraulic conductivity may perform differently in practice due to compaction, thixotropy and other factors. Moo-Young et al. (2004) investigated several clay-lined surface impoundments and landfills designed to a 1×10^{-7} cm/sec hydraulic conductivity. This study found clay-lined impoundments to have field hydraulic conductivities ranging from 3.0×10^{-6} to 3.2×10^{-5} cm/sec and clay-lined landfills have field hydraulic conductivities ranging from 2.0×10^{-9} to 4.4×10^{-8} cm/sec. Given the relatively small sample size, EPA draws no conclusions about actual range of hydraulic conductivities that may occur in the field or the tendency of different WMUs to perform better or worse than designed. However, these data do indicate that the assumption of a fixed hydraulic conductivity of 1×10^{-7} cm/sec could under- or overestimate risks on a case-by-case basis.

Composite Liner Leakage Rates

The composite liner leakage rates used in the probabilistic analysis were originally developed and peer-reviewed as part of the Industrial Waste Management Evaluation Model (U.S. EPA, 2002a). EPA excluded measurements for composite liners with a compacted clay layer from the distribution. This exclusion was based on the assumption that significant volumes of water can be released from clay due to consolidation from mechanical compaction from the weight of overlying waste. Several researchers have compared the chemical composition of leachate versus leak detection system water and concluded that a significant fraction of the water released is due to consolidation of the clay liner, rather than leachate from the overlying waste (Bonaparte et al., 2002; Bergstrom et al., 1993; Gross et al., 1990; Workman, 1993; Feeney and Maxson, 1993). Although clay liners have been shown to release consolidation water, the fraction of leakage attributable to consolidation has not been well quantified to date. These data were excluded due to the absence of consensus on an approach to determine the difference between consolidation flow and liner leakage. EPA conducted a sensitivity analysis as part of the 2010 Risk Assessment to provide a bound on the effects that different leakage rates may have on modeled risks. In this sensitivity analysis, the Agency reran EPACMTP for composite-lined landfills the same as in the full probabilistic analysis, except with all composite liner leakage rates. **Figure 5-4** compares the resulting distribution of DAFs for landfill runs with arsenic.

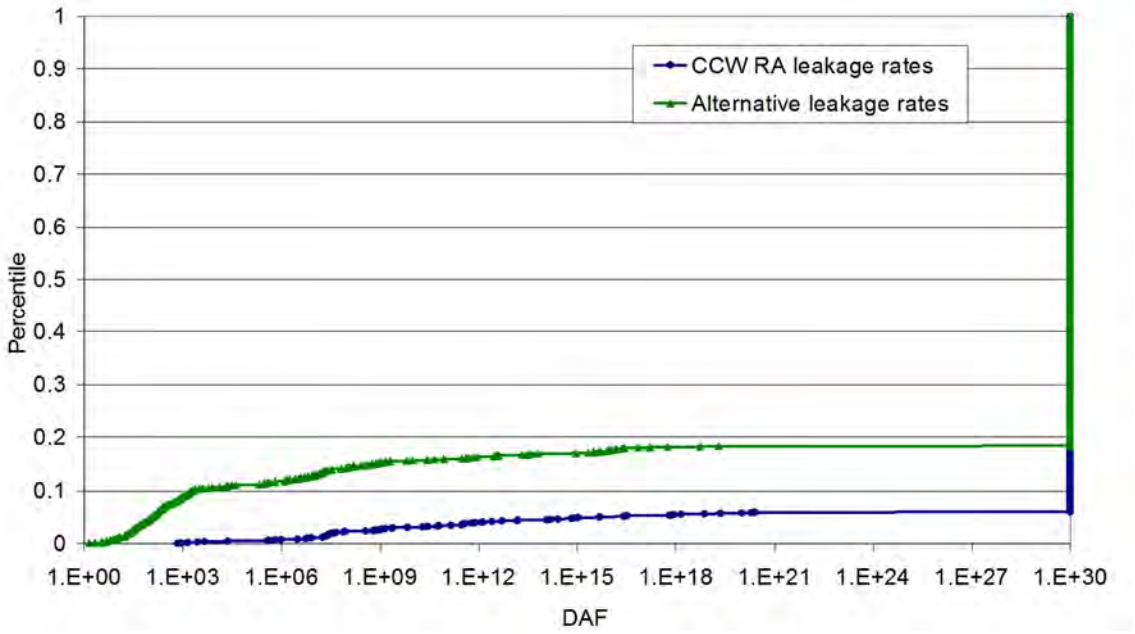

Figure 5-4. DAF Comparison for different leakage rates (landfills, arsenic).

In the figure above, the dramatic increase at a DAF of 1×10^{30} represents simulations where the constituent did not reach the receptor within the modeled timeframe. As anticipated, the use of higher infiltration rates for compacted clay layer units resulted in lower dilution and attenuation and a greater fraction of model iterations where the constituents reach the receptor well. Although use of all liner leakage rates would increase risks modeled for composite-lined facilities, the magnitude of the increase would not alter the finding that risks from composite-lined landfills are far lower risks than unlined and clay-lined landfills. Therefore, given that this conservative bound on releases from composite-lined releases would not appreciably increase risks, the potential impact of this uncertainty on the modeled risks is negligible.

Cap Degradation

For both unlined and clay-lined landfills, EPA used HELP Model–derived infiltration rates. These infiltration rates assume that the cap placed on top of the landfill at closure will remain intact for the duration of the probabilistic analysis, which extends up to a maximum of 10,000 years. Peer reviewers pointed out that the hydraulic conductivity of a clay cap may increase by orders of magnitude due to desiccation resulting from natural temperature cycles. In the near term, landfill caps will be maintained through periodic inspection and maintenance, but may degrade in the future without proper maintenance (Suter et al., 1993). However, predictions about the management and resulting performance of landfill caps centuries or more into the future would be speculative. To the extent that the performance of the cap does decrease over time, the modeled infiltration rates may underestimate infiltration into the landfill. However, since high-end risks will occur in on a shorter timeframe, the impact of this uncertainty on risk results is anticipated to be small.

Summary

A summary of the different uncertainties associated with source term models, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-23**. The majority of uncertainties identified are unlikely to have an appreciable impact on the principal risk results. EPA was not able to characterize the potential magnitude or direction of the uncertainties associated with modeling landfills postclosure or variations in clay-liner design and performance. The Agency relied on the best data available at the time of the analysis; however, the potential of these uncertainties to overestimate or underestimate risk results is uncertain.

5.1.8 Isotherm Model

MINTEQA2

MINTEQA2 has a long history of both internal review by the EPA Science Advisory Board (SAB) and external peer review during model development and implementation over the past two decades. These reviews largely focused on the use of MINTEQA2 to generate metal sorption isotherms for EPACMTP. During the most recent review, peer reviewers found that the revisions made to the MINTEQA2 model to account for CCR wastes were appropriate, but suggested further improvements that could be made to address the basic environments that are characteristic of many CCRs (U.S. EPA, 2003e). The version of MINTEQA2 used in this risk assessment addressed these recommendations by developing sorption isotherms specific to the geochemical conditions encountered in CCR surface impoundments and landfills. Due to the extensive peer reviews conducted, EPA has a high level of confidence in the model. However, there are many assumptions inherent in the application of MINTEQA2 to the revised risk assessment. These assumptions and the resulting limitations, discussed in detail in **Appendix H**, include:

- Site-specific data on the ground water chemistry was not available.
- The types and numbers of sorption sites modeled likely do not reflect the full range of sorption sites possible in nature.
- There was more limited data on the specific ion concentrations present in CCR leachate that may influence K_d values.
- The model did not account for the potential of redox to influence K_d values.
- Because each constituent was considered separately, the model did not account for potential competition between constituents for sorption sites.

Although the direction of the potential uncertainties are apparent for some of these uncertainties, it is difficult to quantify the magnitude of the resulting uncertainty. Thus, the direction and magnitude of this class of uncertainties is unknown.

Lithium

At the time the probabilistic analysis was conducted, sufficient information was not available to develop chemical-specific K_d values for lithium. MINTEQA2 could not be used because iron oxide is not an appropriate sorbent for this constituent. Available literature indicates that lithium does adsorb weakly to clay soils, resulting in low retardation (Fuentes, 1989). This has resulted in its use as a conservative environmental tracer in some studies (LeBlanc et al., 1991; Anghel et al. 2002). The current evaluation used a conservative K_d of 0 to estimate lithium fate and transport. This may result in an overestimation of downgradient exposures. Given the moderate exceedance of noncancer risk criteria observed, it is possible that accounting for this low amount of retardation in the environment may reduce national-scale risks below risk criteria. However, as demonstrated by identified damage cases, lithium risks may be present on a site-specific basis. Thus, this uncertainty is unlikely to alter the final conclusions of the risk assessment.

Summary

A summary of the different uncertainties associated with MINTEQA2, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-24**. There are multiple uncertainties associated with the implementation of MINTEQA2, many of which were associated with the absence of site-specific data. Given the broad, national scope of the risk assessment, the potential magnitude or direction of this uncertainty remains uncertain.

Lithium		●	

5.1.9 EPACMTP Ground Water Modeling

EPA has used EPACMTP and its predecessors to conduct ground water risk assessments in support of numerous regulations for land disposal of hazardous and nonhazardous wastes. During this time, EPACMTP has undergone multiple rounds of internal and external review, including several by the EPA SAB. Each of these reviews has determined that the use of this model for developing national regulations and guidance is appropriate. Some of the reviews include the following:

- **1994:** Consultation with the SAB on the use of EPACMTP for determining DAFs for the EPA's Soil Screening Guidance (U.S. EPA, 1996c); and peer-reviewed publication of EPACMTP in the Journal of Constituent Hydrology (Kool et al., 1994);
- **1995:** In-depth SAB review on the use of EPACMTP in the proposed/draft 1995 Hazardous Waste Identification Rule (U.S. EPA, 1996b);
- **1999:** Peer review of the implementation of EPACMTP in the EPA's multimedia, multiple exposure pathway, multiple receptor risk assessment (3MRA) model (U.S. EPA, 1999); and
- **2003:** SAB review of the 3MRA implementation of EPACMTP (SAB, 2004).

These reviews verified that the mathematical formulation of the model is scientifically sound and the code executes properly. In addition, recommendations from these reviews have been incorporated, resulting in a number of improvements to the model. Due to the high level of review and comment that this model has received, EPA has a high confidence in the accuracy of the model. Thus, EPA limited the discussion of uncertainties associated with EPACMTP in this document to those that were raised through public comments or that arose from the specific handling of inputs in this risk assessment. For a further discussion of the uncertainties associated with EPACMTP, see U.S. EPA (2003b).

10,000 Year Time Frame

This risk assessment assumed a constant hydrogeological environment and population distribution over the modeled timeframe. Peer reviewers and public commenters questioned the accuracy of using a maximum 10,000 year model duration. However, EPACMTP only ran to 10,000 years if a peak concentration had not been reached before that time. Arrival times for the peak well concentrations used to calculate ground water to drinking water risks for select CCR constituents (arsenic, boron, cobalt, selenium, and thallium) are plotted as cumulative distributions for surface impoundments and landfills in the figures in **Appendix K.** These constituents were selected both to capture those with the highest risks and highest mobility.

Tables 5-25 summarizes the time of travel results from the 2010 Risk Assessment sensitivity analysis by showing selected percentiles from these distributions for surface impoundments. For both unlined and clay-lined surface impoundments, the 10th percentile time to peak was less than 100 years for all constituents considered. The 50th percentile time to peak also remained under 100 years for multiple constituents, though the time for less mobile constituents increased appreciably. For composite-lined surface impoundments, even the faster time to peak approached 1,000 years. High-end risks will be associated with these lower percentile times. Thus, for unlined

and clay-lined surface impoundments, the uncertainties about future environmental settings have minimal impact on the peak risks. Uncertainties are much higher for composite-lined units. However, risks for these units were all well below all cancer and noncancer criteria. Therefore, use of a 10,000 year modeling timeframe adds a low uncertainty to the results of the probabilistic analysis.

Table 5-25. Years to Peak Well Concentration for Surface Impoundments by Liner Type

Percentile	Boron	Selenium VI	Arsenic III	Cobalt	Arsenic V	Selenium IV	Thallium
Unlined							
10th	70	70	70	71	73	76	—
50th	74	74	78	97	220	4,400	—
90th	110	110	170	970	6,500	> 10,000	—
Clay							
10th	75	75	75	86	95	81	—
50th	90	90	110	270	1,300	7,900	—
90th	150	150	340	3,100	10,000	>10,000	—
Composite							
10th	960	990	1,300	9,500	10,000	1,900	—
50th	4,400	4,600	8,600	>10,000	>10,000	>10,000	—
90th	10,000	10,000	>10,000	>10,000	>10,000	>10,000	—

Notes: Arrival times have been rounded to two significant digits.

A value of 10,000 means the concentration at the end of the maximum simulation time, 10,000 years, was the highest observed during the simulation. A value of >10,000 indicates that the constituent plume did not reach the receptor well during the modeled period.

Table 5-26 summarizes the time of travel results from the 2010 Risk Assessment sensitivity analysis by showing selected percentiles from these distributions for landfills. For both unlined and clay-lined landfills, the 10th percentile time to peak were all several hundred years. For both unlined and clay-lined landfills, the 50th percentile time to peak were all several thousand years. For all units, 90th percentile time to peak took more than 10,000 years to reach the receptor well for many constituents. Thus, for landfills, uncertainties about future environmental settings have much greater impact on peak risks than for surface impoundments. The potential magnitude of these uncertainties is unknown.

Table 5-26. Years to Peak Well Concentration for Landfills by Liner Type

Percentile	Boron	Selenium VI	Arsenic III	Thallium	Cobalt	Arsenic V	Selenium IV
Unlined							
10th	300	400	400	580	1,200	2,000	4,600
50th	2,000	2,600	2,800	2,300	7,800	9,700	10,000
90th	9,400	10,000	>10,000	9,700	>10,000	>10,000	>10,000
Clay							
10th	550	400	400	570	1,400	1,900	8,100
50th	5,600	5,100	4,000	4,300	10,000	10,000	>10,000
90th	>10,000	>10,000	>10,000	>10,000	>10,000	>10,000	>10,000
Composite							
10th	9,600	9,000	10,000	>10,000	>10,000	>10,000	10,000
50th	>10,000	>10,000	>10,000	>10,000	>10,000	>10,000	>10,000
90th	>10,000	>10,000	>10,000	>10,000	>10,000	>10,000	>10,000

Notes: Arrival times have been rounded to two significant digits.
A value of 10,000 means the concentration at the end of the maximum simulation time, 10,000 years, was the highest observed during the simulation. A value of >10,000 indicates that the constituent plume did not reach the receptor well during the modeled period.

The arrival times presented in these tables correspond to the arrival of the maximum estimated risks for each model run. However, for model runs where risk criteria were exceeded, the first exceedance may occur long before the maximum risks arrive.

Arsenic, Chromium, and Selenium Speciation

The speciation of arsenic, chromium and selenium can impact the mobility of these constituents in the environment, as well as the resulting toxicity to receptors. Arsenic can occur in either a +3 (arsenic III) or +5 (arsenic V) oxidation state, with arsenic III as the more mobile form. Chromium can occur in either a +3 (chromium III) or +6 (chromium VI) oxidation state, with chromium VI as the more mobile form. Selenium can occur in either a +4 (selenium IV) or +6 (selenium VI) oxidation state, with selenium VI as the more mobile form.

Although arsenic is generally thought to occur as arsenic III in leachate (Turner, 1981), evidence from damage cases suggests arsenic III can be converted to arsenic V during subsurface transport at some facilities (U.S. EPA, 2000a, 2003d; Lang and Schlictmann, 2004; Zillmer and Fauble, 2004). Similarly, although the dominant form of chromium leached from CCR wastes is chromium VI (Huggins et al., 1999; Stam et al., 2011), it is known to be converted to much less mobile chromium III form in ground water and soils (Palmer and Puls, 1994). However, the models used in this risk assessment do not consider changes to the speciation of metals during transport through the environment. To address this uncertainty, EPACMTP was run twice for both valence states of arsenic, chromium and selenium. The results from the two model runs bracket the full range of possible risks, given that there is likely some change in oxidation state during subsurface transport.

As a result of changes in speciation during fate and transport, actual risks could fall anywhere in the range presented in each table, with arsenic III, chromium VI and selenium VI providing an upper bound and arsenic V, chromium III and selenium IV providing a lower bound. Both chromium and selenium fell below risk criteria for each species. For arsenic, arsenic III fell above risk criteria, while arsenic V fell just below a cancer risk of 1×10^{-5}. Because risks for both species fell mostly above or below criteria, this uncertainty has minimal effect on the results of the probabilistic analysis.

Aquifer pH

In the field, leachate plumes mix gradually with ground water over time through advection and diffusion. However, the probabilistic analysis assumed that leachate pH equilibrated with the ambient ground water on contact. Because the solubility of inorganic constituents can vary drastically with minor changes in pH (U.S. EPA, 2009b), EPA conducted a sensitivity analysis as part of the 2010 Risk Assessment to provide an upper bound on the potential effect this simplifying assumption may have on modeled risks. This sensitivity analysis consisted of an additional run of EPACMTP for landfills that assumed leachate does not mix with ground water at all, and that the pH of the plume is driven solely by the initial characteristics of the leachate. EPA chose to model the fate and transport of arsenic as both arsenic III and arsenic V for the following reasons:

- Arsenic is the constituent found to pose the greatest ground water risks for both surface impoundments and landfills.
- For the sorbents considered in this risk assessment, these arsenic species respond differently to changes in pH. For arsenic III, K_d values tend to decrease (i.e., increased mobility) as pH transitions from acidic to basic. For arsenic V, K_d values tend to increase (i.e., decreased mobility) as pH moves from acidic to neutral, and then decrease as the pH becomes more basic. Differences between K_d values for these species can be orders of magnitude.

The results from this model run were compared with the results of the full modeling conducted in 2010. **Table 5-27** summarizes the percent change in peak arsenic III and arsenic V well concentrations that results from modeling leachate pH as unchanged in the aquifer.

Table 5-27. Change in Peak Receptor Well Concentrations for CCR Waste Disposed in Landfills Assuming Leachate Does Not Mix in Aquifer

Percentile	Percent Decrease	
	Arsenic III	Arsenic V
10th	0.0 %	0.0 %
30th	0.9 %	0.0 %
50th	0.3 %	2.3 %
70th	0.2 %	58.0 %
90th	0.0 %	11.8 %

The modeled well concentrations of arsenic V are somewhat sensitive to changes in pH, while those of arsenic III are not at all. This is because, while K_d values for both arsenic III and V increase

as the pH becomes more basic, the magnitude of the increase for arsenic V are much larger. As a result, while both species tend to sorb more at higher pH values, the effects are more pronounced for arsenic V. These results indicate that the assumption of complete equilibrium may slightly overestimate risks for constituents that behave similar to arsenic V. However, because the fate and transport of arsenic III is not sensitive to changes in pH, and because the predicted decrease in high-end arsenic V concentrations is minimal, this uncertainty will have no appreciable effect on the conclusions of the analysis.

Lateral Dispersion

EPACMTP simplifies flow in both the vadose zone (i.e., unsaturated soil) and in the aquifer. In the vadose zone, flow is modeled as vertical (one-dimensional) movement of infiltrating water flow. Since lateral migration is not modeled in the vadose zone, the concentration reaching the ground water table is somewhat higher than it may be in real-world conditions. Thus, this simplification may lead to an overestimation of risks. However, the magnitude of lateral dispersion in the vadose zone is typically relatively small, with a magnitude of one hundredth the vertical dispersivity as a reasonable first approximation (Simunek and van Genuchten, 2006), Because the areal extent of WMUs from which leachate occurs is orders of magnitude larger than the additional spreading that may occur in the vadose zone from lateral diffusion, the magnitude of this overestimation is likely to be small.

Preferential Flows

Ground water advection in the saturated zone is also modeled as a one-dimensional process in a homogeneous aquifer subject to surface infiltration and recharge. The flow direction is aligned with the regional flow direction. As the aquifer properties are regionally averaged, EPACMTP does not explicitly account for preferential pathways such as fractures and macropores. These assumptions could lead to either an overestimation of risk if actual flow paths direct flow away from receptors, or an underestimation of risk if preferential pathways lead to more streamlined transport than modeled. Without detailed, site-specific data on hydrogeologic conditions, the exact magnitude and direction of this uncertainty is unknown.

Ground Water Receptor Well Placement

Ground water wells were placed using a distribution of nearest wells described in **Appendix B**. Based on this distribution, wells were placed within approximately 1,600 meters for surface impoundments and 2,100 meters for landfills. However, it is possible that receptor wells may be located even further downgradient. EPA conducted a sensitivity analysis to examine the effect of not evaluating these further wells. First, EPA modeled arsenic as arsenic III in EPACMTP for wells at a variety of distances from surface impoundments and landfills. Wells were constrained to be within 5 m of the centerline of the plume where concentrations would be highest. EPA then calculated the percent of model runs where ground water concentrations exceeded the MCL for arsenic (10 µg/L). The results of the sensitivity analysis show that, while 2.2 percent of surface impoundment runs between 1,000 m and 1,500 meters exceeded the MCL, only 0.1 percent of model runs beyond 1,500 meters exceeded the MCL. Landfill model runs resulted in an even lower percent of MCL exceedances at both distances. The results of the sensitivity analysis show that

arsenic concentrations fall dramatically as the distance from the WMUs increases. This supports EPA's choice of a distribution of nearest receptor wells to represent a highly exposed individual, rather than considering even further distances. Thus, EPA finds that the placement of ground water receptor wells has a minimal effect on the highly exposed individual risks.

Ground Water Receptor Well Depth

Ground water receptor well concentrations were drawn from a single aquifer depth for each model iteration. Actual wells may be screened across an extended depth, resulting in capture of a combination of contaminated and pristine ground water. Sampling from a single depth may overestimate or underestimate risks on a case-by-case basis. However, given the size of the WMUs and the range receptors distances modeled in this analysis, the constituent plume within the first ten meters is expected to be fairly well mixed. Thus, the magnitude of this uncertainty is likely to be small.

Summary

A summary of the different uncertainties associated with the use of EPACMTP to model ground water transport, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-28**. The majority of uncertainties identified are unlikely to have an appreciable impact on the principal risk results. EPA was not able to characterize the potential magnitude or direction of the uncertainties associated with site-specific preferential flow in the subsurface. The Agency relied on the best regional data available at the time of the analysis; however, the potential of these uncertainties to overestimate or underestimate national risks remains uncertain.

Table 5-28. Likely Effect on Risk from EPACMTP Uncertainties

Uncertainty	Potential to Affect Probabilistic Analysis Results		
	Uncertain	Low	High

5.1.10 Surface Water Fate and Transport Modeling

Surface Water Plume Interception

An EPACMTP post-processor was created to calculate the fraction of the ground water plume that is intercepted by a surface water body. This calculation assumes that ground water continues to flow in the same direction on the opposite side of the water body. In the field, ground water on both sides can flow toward the same water body. Overall, this uncertainty is anticipated to have a

minimal effect on modeled risk results. For GW→DW exposure pathways, the high-end ground water risks for these pathways will be driven by model iterations where no surface water interception occurs. For GW→SW exposure pathways, the additional flow of uncontaminated ground water may result in further dilution of the constituent plume than predicted by the model and an overestimation of risks. Because this type of site-specific data is not available, the exact magnitude of this overestimation is unknown. However, given that the modeled risks for these pathways all fell below risk criteria, the potential for this overestimation to alter the results of the probabilistic analysis is negligible.

Equilibrium Partitioning

The equilibrium partitioning model used in the probabilistic analysis divided constituent loading rate (mass/time) by the water body flow rate (volume/time) to obtain an overall water body concentration. Following calculation of the constituent loading rates, the partitioning model determined the equilibrium constituent concentrations in each of the four compartments. As implemented in this analysis, the model does not account for losses that may result from burial. This is a conservative assumption that will overestimate risks to sediment receptors to some degree. However, given that all risks associated with sediment exposures fell at least an order of magnitude below risk criteria, the potential for this overestimation to alter the conclusions of the probabilistic analysis is negligible.

Summary

A summary of the different uncertainties associated with constituent data, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-29**. The uncertainties identified are unlikely to have an appreciable impact on the principal risk results.

Table 5-29. Likely Effect on Risk from Surface Water Model Uncertainties

Uncertainty	Potential to Affect Probabilistic Analysis Results		
	Unknown	Low	High

Equilibrium Partitioning		●	

5.1.11 Risk Models

Cumulative Pathways for Human Health Risk

This risk assessment considered the potential risks to human health from individual constituents and individual pathways. It is possible that individuals could be exposed to risks from drinking contaminated ground water, as well as eating contaminated fish from a local surface water body. However, it is unlikely that this will occur with any frequency in the real world for the following reasons:

- Only 27.5 million U.S. residents out of 312 million, or approximately 9 percent of the population, are recreational fishers (U.S. Census, 2012).

- Of those who fish recreationally, approximately 49 percent eat at least some of the fish that are caught (Table 10-63, U.S. EPA, 2011).
- EPA assumes that the contaminated water bodies in this assessment are fishable, and that preferential fishing locations are not located nearby.
- On average, recreational fishers have been shown to travel between 35 to 41 miles to fish (Table 10-81 and Table 10-85, U.S. EPA, 2011). This provides a large area around a contaminated surface water body that individuals could come from to fish, and thus a smaller probability that they are also from an area within the contaminated ground water plume.
- If a fisher also resides within the ground water plume, approximately 15 percent of U.S. households rely on ground water as a source of potable water (U.S. EPA, 2002b).
- If the receptor lives close to the water body, there is a greater potential that the receptor well will be located downgradient from the water body, resulting in surface water interception of some or all constituent mass and lower drinking water risks than reported in this document.
- Were an individual exposed through both pathways, the different locations of the well and water body would result in different transit times until peak risks. Therefore, the cumulative exposure would be less than predicted by adding the risks reported in this document.

Because of the considerations listed above, EPA did not consider cumulative exposures from these pathways. This is a source of uncertainty that may result in an underestimation of risks to some individuals. However, given that risks were identified for individual COPCs and that these additional exposures will occur with a low frequency, the potential for any underestimation of risk to alter the principal results of the probabilistic analysis is small.

Cumulative COPCs for Human Health Risk

It is possible for an individual to be exposed to multiple constituents through a single pathway. This is a likely scenario because, as demonstrated by the available data, CCRs may leach multiple inorganic constituents. An individual COPC may interact with other constituents present, resulting in synergistic or antagonistic effects that exacerbate or diminish the health impacts predicted by evaluating each COPC independently. Where the potential for simultaneous exposure to multiple constituents exists, current EPA policy is to assume that the risks resulting from these exposures are additive (U.S. EPA, 2000b). However, the revised risk assessment did not consider additivity for the following reasons:

- The time to peak results presented earlier in this section indicate that while some constituents will migrate and reach peak concentrations in tens or hundreds of years, others may take thousands or tens of thousands of years. Thus, not all constituents will reach a receptor at the same time.
- Individual WMUs would not leach all constituents at the high-end concentrations considered in this risk assessment.
- EPACMTP is designed to use variable time steps to minimize computer processing time. These time steps are determined based on the rate of change of the modeled constituent

concentration, with longer time steps used for slowly changing concentrations. To account for cumulative exposures, EPACMTP would need to undergo significant modifications to make the time steps the same for every constituent run so that risks from combined constituent concentrations could be modeled.

- The human health benchmarks used are based on the most sensitive adverse effect. Thus, the addition of constituent risks along the range of potentially affected organ systems would overestimate cumulative risks to less sensitive organ systems.

Because of the considerations listed above, EPA did not consider cumulative risk. This is a source of uncertainty that may result in an underestimation of risk. However, the probabilistic analysis identified individual constituents above risk criteria. Many of the other constituents modeled resulted in risks an order of magnitude or more below risk criteria. Thus, the consideration of additive risk, even with the high-end risks modeled in this risk assessment, is unlikely to alter the principal results of the probabilistic analysis.

Presence of Sensitive Ecological Receptors

Unlike for human receptors, where Census and other population statistics can be used to locate potential receptors with some accuracy, site-specific surveys are needed to confirm the presence of specific ecological receptors. In the absence of site-specific data, this risk assessment made the assumption of co-occurrence of sensitive ecological receptors and waste sites. However, the likelihood that sensitive receptors will be found downgradient from CCR WMUs is unknown. Nor is it known whether those areas support the type of habitat needed by these receptors. Therefore, this assumption may overestimate the potential risks to ecological receptors. The magnitude of this overestimation is unknown. However, given that the modeled risks for these receptors all fell below risk criteria, the potential for this overestimation to alter the results of the probabilistic analysis is negligible.

Ecological Receptor Diet

This analysis assumed that the entire diet of modeled receptors originates from the contaminated area downgradient of WMUs. This may be an appropriate assumption for plants and other relatively sedentary receptors. However, in the wild, many animals are opportunistic feeders with substantial variability in both the type of food items consumed and the geospatial patterns of feeding and foraging. Therefore, the actual proportion of wildlife receptors' diets that would be contaminated depends on a number of factors such as species foraging range, quality of food source, season, climate, and intra- or interspecies competition. Therefore, this assumption may overestimate the potential risks to some ecological receptors. The magnitude and frequency of this overestimation is unknown. However, given that the modeled risks for these receptors all fell below risk criteria, the potential for this overestimation to alter the results of the probabilistic analysis is negligible.

Indirect Ecological Effects

Indirect ecological effects (e.g., depletion of food resources) resulting from the on-site disposal of CCRs were not considered in the probabilistic analysis. Identifying the ways that impacts on food

supply and habitat quality may adversely impact the overall health of ecological receptors is difficult, even for a site-specific evaluation, and is not currently possible on a national scale. However, for any given facility, the spatial scale of potential contamination would generally be a small fraction of the full home range for many species. In addition, many species are opportunistic feeders that will actively seek other food sources if those near the CCR facilities decline, regardless of the cause of this decline. Exclusion of these indirect effects may underestimate the potential risks to ecological receptors. The magnitude of this underestimation is unknown, but not anticipated to affect the final conclusions of the risk assessment.

Ecosystems and Ecological Receptors at Risk

One challenge in conducting a national risk assessment is representing all receptors and ecosystems at risk. In *Wastes from the Combustion of Coal by Electric Utility Power Plants - Report to Congress* (Exhibit 5-27; U.S. EPA, 1988), EPA noted that managed lands, critical habitats, or threatened and endangered species were located within a five kilometer radius of CCR WMUs at between 12 and 32 percent of facilities:

- **Managed Lands:** Because protected lands play a critical role in preserving plant and animal species, managed areas in the United States represent well recognized ecological values. Managed lands refer to a variety of lands designated by the federal government as worthy of protection, including National Wildlife Refuges, National Forests, Wilderness areas, and National Recreation areas.
- **Critical Habitats:** Critical habitats may be defined in a number of ways (e.g., presence of threatened species, fragmented habitat area). Wetlands are widely recognized as an important habitat serving critical ecological functions (e.g., maintenance of water quality). The U.S. Fish and Wildlife Service estimates that approximately 45 percent of the Nation's threatened and endangered species directly depend on aquatic and wetland habitats. Consequently, impacts of chemical stressors on wetland habitats may have high ecological (and societal) significance.
- **Threatened and Endangered Species:** A threatened species is one that "is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range." An endangered species is one that "is in danger of extinction throughout all or a significant portion of its range."

EPA did not consider impacts to managed lands and critical habitats for similar reasons as indirect ecological effects, as the necessary data on the negative impact on overall ecosystem health is difficult to quantify, even for a site-specific evaluation. Direct risks to threatened and endangered species were not explicitly evaluated as part of this risk assessment because of the lack of species-specific toxicity data. While these species were not explicitly considered, the ecological benchmarks used are based on the most sensitive receptors for which data are available, which are believed to be protective of the majority of species. In certain instances, exclusion of these effects to habitat and specific species may underestimate risks. The magnitude of this underestimation is unknown, but not anticipated to affect the final conclusions of the risk assessment.

Summary

A summary of the different uncertainties associated with the implementation of risk models, as well as the potential for each to affect the risks modeled in the probabilistic analysis is shown in **Table 5-30**. The uncertainties identified are unlikely to have an appreciable impact on the principal risk results.

Cumulative COPCs for Human Health Risk		●	
Presence of Sensitive Ecological Receptors		●	
Ecological Receptor Diet		●	
Indirect Ecological Effects		●	
Ecosystems and Ecological Receptors at Risk		●	

5.2 Results of the 2009 Sensitivity Analysis

The discussion of uncertainties in **Section 5.1** considered each uncertainty in isolation; however, the effects of these different sources can compound. In support of the 2010 Risk Assessment, EPA conducted a sensitivity analysis to determine the combination of parameters and associated uncertainties that have the greatest impact on calculated risks (U.S. EPA, 2009b). In this risk assessment, EPA used the results of the 2009 analysis to validate the findings of the revised sensitivity and uncertainty analyses. Although some of the data sources used in the revised risk assessment have changed, the type of inputs used by EPACMTP remained the same. Thus, for the purposes of understanding the sensitivities of the model, the results of this sensitivity analysis are still as relevant.

The 2009 sensitivity analysis used a response-surface regression method to derive a statistical model for ground water concentration (as the dependent variable) based on the input parameters from the probabilistic analysis (as independent variables). Concentration, rather than risk, was chosen as the dependent variable for the sensitivity analysis because the additional exposure factors used to calculate human health risk from environmental concentration (e.g., body weight) have well established, peer-reviewed distributions based on EPA policy. The outputs of the sensitivity analysis were goodness-of-fit values used to determine the relative importance of each input parameter. The most sensitive parameters identified are presented in **Table 5-31**.

Table 5-31. Parameters Identified in the 2009 Sensitivity Analysis

Pathway:	GW→DW Pathway		GW→SW Pathway
Constituents:	**All Constituents**	**Strongly Sorbing**	**All Constituents**
Sensitive Parameters	▪ Infiltration Rate ▪ Leachate Concentration ▪ Hydraulic Gradient ▪ Hydraulic Conductivity	▪ K_d Value ▪ Depth to Ground Water ▪ Distance to Receptor Well	▪ Infiltration Rate ▪ Leachate Concentration ▪ Water Body Flow Rate

As seen in the table above, the GW→DW exposure pathway had more input parameters that were highly sensitive (seven) than the GW→SW exposure pathways (three). The most sensitive parameters for the GW→DW pathways were parameters that impact flux (infiltration rate and leachate concentration) and ground water flow (hydraulic conductivity and gradient). When modeling strongly sorbing constituents, the K_d values and distance to receptor also become important. The most sensitive parameters for the GW→SW exposure pathways were parameters impacting flux (infiltration rate and leachate concentration) and the water body flow rate.

In the probabilistic analysis, risks were identified for the GW→DW exposure pathway. Further sensitivity and uncertainty analyses identified two input parameters with the greatest potential to affect the probabilistic risk results. These parameters align well with the findings of the 2009 sensitivity analysis:

- **Liner Type:** Liner type and design was shown to have one of the most significant effects on modeled risks. The higher hydraulic conductivity of unlined units resulted in the highest risks. Risks from clay-lined units were lower than unlined units, but still close to criteria. Thus, changes to the configuration of the liner, such as adjusting the thickness from three to two feet, has the potential to result in risks above the criteria. Composite liners, with the lowest hydraulic conductivity of any units, resulted in the lowest risks. This is consistent with the finding that infiltration rate is one of the most sensitive parameters, as the hydraulic conductivity of the liner is one of the major factors determining infiltration rate at each unit.
- **Waste pH:** Waste pH was shown to have a significant effect on risk. Multiple constituents presented higher risks when considered in WMUs managing ash and coal refuse at more acidic pHs or FGD wastes at more basic pHs. This is consistent with the finding that leachate concentrations and K values are two of the most sensitive parameters of the model, as pH is one of the driving factors for both parameters.

5.3 Field Comparisons

The comparison of model inputs and results to data collected in the field is a useful means of validation. As discussed previously, EPACMTP has been extensively reviewed and validated, but the specific set of inputs and assumptions applied to the model results in additional sources of

uncertainty. EPA used two comparisons to assess whether the results of the probabilistic analysis accurately reflect with what may occur in the field. First, EPA examined the leachate data measured with LEAF methods and compared these concentrations to those measured in the field. Second, EPA examined the damage cases to identify the WMU types and constituents most frequently found at damage cases and compared these to the result of the sensitivity and uncertainty analyses.

Leachate Concentrations

EPA characterized leachate from surface impoundments using pore water data and leachate from landfills using LEAF data. Pore water data were collected from core samples both in and beneath surface impoundments. Since the cores take leachate directly from the field, these data are known to represent field conditions and no further comparison is necessary. For landfills, U.S. EPA (2014b) compared LEAF test methods to actual field leachate, both in Europe and the United States. In general, the report demonstrates that LEAF methods accurately capture the leachate characteristics found in the field. Properly accounting for both the pH of the waste in field conditions, as well as the liquid-to-solid ratio of the leachate and waste, was shown to result in lab results very close to those found in the corresponding field conditions.

Comparison of Results to Damage Cases

EPA reviewed the available data on both proven and potential damage cases and compared the findings with the results of the sensitivity and uncertainty analyses. Each damage case reflects a combination of site-specific conditions present at that site. This contrasts with the risk assessment, which is nationwide. Due to the differing nature of these two sources of information, a direct comparison would not be relevant. However, general characteristics and conclusions from the damage cases are relevant to support the findings of the risk assessment, and are discussed below.

The vast majority of damage cases were associated with unlined surface impoundments and landfills. No damage cases were identified for composite-lined units. This agrees well with the results of the sensitivity analyses, which showed that risks were significantly higher for unlined WMUs than for other units, and that risks for composite-lined units were far below all cancer and noncancer criteria.

Arsenic was by far the most common constituent associated with damage cases. Similarly, it was the constituent that exceeded the risk criteria in the most scenarios, and by the greatest magnitude. Other common constituents from the damage cases such as boron and cadmium also exceeded the criteria in the sensitivity analyses. Additional damage cases were identified for other constituents for which no risks were identified in the sensitivity analyses. There are a number of reasons why modeled ground water risks and damage cases do not perfectly align:

- **Different Benchmarks:** In some cases, state standards are more conservative than EPA standards. Other times, state standards exist for constituents where EPA has not yet established a benchmark.
- **Closer Monitoring Distances:** In many of the potential damage cases, ground water exceedances were discovered near the boundary of the WMU. The risk assessment

considered further dilution and attenuation would occur between the WMU and potential ground water receptors. Thus, concentrations should be higher for all constituents in the damage cases than they would be at the modeled distances in the risk assessment. This is borne out by the fact that so many fewer proven damage cases exist, as these damage cases require, for example, off-site migration.

- **Disposal Practices:** Some damage cases occurred for disposal practices that could not be modeled in the risk assessment. For example, disposal below the water table. In this situation, the sorption that occurs in the unsaturated zone of the risk assessment model does not occur in the field. This and other site-specific risk factors could lead to additional contamination beyond what was modeled nationwide.

These differences between the modeled risks and site-specific damage cases provide examples of why a direct comparison of the risk assessment results to the damage cases is difficult. However, since the scenarios and constituents presenting the most risk are in general agreement, it still strengthens the results of the risk assessment.

5.4 Conclusions

In **Section 5.1**, the uncertainties were discussed in light of their ability to affect the risks of the full probabilistic analysis. Several of the uncertainties related to collecting data and filling data gaps, while the remaining uncertainties were a result of model development and use. **Table 5-32** presents the estimated effect of these uncertainties.

Table 5-32. Summary of Potential Effects of Uncertainty on Risk Results

Uncertainty	Potential to Affect Probabilistic Analysis Results		
	Uncertain	Low	High
CCR WMU Database	0	8	2
Environmental Parameters	1	6	0
CCR Constituent Database	0	3	0
Human Exposure Factors	1	5	0
Human Health and Ecological Benchmarks	2	3	0
Bioconcentration Factors	1	0	0
WMU Source Term Models	3	7	0
MINTAQA2 Isotherm Model	1	0	0
EPACMTP Ground Water Model	1	6	0
Surface Water Model	0	2	0
Risk Models	0	6	0
All Uncertainties	**10**	**46**	**2**

The majority of uncertainties identified (46) are expected to have a minimal effect on the principal results of the probabilistic analysis. EPA was unable to fully characterize the effects of several

uncertainties (10). These uncertainties have the potential to underestimate or overestimate risks on a case-by-case basis. However, the Agency used the best available data sources to characterize these parameters and minimize potential influence of these uncertainties on modeled results. The remaining uncertainties (2), liner prevalence and waste type prevalence, had a strong influence on modeled results and resulted in appreciably higher risks when different subsets of national disposal practices were considered.

The 2009 sensitivity analysis discussed in **Section 5.2** identified the input parameters that have the greatest potential to influence the fate and transport of constituents. The two uncertainties found to have a high potential to affect modeled risks aligned well with sensitive parameters identified in the 2009 analysis.

Finally, as discussed in **Section 5.3**, EPA compared the risk assessment to field data and damage cases to validate the results. In general, leachate data were strongly corroborated by leachate concentrations observed in the field. The risk assessment results also generally agreed with the damage cases in that they both showed the same type of liners and constituents to cause the most risk to human health and the environment, and resulted in the same constituents exceeding the risk criteria most frequently. Where differences were observed, these were likely due to site-specific considerations that were not modeled in the risk assessment (e.g., placement of waste below the water table). As a result of these comparisons, and the analysis of the sensitivities and uncertainties of the model, EPA finds that the risk assessment provides a good representation of real-world, national-scale risks.

[This Page Intentionally Left Blank]

6 Risk Characterization

The purpose of this document is to characterize the risks associated with current CCR disposal practices across the United States. To accomplish this task, EPA used mathematical models to estimate the rate at which chemical constituents are released from surface impoundments and landfills, the fate and transport of these constituents through the environment, and the potential risk of adverse effects to individual receptors within the exposed population. Modeling for each potential exposure pathway was conducted in a stepwise fashion, with more refined analyses used at each subsequent step until risks were sufficiently characterized. The purpose of this section is to summarize the analyses conducted and results obtained for each exposure pathway, provide further context for these results, and present the final Agency conclusions. This discussion is divided into the following subsections:

- **Section 6.1:** exposures to ambient air that result from the release of fugitive dust by wind.
- **Section 6.2:** exposures to soil, sediment, produce and animal products that result from the release of particulates by wind and overland run-off.
- **Section 6.3:** exposures to impoundment wastewater, ground water, surface water, and sediment that result from the release of leachate.

6.1 Exposure to Ambient Air

6.1.1 Problem Formulation

Many CCR wastes are composed of fine particulates that may become suspended in the air by the wind. These pathways are primarily associated with landfills during operation, as the postclosure cap for landfills and constant water cover for impoundments will limit the release of particulate matter. Although airborne releases may occur from surface impoundments if water levels decrease due to evaporation or other irregular events, EPA focused the analysis on landfills because of the potential for higher and more frequent releases. These particulates may be carried downwind, where the fine particulates and any chemical constituents contained therein may be inhaled by receptors. **Figures 6-1** depicts the potentially complete exposure pathways for these releases.

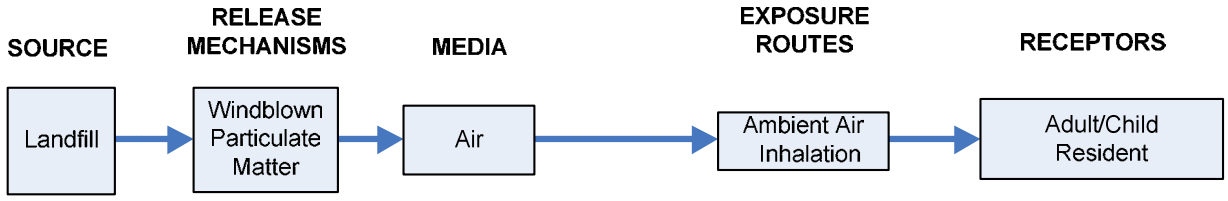

Figure 6-1. Conceptual model for ambient air exposures.

EPA first conducted a simplified hazard identification to identify the constituents that could be quantitatively evaluated. The confirmed presence of a constituent in CCR wastes, combined with the availability of at least one toxicity benchmark, was considered sufficient demonstration of

hazard potential. Because air concentrations can vary considerably over time, EPA considered three sets of toxicity benchmarks to capture the range of potential exposures. The first are acute benchmarks, which represent short-term exposures. The second were chronic cancer and noncancer benchmarks, which represent long-term exposures. The third were NAAQS, which represent EPA-developed regulatory standards based on varying exposure durations. **Table 6-1** lists each of the constituents which both concentration data and toxicity benchmarks were available. Each of these constituents was retained as COPCs for further analysis.

Table 6-1. List of Constituents Evaluated for Ambient Air Exposures

COPC (Benchmark)		COPC (Benchmark)		COPC (Benchmark)		COPC (Benchmark)	
Aluminum	(A,C)	Antimony	(A,C)	Arsenic	(A,C)	Barium	(A)
Beryllium	(A,C)	Boron	(A)	Cadmium	(A,C)	Calcium	(A)
Chloride	(A)	Chromium	(A,C)	Cobalt	(A,C)	Copper	(A)
Fluoride	(A)	Iron	(A)	Lanthanum	(A)	Lead	(A,N)
Magnesium	(A)	Manganese	(A,C)	Mercury	(A,C)	Molybdenum	(A)
Nickel	(A,C)	Nitrate/Nitrite	(A)	Selenium	(A,C)	Silicon	(A)
Silver	(A)	Sodium	(A)	Strontium	(A)	Sulfate	(A)
Thallium	(A)	Uranium	(A,C)	Vanadium	(A,C)	Zinc	(A)
PM_{10}	(N)	$PM_{2.5}$	(N)				

A – Acute Toxicity Benchmark
C – Chronic Toxicity Benchmark
N – National Ambient Air Quality Standard.

6.1.2 Screening Analysis

The screening analysis was conducted using the steady-state plume models, AERSCREEN and AERMOD. These models were used to calculate the maximum air concentrations that may occur, averaged over the course of 1 hour, 24 hours, 1 month and 1 year. Each of these exposure durations was calculated for two management scenarios: uncontrolled and controlled releases. Uncontrolled releases occur when no action is taken to reduce particulate emissions, while controlled releases occur when management practices are put in place to minimize the rate of particulates emissions. Yet, even with the best available fugitive dust controls, some emissions may still occur. Therefore, EPA modeled these reduced releases based on available field data. The modeled air concentrations reflect a combination of multiple high-end parameters, including emission rate, landfill size, weather, distance to receptor and waste COPC concentration. EPA used these air concentrations, together with available toxicity benchmarks, to estimate the likelihood of adverse effects to downgradient receptors.

- **Acute Risks** were calculated based on the maximum 1-hour concentration. Risks above an HQ_A of 1 was identified for arsenic (2) under an uncontrolled management scenario, but decreased below risk criteria when fugitive dust controls were considered.

- **Chronic Risks** were calculated based on the maximum annual concentration. All risks fell below the selected human health risk criteria under both a controlled and uncontrolled management scenario.
- **NAAQS** exceedances were calculated based on the available averaging time closest to that specified by the standards. An air concentration above the NAAQS for 24-hr $PM_{2.5}$ by a factor of 2 was identified under an uncontrolled management scenario, but decreased below risk criteria when fugitive dust controls were considered.

The screening analysis shows the potential for risks under an uncontrolled management scenario for acute arsenic exposure; chronic arsenic, cobalt and chromium VI exposures; and short-term $PM_{2.5}$ exposures. Due to the conservative nature of the screening, there is a great deal of uncertainty surrounding the calculated risks. The modeled ambient air concentrations represent a protective, but unlikely, combination of conditions that reflect at least an upper bound on potential exposures. Thus, the cumulative effect of these uncertainties results in an overestimation of potential risks to most or all receptors. Therefore, EPA makes no direct findings concerning the magnitude of the risks that may occur under either an uncontrolled or controlled management scenario, but concludes with a high degree of confidence that the reductions achievable with available management practices are sufficient to be protective even under this conservative screening assessment. Based on these lines of evidence, EPA concluded that no further characterization of is warranted.

6.2 Releases to Soil

6.2.1 Problem Formulation

Many CCR wastes are composed of fine particulates that may become suspended in the air by the wind or washed away overland by run-off and erosion. These pathways are primarily associated with landfills during operation, as the postclosure cap for landfills and constant water cover for impoundments will limit the release of particulate matter. Although these releases may occur from surface impoundments if water levels decrease due to evaporation, overtopping from extreme rainfall or other irregular events, EPA focused the analysis on landfills because of the potential for higher and more frequent releases. Released particulates may be carried downgradient, where COPCs may accumulate on top of soil, sediment and plant surfaces, as well as concentrate within plants and animals raised on contaminated soils. Receptors may be exposed through contact with or ingestion of the contaminated media. **Figures 6-2** depicts the potentially complete exposure pathways for these releases.

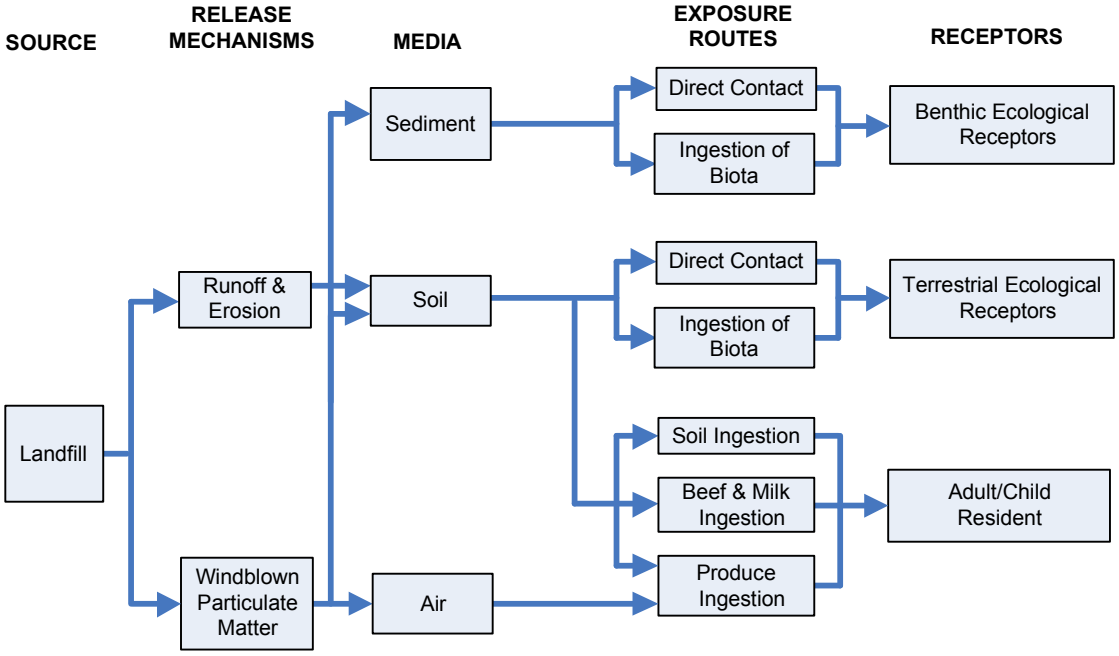

Figure 6-2. Conceptual model for soil exposures.

EPA first conducted a simplified hazard identification to identify the chemical constituents to be quantitatively evaluated. The confirmed presence of a constituent in CCR wastes, combined with the availability of at least one toxicity benchmark, was considered sufficient demonstration of hazard potential. EPA used chronic toxicity benchmarks to evaluate these exposures. Adverse effects from chronic exposures occur at lower concentrations than acute exposures. Therefore, the risks calculated for chronic exposures will also be protective of more acute exposures. **Table 6-2** lists each of the constituents for which both concentration data and toxicity benchmarks were available. Each of these constituents were retained as COPCs for further analysis.

Table 6-2. List of Constituents Evaluated for Soil, Sediment, Produce and Animal Product Exposures

COPC (Benchmark)		COPC (Benchmark)		COPC (Benchmark)		COPC (Benchmark)	
Aluminum	(N,E)	Antimony	(N,S,D)	Arsenic	(C,N,S,D)	Barium	(N,S,D)
Beryllium	(N,S)	Boron	(N,S)	Cadmium	(N,S,D)	Chromium	(C,N,S,D)
Cobalt	(N,S)	Copper	(N,S,D)	Fluoride	(N)	Iron	(N)
Lanthanum	(N)	Lead	(S,D)	Manganese	(N,S)	Mercury	(N,S,D)
Molybdenum	(N,S,D)	Nickel	(N,S,D)	Nitrate/Nitrite	(N)	Selenium	(N,S)
Silver	(N,S,D)	Strontium	(N)	Thallium	(N)	Uranium	(N)
Vanadium	(N,S,D)	Zinc	(N,S,D)				

C – Human Health Cancer Benchmark
N – Human Health Noncancer Benchmark
S – Ecological Soil Benchmark
D – Ecological Sediment Benchmark

6.2.2 Screening Analysis

The screening analysis was conducted using a combination of a conservative DAF of 10 and deposition rates calculated with AERMOD. Exposures were calculated for two management scenarios: uncontrolled and controlled releases. Uncontrolled releases occur when no action is taken to reduce particulate emissions. Controlled releases occur when management practices are put in place to minimize the rate of particulates emissions. Yet, even with the best available management practices, some emissions may still occur. Therefore, EPA modeled these reduced releases based on available field data. The modeled media concentrations reflect a combination of multiple high-end parameters, including emission rate, landfill size, weather, distance to receptor and waste COPC concentration. EPA used the modeled media concentrations, together with available toxicity benchmarks, to estimate the likelihood of adverse effects.

- **Human Health Cancer Risks** all fell below the selected human health risk criteria under both a controlled and uncontrolled management scenario.
- **Human Health Noncancer Risks** above an HQ of 1 were identified under the uncontrolled scenario. Thallium risks were identified for exposures to soil (2), beef (10) and milk (8). When fugitive dust and run-off controls were considered, all cancer risks fell below the risk range.
- **Ecological Soil Risks** above relevant criteria were identified under the uncontrolled scenario. Ecological risks above an HQ of 1 were identified were identified for, listed from highest to lowest: boron (80) antimony (20) vanadium (7) and selenium (3). When fugitive dust and run-off controls were considered, all risks fell below the risk range.
- **Ecological Sediment Risks** above relevant criteria were identified under the uncontrolled scenario. Ecological risks above an HQ of 1 were identified were identified for, listed from highest to lowest: vanadium (3), antimony (2), arsenic (2) and silver (2). When fugitive dust and run-off controls were considered, all risks fell below the risk range.

The screening analysis shows the potential for risks to both human and ecological receptors under an uncontrolled management scenario. Risks to human health resulted from ingestion of arsenic, chromium and thallium present in soil, produce and animal products. Ecological risks resulted from antimony, boron, selenium and vanadium present in soils and antimony, arsenic, silver and vanadium present in sediments. Due to the conservative nature of the screening, there is a great deal of uncertainty surrounding the calculated risks. The modeled media concentrations represent a protective, but unlikely, combination of conditions that most likely reflects an upper bound on potential exposures. The cumulative effect of these uncertainties results in an overestimation of potential risks. Therefore, EPA makes no direct findings concerning the magnitude of the risks that may occur under either an uncontrolled or controlled management scenario, but concludes with a high degree of confidence that the reductions achievable with available management practices are sufficient to be protective even under this conservative screening assessment.

Based on these lines of evidence, EPA concluded that no further characterization of soil, produce, or animal products is warranted. Although sediment exposures also screened out under the

controlled management scenario, EPA did retain sediment for further characterization. The results of the uncontrolled exposure scenario were used as a conservative screen for risks that may occur from subsurface transport of COPCs through ground water to sediment.

6.3 Releases to Ground Water

6.3.1 Problem Formulation

When CCR wastes are disposed on the ground, it may result in leaching to ground water. Many of these pathways are associated with both surface impoundments and landfills. Once mixed with ground water, the COPCs may migrate downgradient to private wells where it is ingested by receptors, to water bodies were **Figures 6-3** depicts the potentially complete exposure pathways for these releases.

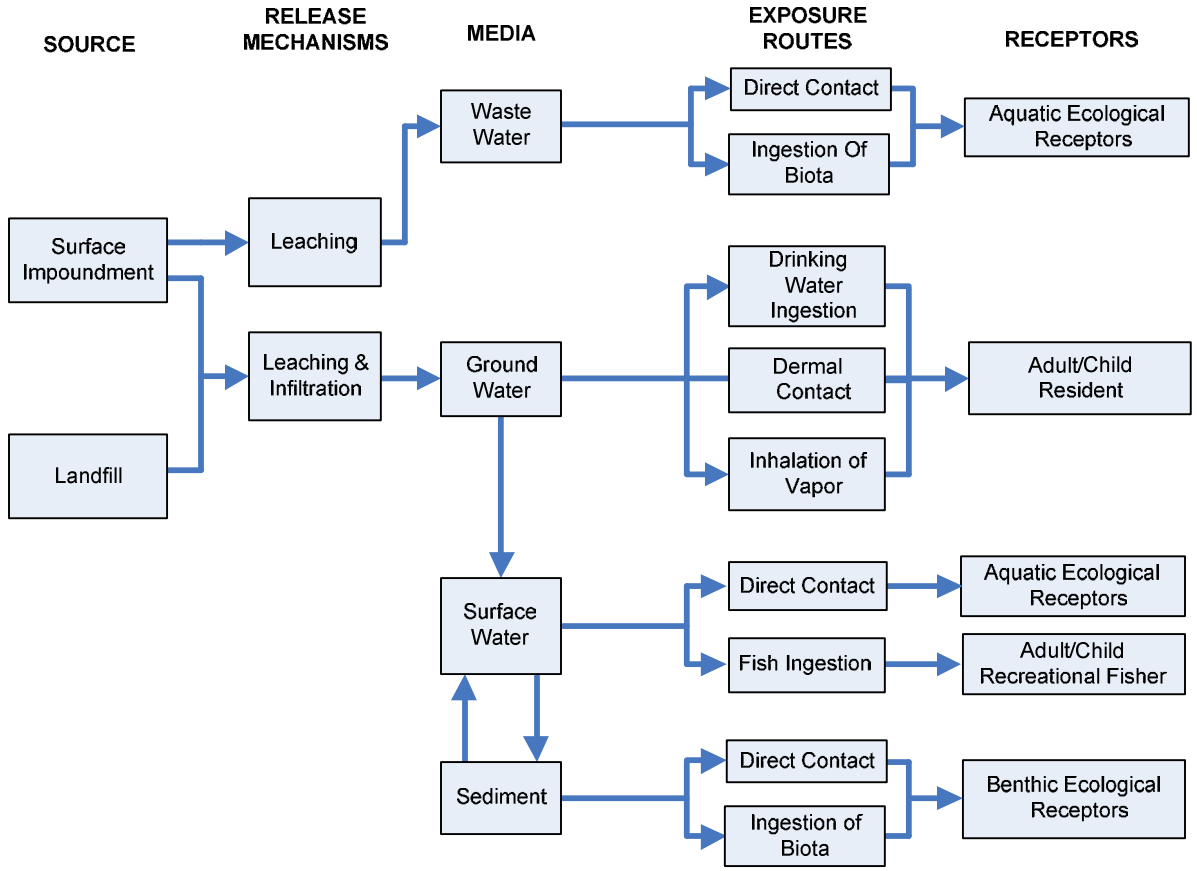

Figure 6-3. Conceptual model for ground water exposures.

EPA first conducted a simplified hazard identification to identify the constituents that could be quantitatively evaluated. The confirmed presence of a constituent in CCR wastes, combined with the availability of at least one toxicity benchmarks, was considered sufficient demonstration of hazard potential. EPA used chronic toxicity benchmarks to evaluate these exposures. Adverse effects from chronic exposures occur at lower concentrations than acute exposures. Therefore, the risks calculated for chronic exposures will also be protective of more acute exposures. **Table 6-3**

lists each of the constituents for which both concentration data and toxicity benchmarks were available. Each of these constituents were retained as COPCs for further analysis.

Table 6-3. List of Constituents Evaluated for Ground Water, Surface Water and Wastewater Exposures

COPC (Benchmark)		COPC (Benchmark)		COPC (Benchmark)		COPC (Benchmark)	
Aluminum	(N,E)	Ammonia	(N)	Antimony	(N,E)	Arsenic	(C,N,E)
Barium	(N,E)	Beryllium	(N,E)	Boron	(N,E)	Cadmium	(N,E)
Chloride	(E)	Chromium	(C,N,E)	Cobalt	(N,E)	Copper	(N,E)

6.3.2 Screening Analysis

EPA used a conservative DAF of 1 to estimate the COPC concentrations that may be present in ground water, surface water and wastewater. The resulting exposure concentrations are equivalent to direct receptor exposures to undiluted CCR leachate. For these exposure pathways, EPA did not identify any post-construction management practices that could mitigate releases, so only one release scenario was considered. In addition, because the 2010 Risk Assessment (U.S. EPA, 2010a) previously demonstrated that risks from surface impoundments are consistently higher than those from landfills, EPA used the screening results for surface impoundments to also identify the initial set of COPCs for landfills. A summary of the modeled risks above relevant human health or ecological criteria is provided below:

- **Ground Water:** Ingestion of ground water resulted in risks above the human health criteria. Cancer risks above 1×10^{-5} were identified for arsenic (3×10^{-3}) and chromium VI (2×10^{-4}). Noncancer risks above an HQ of 1 were identified, from highest to lowest, for: arsenic (50), molybdenum (30), boron (10), fluoride (7), thallium (6), lithium (4), cobalt (3), antimony (2) and cadmium (2).
- **Surface Water:** Ingestion of fish resulted in risks above the human health criteria. Cancer risks above 1×10^{-5} were identified for arsenic (4×10^{-5}). Noncancer risks above an HQ of 1 were identified, from highest to lowest, for: selenium (10), mercury (7), thallium (4) and cadmium (2).
- **Surface Water:** Direct contact with and ingestion of surface water resulted in risks above ecological criteria. Ecological risks above an HQ of 1 were identified, from highest to lowest,

for: cadmium (200), aluminum (100), arsenic (100), boron (100), selenium (60), barium (50), lead (40), vanadium (30), chromium III (20), molybdenum (20), copper (10), iron (10), silver (10), chloride (9), nickel (6), beryllium (2), cobalt (2) and zinc (2).

- **Wastewater:** Direct contact with and ingestion of impoundment wastewater resulted in risks above ecological criteria. Ecological risks above an HQ of 1 were identified, from highest to lowest, for: arsenic (100), barium (50), aluminum (30), boron (30), selenium (20), cadmium (10), vanadium (10), beryllium (2), chloride (2) and chromium (2).

Multiple COPCs resulted in risks above human health and ecological criteria. For these pathways, there were no post-construction management practices identified to mitigate releases. However, considerable dilution and attenuation may occur before leachate reaches downgradient private wells, surface water and sediments. Therefore, EPA retained all of the COPCs found to be above risk criteria in ground water and surface water for further characterization in the probabilistic analysis. In addition, EPA carried forward the COPCs identified in the sediment screening previously discussed in **Section 6.2.2**.

Unlike the other exposure pathways, there will be little to no dilution and attenuation that will occur in impoundment wastewater prior to ecological exposures. Because of this, the screening analysis conducted provides sufficient characterization of this exposure pathway. Therefore, EPA concludes that there is the potential for risks to ecological receptors from concentrations of aluminum, arsenic, barium, beryllium, boron, cadmium, chloride, chromium, selenium and vanadium in surface impoundment wastewater.

6.3.3 Probabilistic Analysis

EPA conducted national-scale, probabilistic modeling to better characterize the risks to human and ecological receptors associated with leachate released from surface impoundments and landfills. A combination of models were used to predict COPC fate and transport through the environment, receptor exposures, and the resulting risks. EPA used the most complete and current data sets available to run these models. Site-specific data were used, supplemented by regional and national data sets, to capture the national variability of disposal practices, environmental conditions and receptor behavior. EPA modeled risks for both highly exposed individuals (90th percentile risks) and moderately exposed individuals (50th percentile risks). A summary of the modeled risks above relevant human health or ecological criteria is provided below:

- **Surface Impoundments:** Ingestion of ground water was the only exposure pathway that resulted in risks above the relevant criteria. 90th percentile cancer risks above 1×10^{-5} were identified for arsenic III (2×10^{-4}). 90th percentile noncancer risks above an HQ of 1 were identified for arsenic III (5), lithium (2), and molybdenum (2).
- **Landfills:** 90th percentile cancer and noncancer risks were all below human health criteria.

High-end risks for surface impoundments are consistently higher than those for landfills. These results are attributed primarily to the higher infiltration rates through surface impoundments, which is controlled by the hydraulic head of ponded water. Median risks for both surface impoundments

and landfills were substantially lower than both the high-end risks in this risk assessment and the median risks modeled in the 2010 Risk Assessment. This decrease is attributed primarily to the interception of ground water by surface water bodies, which is accounted for in the revised risk assessment to provide a more accurate mass balance of constituent mass during transport. It is common for coal-fired utilities to be located near water bodies, which are used as a source of cooling water and conveyance of waste. As a result, in the majority of model iterations, the interception of ground water by surface water bodies resulted in negligible downstream well concentrations.

The modeled probabilistic risks capture the range of current, nationwide CCR disposal practices. However, because of the broad scope of the analysis, there are a number of sources of variability and uncertainty present. Therefore, to confirm the results of the probabilistic analysis and to better understand whether any particular subset of disposal practices drives the risks identified, EPA retained each of the exposure pathways from the probabilistic analyses for additional sensitivity and uncertainty analyses.

6.3.4 Sensitivity and Uncertainty Analyses

EPA reviewed the models used, as well as all of the data and assumptions input into these models, to better understand the sources of variability and uncertainty inherent in the probabilistic analysis. The Agency then qualitatively and, where possible, quantitatively analyzed these sources to understand the potential effects each may have on the modeled risk results. During this review, specific attention was focused on the parameters shown to have the greatest influence on model results. The review found that, on the whole, the risk assessment results do not appear to be strongly biased toward overestimation or underestimation of risks, and there is a high degree of confidence in the principal findings of the probabilistic analysis. However, the review of sensitive parameters revealed some specific disposal practices that may result in greater risks than identified in the probabilistic modeling.

Two sensitive parameters are the leachate concentration and the subsurface K_d values. Both of these parameters are greatly influenced by the pH of the disposed waste. To explore the effect of pH on modeled risk results, EPA separated the full-scale national results into separate distributions to capture changes in risk at different pH values. Because of the very low 50th percentile risks identified in the probabilistic analyses, all risks presented are 90th percentile.

- **Surface Impoundments (low pH):** More acidic wastes, represented by the codisposal of ash and coal refuse (pH 1.7–8.2) resulted in risks above human health and ecological criteria. Cancer risks above 1×10^{-5} were identified for arsenic III (1×10^{-3}) and arsenic V (4×10^{-4}) from ingestion of ground water. Noncancer risks above an HQ of 1 were identified for arsenic III (26), arsenic V (14) and cobalt (13) from ingestion of ground water; for mercury (5) from fish ingestion; and for cadmium (3) from ecological exposure to surface water.
- **Surface Impoundments (high pH):** More basic wastes, represented by the disposal of FGD materials (pH 8.7–11.3) resulted in risks above human health criteria. Cancer risks above 1×10^{-5} were identified for arsenic III (2×10^{-4}) and arsenic V (2×10^{-5}) from ingestion of

ground water. Noncancer risks above an HQ of 1 were identified for arsenic III (5), boron (2) and fluoride (2) from ingestion of ground water.

- **Landfills:** 90th percentile cancer and noncancer risks were all below human health criteria over the relevant pH range.

The results show that the potential for higher risks from disposal of CCRs under more acidic and basic conditions. Additional risks from surface impoundments were identified for boron, cobalt, fluoride and mercury. Given the smaller fraction of units that manage wastes at these pH values, there is greater uncertainty associated with these risks. However, damage cases were identified for all of these constituents except fluoride.

Another sensitive parameter is the rate at which leachate can infiltrate through the WMU and into underlying soils. This parameter is controlled primarily by the type of liner present. To explore the effect of liner type on modeled risk results, EPA divided full-scale national results for surface impoundments and landfills into three separate distributions, one for each liner type modeled. Because of the very low 50th percentile risks identified in the probabilistic analyses, all risks presented are 90th percentile.

- **Unlined Units** were found to present the greatest risks. Unlined impoundments result in cancer risks above 1×10^{-5} for arsenic III (3×10^{-4}) and arsenic V (4×10^{-5}), as well as noncancer risks above an HQ of 1 for arsenic III (8), molybdenum (4), lithium (3) and thallium (2). Unlined landfills result in cancer risks above 1×10^{-5} for arsenic III (2×10^{-5}).
- **Clay-lined Units** were found to present risks lower than unlined units. Clay-lined impoundments result in noncancer risks for lithium (2).
- **Composite-lined Units** were found to result in risks far below all relevant risk criteria.

As modeled, unlined units present the greatest risks to human health and the environment. There is a high degree of confidence in these modeled results. EPA modeled these units with site-based soil hydraulic conductivities selected based on geographic location. In addition, these findings are corroborated by field observations that show the vast majority of damage cases to be associated with unlined units. The hydraulic conductivity of clay liners is based on a single value specified by the EPA Industrial Subtitle D Guidance (U.S. EPA, 2006b). Therefore, to the extent that clay-lined units behave differently in the field; because of a different effective hydraulic conductivity, liner thickness, or other factors; the risk assessment may over- or underestimate risks from these units. The hydraulic conductivity of composite-lined units was based on a range of field-measured values. Given the very low risks associated with these units, the various uncertainties are unlikely to affect the modeled results.

Additional damage cases were identified for other constituents for which no risks were identified in these sensitivity analyses (e.g., beryllium, lead, selenium). There are a number of reasons why modeled ground water risks and damage cases do not perfectly align. EPA considered a range of distances to receptor wells, whereas damage cases for ground water are typically associated with monitoring wells near the WMU. Furthermore, some individual damage cases reflect site-specific

disposal scenarios, such as placement of waste in contact with the water table, which could not be explicitly modeled. Therefore, EPA believes that these real-world risks validate those identified in the probabilistic and sensitivity analyses.

6.3.5 Conclusions

Based on the results of the probabilistic analysis, EPA concludes that leaching from CCR waste management units has the potential to pose risk to both human and ecological receptors. Arsenic, lithium and molybdenum are the chemical constituents found to pose the greatest risks from surface impoundments, while arsenic posed the greatest risks from landfills. Risks from arsenic ingestion are linked to an increase the risk of cancer in the skin, liver, bladder and lungs, as well as nausea, vomiting, abnormal heart rhythm, and damage to blood vessels. Risks from lithium ingestion are linked to neurological and psychiatric effects, decreased thyroid function, renal effects, cardiovascular effects, skin eruptions, and gastrointestinal effects. Risks from molybdenum ingestion are linked to higher levels of uric acid in the blood, gout-like symptoms, and anemia. EPA found that there is a high degree of confidence in underlying data for these modeled risks. In addition, these results are supported by damage cases. Arsenic is the constituent found most frequently in ground water damage cases and, while no MCL exists for lithium or molybdenum, exceedances of other criteria were identified for these two constituents in ground water damage cases.

Through additional sensitivity and uncertainty analyses that explored different subsets of disposal practices, EPA identified the potential for higher risks than those identified in the broader, national analysis. Consideration of different waste pH values showed higher risks for arsenic at more acidic and basic pH values, as well as additional risks for boron, cadmium, cobalt, fluoride and mercury at these more acidic and basic pHs. Consideration of specific liner types showed that ground water risks are driven by disposal in unlined units and, in particular, unlined surface impoundments. For these units, EPA identified higher risks for arsenic, lithium and molybdenum, as well as additional risks for thallium. Clay-lined units were found to pose risks that, while lower than unlined units, were still above the noncancer risk criteria for lithium. Consideration of uncertainties associated with the analysis of clay-lined units may result in somewhat lower or higher risks, which may decrease lithium risks below noncancer criteria, but may also result in additional constituents above cancer or noncancer risk criteria. Composite-lined units were found to be the most protective disposal practice, resulting in risks far below all criteria identified in this risk assessment.

The comparison of recent 2009/2010 EPA surveys with an older, 1995 EPRI survey indicates that the majority of newly constructed units are lined, and that that the practice of codisposal with coal refuse is declining. However, this risk assessment presents a static snapshot of current disposal practices. While newer units may be managed in a more protective manner, older units, which still comprise the majority of currently operating units, continue to operate in a manner that may pose risks to human health and the environment.

Appendix A.

CCR Waste Management Unit Database

[This Page Intentionally Left Blank]

A.1 Introduction

The U.S. Environmental Protection Agency (EPA or the Agency) relied on the U.S. Department of Energy (DOE) Energy Information Agency (EIA) Database for information on the location, generating capacity, and coal burned for each coal-fired utility power plant (hereafter referred to as "facilities"). The 2009 EIA database contained information on the tons of coal combustion residuals (CCRs) generated annually, as well as their disposition (e.g., landfilled) at 507 facilities. However, EIA does not provide information on the characteristics of the waste management units (WMUs) where the disposed CCRs are managed. For this information, two recent EPA surveys of on-site WMUs have since been completed:

- 2009 *Information Request Responses* [obtained under Section 104(e) of the Comprehensive Environmental Response, Compensation, and Liability Act][1] together with *Impoundment Assessment Reports*,[2] hereafter jointly referred to as "the 2009 EPA Survey"; and
- 2010 Questionnaire for the Steam Electric Power Generating Effluent Guidelines, hereafter referred to as "the 2010 EPA Survey.[3]"

A.1.1 2009 EPA Information Request Letters and Impoundment Assessment Reports

Following the massive coal ash spill at the Tennessee Valley Authority's Kingston facility in December 2008, EPA took aggressive steps to assess surface impoundments and other WMUs that manage residuals from coal combustion and that contain free liquids. Beginning on March 9, 2009, EPA mailed information request letters to electric utilities and corporations that reported wet CCR disposal to EIA in 2005. These letters requested information on the location (latitude/longitude) of each surface impoundment, as well as the surface impoundment area, capacity, liner type, operating period and waste type managed.

The Agency also conducted site assessments at many of these impoundments using contractors with expertise in dam integrity. To ensure that surface impoundment data were as accurate as possible, the site assessment reports were reviewed by EPA for the same information requested in the information request letters. The data from these two sources included information on a total of 729 surface impoundments as of June 2011. These data were extracted for inputs in the revised risk assessment. Further impoundment assessment reports have been compiled since this time, but the data from these reports are not reflected in this analysis. However, the Agency has continued to update this information on its website.[4]

[2] Additional impoundment assessment reports have been conducted since the model inputs were developed. Available online at: www.epa.gov/osw/nonhaz/industrial/special/fossil/surveys2/index.htm

[3] Available online at: water.epa.gov/scitech/wastetech/guide/steam_index.cfm

[4] Available online at: www.epa.gov/wastes/nonhaz/industrial/special/fossil/coalashletter.htm

A.1.2 2010 Questionnaire for the Steam Electric Power Generating Effluent Guidelines

In 2010, EPA distributed questionnaires to approximately 700 fossil- and nuclear-fueled steam electric power plants to support its proposed rule amending the effluent guidelines for the Steam Electric Power Generating category. The questionnaire requested information about many facets of facility operation, including surface impoundment and landfill operations. To reduce burden under the Paperwork Reduction Act (44 U.S.C. §3501 et seq.), the survey was comprised of nine sections (A through I), and EPA organized the respondents into four groups that completed different sections. Most coal-fired power plants received only Parts A through D, H and I of the survey. However, a statistically representative subset received all sections of the survey (Parts A through I).

The 2009 survey discussed above only contained surface impoundments information from facilities and companies that reported wet disposal to EIA in 2005. However, this survey captured both surface impoundment and landfill information from all facilities within the regulatory scope of the rulemaking. Thus, it accounted for both surface impoundments at facilities that did not report a wet disposal tonnage in EIA 2005 and landfills. Information included geographic location, dimensions (area, capacity and thickness), waste type, liner status and type, and operating period. These parameters were extracted from a database assembled to exclude data considered confidential business information (CBI). This database provided information on a total of 431 landfills and an additional 223 impoundments that had not been captured in the 2009 EPA survey.

A.2 Filling Data Gaps

The data from the surveys discussed above are hereafter collectively referred to as the CCR WMU database. Although facilities and WMUs are constantly opening and closing, the CCR WMU database identified all operating facilities at that time it was compiled. However, some data gaps still existed in the CCR WMU database, with information on some parameters (e.g., WMU size) missing for a subset of the WMUs. This occurred for four reasons. First, as part of its efforts to comply with the Paperwork Reduction Act, EPA sent different, incomplete versions of its 2010 survey to a number of facilities. Second, even when a facility received and answered all relevant questions, those facilities sometimes did not know the answer to some questions, or otherwise provided nonresponsive answers. Finally, even when a response was received, it was sometimes claimed as CBI. The data claimed as CBI that EPA was unable to successfully challenge by the time the data set was compiled for the analysis could not be presented in this document. Thus, to maintain the transparency of this report, EPA chose not to rely on it here.

To fill in data gaps, EPA first attempted to calculate the missing data for a WMU based on other available data for the same WMU. Where this was not possible, EPA filled in the gaps by drawing from a probability distribution created from surface impoundments and landfills with data. If the parameter in question was not anticipated to correlate to plant size (e.g., liner type), then EPA used the distributions developed for all impoundments or landfills. However, if the parameter in question may correlate to plant size (e.g., WMU size), EPA further divided the distributions into

quartiles based on the amount of coal burnt at each facility to avoid unrealistic combinations (e.g., largest WMU size and smallest facility). EPA defined the quartiles based on the coal use reported in the 2009 EIA database. All of the WMUs associated with facilities within a quartile were aggregated to create a new distribution. EPA then drew from the distribution type located at facilities in the same coal use quartile.

A description of the gap-filling procedures for each parameter is included below. **Attachment A-1** provides a summary of the data collected for each facility on geographic location, number of surface impoundments and landfills present, amount of coal burned and the associated coal use quartile. **Attachment A-2** provides a summary of the WMU-specific data collected for the CCR risk assessment, including geographic locations, dimensions, waste type, and liner type. Missing data for individual facilities and WMUs are listed in the attachment as blank fields.

A.2.1 Geographic Location

Each WMU in the survey was matched with a specific electric utility facility in the U.S. Department of Energy's EIA Forms EIA-860 (Annual Electric Generator Report) and EIA-923 (Power Plant Operations Report) using the Office of the Regulatory Information System facility identification code assigned by the EIA. This was done to provide a complete data set of approximate WMU locations. The latitudes and longitudes reported in the EIA Database often represent a centroid or front-gate location for each facility. However, WMUs can be located some distance away from the main facility. Therefore, where possible, the revised risk assessment used the available data from the CCR WMU database to identify the specific locations of individual WMUs and only relied on facility locations when no WMU-specific data was available. The reported locations for both facilities and WMUs were then reviewed based on visual inspection of aerial photography using Google Earth and adjusted, as appropriate. Obtaining and checking the latitude and longitude centroid locations missing in the survey data allowed greater accuracy for collecting the WMU-specific environmental setting information described in **Appendix B**.

A.2.2 Dimensions

The CCR WMU database includes information on the total surface area and total volumetric waste capacity of most surface impoundments and landfills included in the survey. Because the final capacity of a WMU was not always known, the capacity at closure was preferred when multiple values were available, followed by constructed capacity and current capacity as the best estimates for surface impoundment or landfill volume. To impute data for facilities missing either area or capacity data, but not both, linear regression equations were developed based on WMUs with both area and capacity data. The final regression equations are shown in **Figures A-1** and **A-2** for surface impoundments[5] and **Figures A-3** and **A-4** for landfills. In each case, the standard error around the regression line was used during source data file preparation to randomly vary the area or capacity from iteration to iteration within the bounds defined by the standard error. In cases where neither area nor capacity data were available, an area and capacity pairing was

[5] At the time these regressions were developed, EPA had data on 729 surface impoundments from the 2009 survey.

probabilistically selected from available data for units in the same coal use quartile as the units with the missing data.

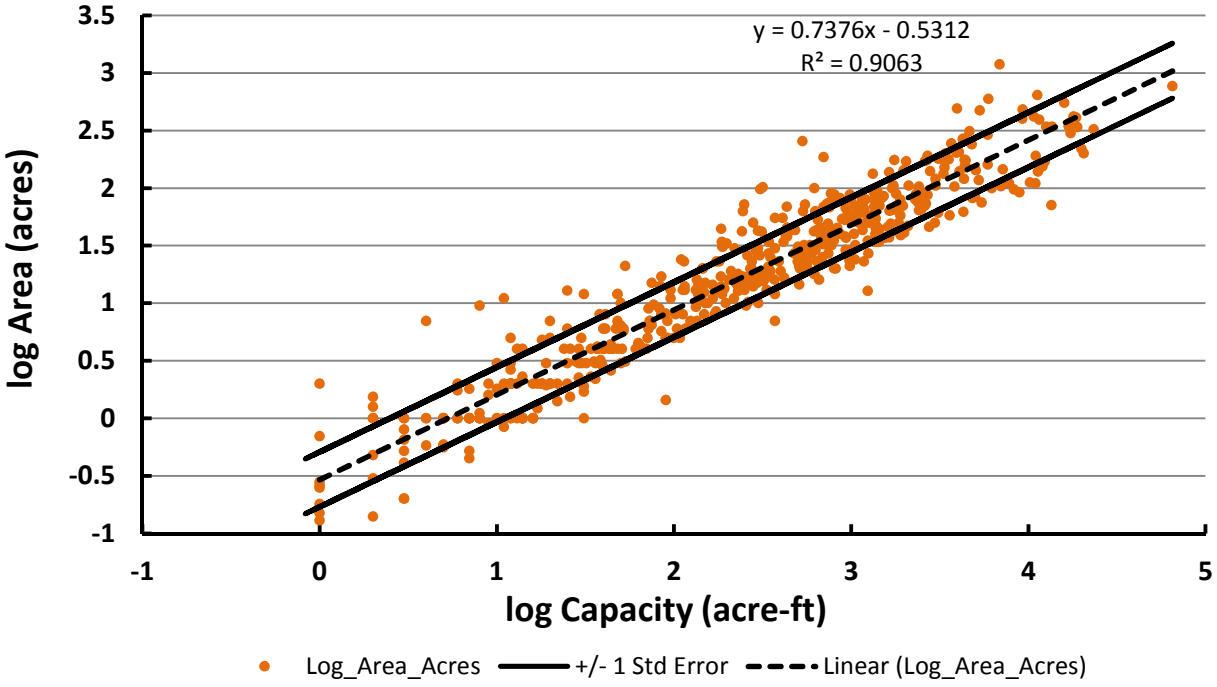

Figure A-1. Linear regression to impute surface impoundment area from capacity.

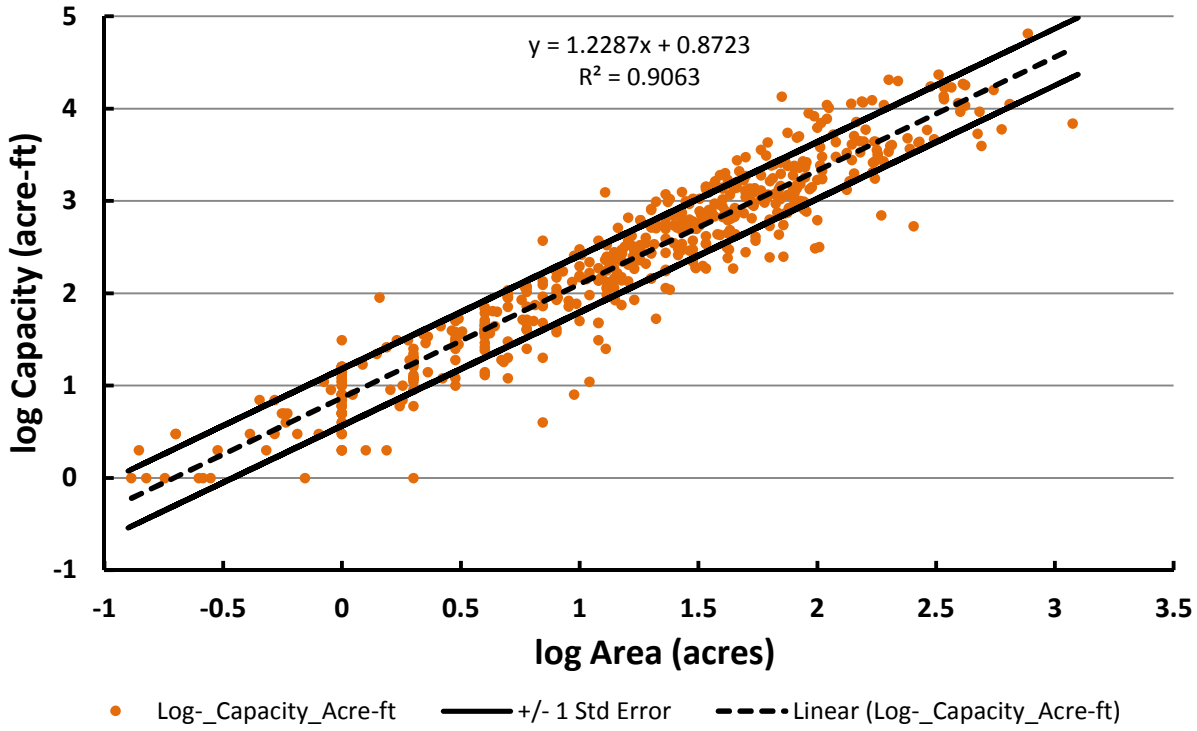

Figure A-2. Linear regression to impute surface impoundment capacity from area.

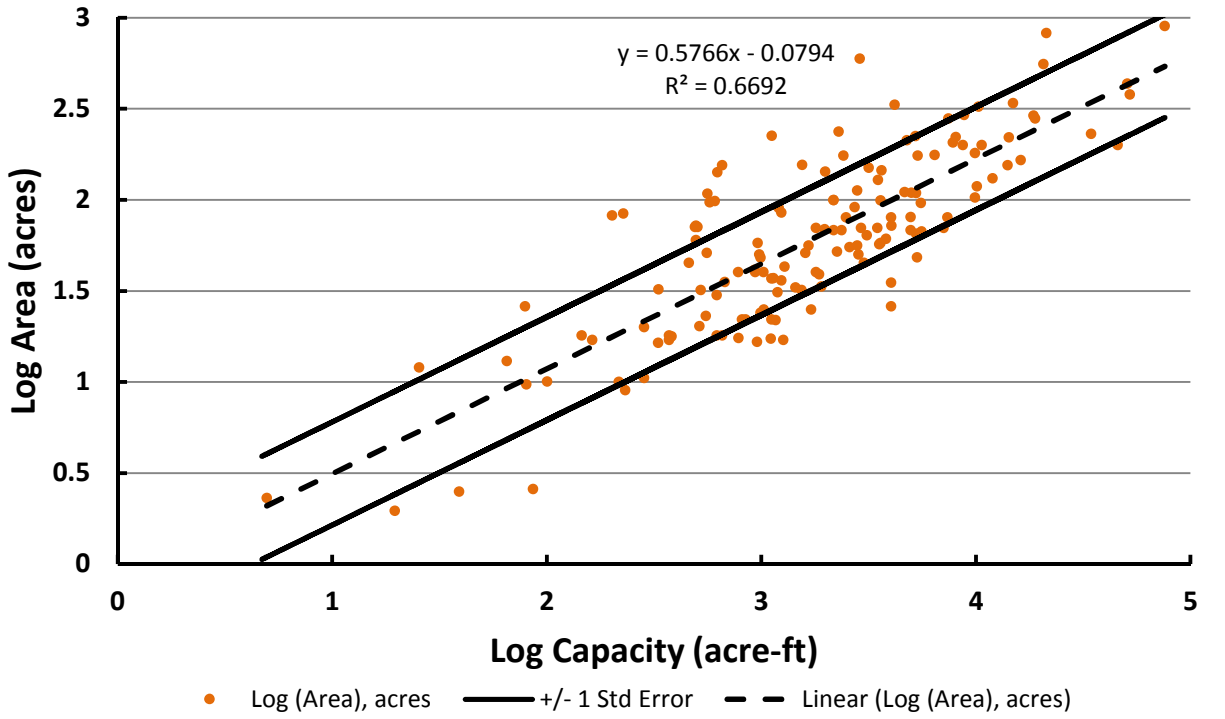

Figure A-3. Linear regression to impute landfill area from capacity.

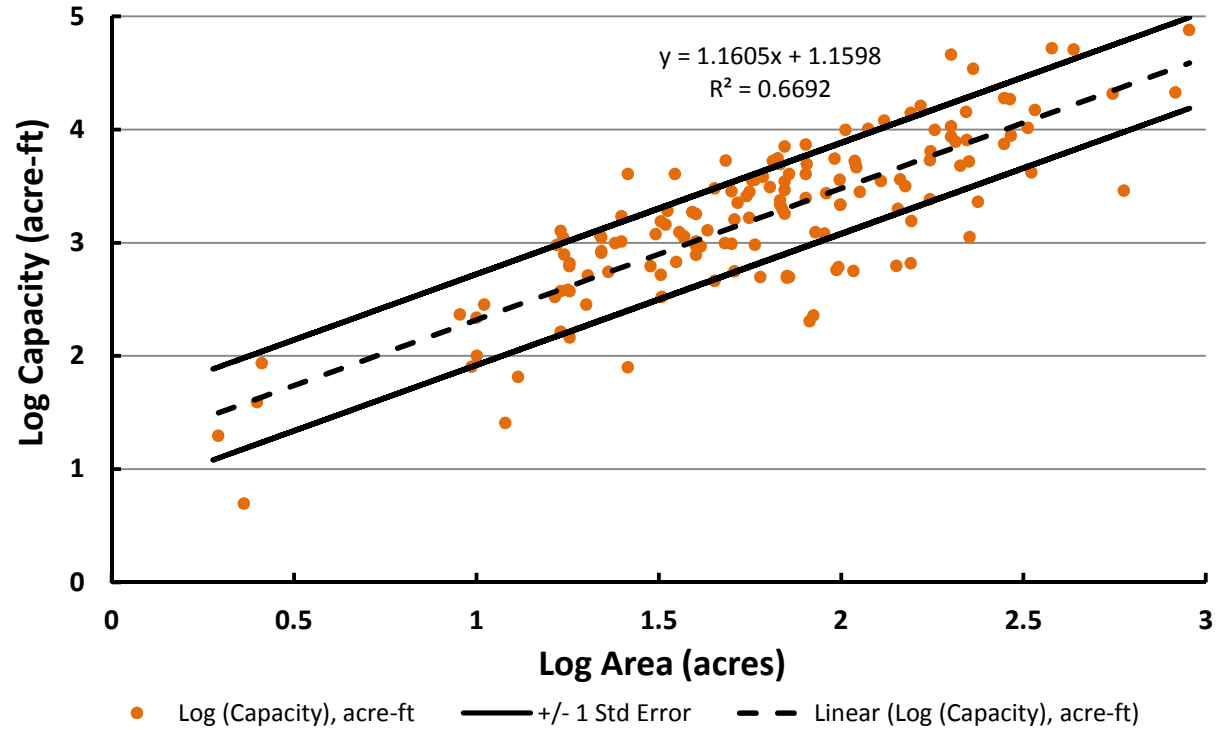

Figure A-4. Linear regression to impute landfill capacity from area.

The survey data do not include total unit depth, so it was calculated from area and capacity. For WMUs with both area and capacity reported, an average depth was calculated by dividing capacity by area. Where either area or capacity was missing, the missing value was imputed using a linear regression of capacity and area combinations reported for other WMUs. The resulting depths were then checked against the depths calculated for WMUs with both capacity and area data. For landfills, depths were compared to the minimum and maximum calculated depths (2 and 240 feet). For surface impoundments, depths were compared to the 1st and 99th percentile of the calculated depths (2 and 91 feet). Where depths for WMUs with imputed area or capacity were outside of these constraints, the imputed area or capacity was discarded and replaced with a new selection based on probabilistic selection within the standard error bounds surrounding the regression line, and the depth recalculated. No range check was performed on depths calculated when both area and capacity were reported; thus, a few surface impoundment depth values fall outside the 2- to 91-foot range.

A.2.3 Waste Type

The CCR WMU database included information on the type of CCRs managed in the WMUs. Waste types are necessary to account for differences in soil-water partition coefficient due to, for example, differences in pH. Based on the types of CCRs reported, the WMUs were assigned to one of three waste types: combined ash, ash and coal refuse, and flue gas desulfurization (FGD) waste. The three model waste types that EPA assigned to each WMU were:

- **Ash and Coal Refuse**: Includes any CCR that is codisposed with coal refuse, which is waste coal produced from coal handling, crushing and sizing operations. This waste type is characterized by a low to moderate pH (1.7–8.2) and high levels of sulfate, iron and manganese.
- **FGD Wastes**: Includes any type of wet or dry FGD waste when disposed in dedicated monofills. This waste type is characterized by a moderate to high pH (8.7–11.3) and high levels of calcium, sulfate, sodium and chlorine.
- **Combined Ash**: Includes any CCRs other than those listed above (e.g., fly ash, bottom ash, boiler slag) either monofilled or in combination with each other. Due to the variability in disposal practices, this waste type is characterized by a broad range in pH (3.9–12.3), sulfate and calcium levels.

In cases where the CCRs were not specified, one of these three waste types was probabilistically assigned to that WMU during each model run based on the prevalence of each among WMUs with reported waste types. **Table A-1** shows the crosswalk used to match reported CCRs to the different waste types for modeling surface impoundments. For landfills all waste types were modeled as combined ash.

Table A-1. Crosswalk Between Reported and Modeled Waste Type for Surface Impoundments

Reported CCRs	Model Waste Type
Fly ash[1,2]	Combined ash
Boiler slag[1], Slag[2]	
Bottom ash[1,2]	
Pozzolonic material[2]	
Any combination of FGD residues and other ash materials	
Flue gas emission control residuals[1]	FGD Waste
Gypsum[2]	
Ca sulfite[2]	
Dry FGD[2]	
Any of the above plus "Other" field containing coal refuse, such as pyrite(s), pyritic material, coal, coal fines, coal pile sludge, coal impurities, coal mill rejects, mill rejects, coal prep plant solids, coal pulverizer rejects, or coal refuse	Ash and coal refuse

1) Specified in 2009 Section 104(e) Information Request
2) Specified in 2010 Questionnaire for the Steam Electric Power Generating Effluent Guidelines

In addition to the waste types modeled in the revised risk assessment, EPA also identified FBC wastes as a distinct waste type. The 2010 Risk Assessment modeled the FBC waste type separately for landfills, but not surface impoundments, because of a lack of pore water data available at that time. This modeling showed that the risks associated with disposal of FBC waste in landfills were lower than those for other CCR waste types and below all risk criteria. Given these results and the lack of additional leachate data available since 2010, EPA did not re-evaluate FBC wastes in the revised risk assessment.

A.2.4 Liner Type

The CCR WMU database included information on the type of liner (if any) for the WMUs. Based on the type of liner reported, the WMUs were assigned to one of three liner types: an unlined (no liner) scenario, a compacted clay liner, and a composite liner that combines a plastic liner (e.g., high-density polyethylene membrane) over either geosynthetic or natural clays. These three liner types are the conceptual liner scenarios developed in support of EPA's *Guide for Industrial Waste Management* (U.S. EPA, 2002), and are described as follows:

- **No Liner Scenario:** Waste is placed directly on local soils, either on grade or excavated to some design depth and without a leachate collection system. At closure, two feet of native soil cover, the minimum required by Subtitle D regulations, is installed and assumed to support vegetation.
- **Clay Liner Scenario:** Waste is placed on a three-foot compacted clay liner that is installed over local soils without a leachate collection system, either on grade or excavated to some

design depth. At closure, a three-foot clay cover is installed and covered with one foot of loam to support vegetation and drainage.

- **Composite Liner Scenario:** Waste is placed on a liner system that consists of a plastic liner (e.g., high-density polyethylene membrane) underlain by either a natural or geosynthetic clay liner. A leachate collection system is assumed to exist between the waste and the liner system. At closure, a three-foot clay cover (graded and otherwise designed to prevent ponding) or functional equivalent is assumed to be installed and covered with one foot of loam to support vegetation and drainage.

In cases where the presence of a liner was not specified, one of these three scenarios was probabilistically assigned to that WMU during each model iteration based on the prevalence of these scenarios reported for impoundments or landfills. In cases where the survey indicated that a WMU was lined, but did not specify the type of liner, a clay or composite scenario was assigned probabilistically based on the prevalence of the different liner types reported for impoundments or landfills. **Table A-2** shows the crosswalk used to match these three conceptual liner scenarios to the different types reported in the CCR WMU database. The five impoundments lined with asphalt and 12 impoundments lined with concrete were treated as effectively unlined because these materials tend to crack, eliminating the effectiveness of the liner without regular maintenance. Thus, these materials are not considered to be adequate liners for regulated waste disposal facilities. The two "natural clay" lined impoundments were also considered to be unlined because they are unlikely to meet the design specifications of the clay-lined scenario.

Table A-2. Crosswalk Between Survey Data and CCR Source Model Liner Types for CCR Surface Impoundments and Landfills

Reported Survey Liner Type	Model Liner Description
Surface Impoundment Liners	
None	Unlined
Natural clay	
Asphalt	
Concrete	
Clay	Clay-Lined
Bentonite	
Composite	Composite-Lined
Flexible Membrane Liner	
Yes	Clay or Composite*
Confidential Business Information	Blank

(continued)

Table A-2. Crosswalk Between Survey Data and CCR Source Model Liner Types for CCR Surface Impoundments and Landfills

Reported Survey Liner Type	Model Liner Description
Landfill Liners	
None	Unlined
Coal Combustion Residual	
Clay	Clay-Lined
Composite	Composite-Lined
Flexible Membrane Liner	
Yes	Clay or Composite*

*Randomly selected from these two options based on the frequency of occurrence of each type in the database for landfills.

Appendix B.

Environmental Parameter Data

[This Page Intentionally Left Blank]

B.1 Introduction

The U.S. Environmental Protection Agency (EPA or the Agency) used the facility and waste management unit (WMU) locations discussed in **Appendix A** to identify site-specific data on soil type, hydrogeologic environment, climate and nearby surface water bodies. Where possible, environmental data were collected using geographic information system (GIS) software to associate geographic coordinates for each WMU to site-specific and region-specific data. However, because uncertainty remained about the precise location for some units, EPA pulled data from a two-kilometer radius around the facility centroid to effectively capture local variability. Regional data were collected by assigning each facility to the nearest reference point in national databases, such as the Hydrologic Evaluation of Landfill Performance (HELP) model climate stations and the U.S. Geological Survey (USGS) hydrological regions. Whenever environmental parameters could not be linked based on location, EPA relied on national distributions.

Information about the methods used to collected and analyze these data is provided below. **Attachment B-1** provides the specific soil texture, pH and organic carbon content associated with each facility. **Attachment B-2** provides hydrogeologic environments. **Attachment B-3** provides climate center, precipitation rate and infiltration rate. **Attachment B-4** provides USGS Hydrologic Region; distance to nearest water body; and water body mean recharge, area, length, mean annual flow and mean annual velocity.

B.2 Soil Data

The ground water model used in the revised risk assessment, EPA's Composite Model for Leachate Migration with Transformation Products (EPACMTP), requires the properties of the entire soil column to model leachate transport through both the unsaturated (vadose) and saturated (ground water table) zones. Soil data were collected using either the reported WMU location and footprint or, where WMU locations were not available, a two-kilometer radius around each facility centroid.

B.2.1 Data Sources

The primary data source for soil properties was the State Soil Geographic (STATSGO) database. STATSGO is a repository of nationwide soil properties compiled primarily by the U.S. Department of Agriculture (USDA) from county soil survey data (USDA, 1994). STATSGO includes 1:250,000-scale GIS coverage that delineates the conterminous United States into map units and an associated database that contains soil data for each map unit. The map units that overlap with either the WMU footprint or two-kilometer radius surrounding a facility, as appropriate, were used to spatially represent soils in the database. USSOILS (Schwarz and Alexander, 1995) and Conterminous United States Multilayer Soil Characteristics (CONUS-SOIL) (Miller and White, 1998) are simplified compilations of STATSGO data which were used to collect soil properties.

- **USSOILS.** The USSOILS data set averages STATSGO data vertically over the entire soil column for each map unit (Schwarz and Alexander, 1995). USSOILS aggregates the STATSGO layer and component information up to the level of a map unit by depth-

averaging median properties within a component over the entire soil column and then area-averaging component values across a map unit.[1]

- **CONUS-SOIL.** The CONUS-SOIL soil data set was compiled by the Earth System Science Center in the College of Earth and Mineral Sciences at Pennsylvania State University (Miller and White, 1998). CONUS contains STATSGO soil properties averaged to 11 standard layer depths from the STATSGO layers to a total depth of 2.5 m. Within each STATSGO map unit and CONUS standard layer, soil properties either represent the predominant property (as with soil texture) or are area-weighted averages of STATSGO component values.[2]

B.2.2 Methodology

EPA first collected soil pH and organic matter data from USSOILS and soil texture data from CONUS-SOIL for each map unit. Soil texture data were used to provide nationally correlated bulk density, saturated water content, saturated hydraulic conductivity, and the van Genuchten soil moisture retention parameters (alpha and beta) based on Carsel and Parrish (1988) and Carsel et al. (1988). GIS software was then used to overlay the WMU footprint or the two-kilometer radius onto the STATSGO map to determine which STATSGO map units fell within these boundaries. Using these overlays, EPA calculated the percent of that bounded area that fell within each map unit. These percentages were used to allow probabilistic sampling of the soil texture, pH, and organic matter data for each WMU.

Table B-1. Soil Texture Crosswalk

STATSGO SCS Soil Texture	EPACMTP Soil Megatexture
Sand	Sandy Loam
Loamy Sand	
Sandy Loam	
Silt Loam	Silt Loam
Silt	
Loam	
Sandy Clay Loam	
Clay Loam	
Silty Clay Loam	Silty Clay Loam
Sandy Clay	
Silty Clay	
Clay	

SCS = Soil Conservation Service

Table B-1 shows the crosswalk that was used to assign the SCS textures to the EPACMTP megatextures. Soil data used for modeling is presented in **Attachment B-1**. STATSGO soils are classified into 12 Soil Conservation Service (SCS) soil textures, but EPACMTP uses three soil megatextures to represent the variability of hydrologic soil properties. Therefore, each STATSGO soil texture was crosswalked in a database to the EPACMTP megatexture with the most similar hydrogeologic properties. When merging these soil texture entries, EPA aggregated the percentages of map units that fell within the same megatexture and averaged both the pH and organic matter proportionally.

[1] Metadata on USSOILS are available online at: water.usgs.gov/GIS/metadata/usgswrd/XML/ussoils.xml

[2] Additional information on CONUS is available online at: www.soilinfo.psu.edu/index.cgi?soil_data&conus

B.3 Hydrogeologic Environment Data

Each facility modeled in this analysis was assigned one or more hydrogeologic environment(s) from EPA's Hydrogeologic Database (HGDB) in order to characterize four subsurface parameters required by EPACMTP: depth to ground water, aquifer thickness, hydraulic gradient, and saturated hydraulic conductivity. The HGDB was developed by the American Petroleum Institute (Newell et al., 1989; 1990) to specify correlated empirical probability distributions of these four parameters for the 12 distinct hydrogeologic environments described in Newell et al. (1990). To assign the HGDB distributions to the CCR WMUs modeled in this assessment, EPA first developed a national geographic coverage of the 12 hydrogeologic environments, and then used GIS software to overlay the CCR WMU locations and dimensions, and assign the hydrogeologic environments to each WMU.

B.3.1 Data Sources

EPACMTP uses the HGDB for national and regional analyses. Therefore, it was necessary to assign each facility to one or more hydrogeologic environments corresponding to the HGDB data set. Given the national scale of the risk assessment, only national data sets were used to delineate hydrogeologic environments, defined by an approximate 1:7,500,000 map scale. The following individual map layers were combined using GIS software to develop a single map layer for assigning the 12 hydrogeologic environments across the United States:

- **Shallowest principal aquifers** from *Principal Aquifers of the Conterminous United States, Hawaii, Puerto Rico, and the U.S. Virgin Islands* [USGS map file: aquifrp025]. 1:2,500,000 map scale, was used as the base layer in the assessment and to delineate several of the 12 hydrogeologic environments.
- **Alluvial and glacial aquifers** from *Aquifers of Alluvial and Glacial Origin* [USGS map file: alvaqfp025]. 1:2,500,000 map scale, was used to represent alluvial and glacial aquifers for the 22 states north of the southernmost line of glaciation. Note that the alluvial aquifers in this coverage are identical to those in the Hunt (1979) surficial geology layer below.
- **Surficial geology** of the conterminous United States was taken from:
  - *Surficial Geology of the Conterminous United States* [map file: geol75m]. 1:7,500,000 map scale, provided by Hunt (1979), these data was used to characterize shallow soil lithology and alluvial aquifers.
  - *The Surficial Deposits and Materials in the Eastern and Central United States (East of 102 degrees West Longitude)* [map file: sfgeoep020]. 1:1,000,00 map scale, includes the line of maximum glacial advance and represents surficial materials that have accumulated or formed during the past two million years, including residual soils, alluvium, and glacial deposits.
- **Karst aquifers** from *Engineering Aspects of Karst* [map file: karst0p075], 1:7,500,000-map scale, showing karst and pseudokarst (i.e., karst-like terrain produced by processes other than the dissolution of rocks) across the United States.

- **Bedrock geology** from *Generalized Geologic Map of the United States* [map file: geolgyp075], 1:7,500,00 map scale, showing the bedrock geology at or near land surface (i.e., beneath surficial soils, alluvium and glacial deposits).
- **STATSGO soils,** 1:250,000 map scale, from the digital map and attribute data for soils described in **Section B.2**.

As described below, these data layers were used to develop a national GIS hydrogeologic environment layer for assigning an aquifer type to a point or area of interest.

B.3.2 Methodology

To create the hydrogeologic environment layer, each individual data layer described above was obtained as a GIS shapefile and processed as needed to ensure that coordinate systems matched and the layers could be overlain. **Table B-2** describes how the polygons comprising the 12 hydrogeologic environments were developed in the GIS using these layers.

Table B-2. GIS Procedures for Assembling National Coverage of Hydrogeologic Environments [map file name in square brackets].

Hydrogeologic Environment		Description
1)	Metamorphic and igneous rock	Select polygons where ROCK_NAME = "igneous and metamorphic-rock aquifers" from the principal aquifer layer [aquifrp025] AND "igneous" or "metamorphic" polygons from the bedrock geology layer [geolgyp075] AND polygons from the Hunt (1979) surficial geology layer [geol75m] derived from or directly overlaying igneous or metamorphic rock.
2)	Bedded sedimentary rock	Select polygons where the ROCK_NAME = "sandstone and carbonate-rock aquifers" OR AQ_NAME was "Other rocks" from the principal aquifer layer [aquifrp025] AND "sedimentary" polygons from the bedrock geology layer [geolgyp075].
3)	Till over sedimentary rock	Select polygons that had a surficial geology [geol75m] = "mg: deposits of mountain glaciers", "tg: till or ground moraine" "ts: ice-laid deposits, like tg but mostly sand and silt", OR "ts/K,T: thin ice-laid deposits, like ts but thin and discontinuous. . ..", AND overlaying "sedimentary" polygons from the bedrock geology layer [geolgyp075].
4)	Sand and gravel	Select polygons where AQ_NAME = "other rocks" OR "high plains aquifer" from the principal aquifer layer [aquifrp025] AND sand and gravel related names in SURFICIALG from the Hunt (1979) surficial geology layer [geol75m] (SURFICIALG contained many different types of sand and gravel deposits).
5)	Alluvial valleys, basins and fans	Select polygons where AQ_NAME = "Unconsolidated sand and gravel aquifers" from the principal aquifer layer [aquifrp025] name OR surficial geology type (SURFICIALG) was either "fg: fan gravels" or "fs: fan sands" in the Hunt (1979) surficial geology layer [geol75m].

(continued)

Table B-2. GIS Procedures for Assembling National Coverage of Hydrogeologic Environments [map file name in square brackets].

Hydrogeologic Environment		Description
6)	River valleys and floodplains with overbank deposits	Select polygons where SURFICIALG = "al: floodplain and alluvium gravel terraces" in Hunt (1979) surficial geology layer [geol75m] AND STATSGO soils with < 50% sand AND a low permeability (< 0.0147 inches per hour).
7)	River valleys and floodplains without overbank deposits	Select polygons where SURFICIALG = "al: floodplain and alluvium gravel terraces" in Hunt (1979) surficial geology layer [geol75m] AND STATSGO soils that do NOT have < 50% sand AND a low permeability (< 0.0147 inches per hour).
8)	Outwash	Select polygons where ORIGIN_AGE = "glaciofluvial (outwash) deposits" in the Surficial Deposits and Materials layer [sfgeomean020] AND where SURFICIALG = anything but "ts: ice-laid deposits, like tg but mostly sand and silt" in the Hunt (1979) surficial geology layer [geol75m].
9)	Till and till over outwash	Select polygons from Hunt (1979) surficial geology layer [geol75,] that were not already classified hydrogeologic environment 8 AND where SURFICIALG = "w: gravel, sand and clay deposited by glacial streams adjacent to or downstream from temporary ice fronts" OR "ts: ice-laid deposits, like tg but mostly sand and silt" OR "tg: till, or ground moraine".
10)	Unconsolidated and semi-consolidated shallow aquifers	Select polygons where AQ_NAME = "coastal lowlands aquifer system," "Mississippi embayment aquifer system," "Northern Atlantic Coastal Plain aquifer system," "Southeast Coastal Plain aquifer system," "Texas coastal uplands aquifer system," or "surficial aquifer system." from the principal aquifers layer [aquifrp025].
11)	Coastal beach	Select polygons where SURFICIALG = "si: sea islands" from the Hunt (1979) surficial geology layer [geol75m].
12)	Solution limestone	Select polygons where ROCK_NAME contains "carbonate-rock aquifers," "sandstone and carbonate-rock aquifers", "unconsolidated sand and gravel aquifers," OR "sandstone aquifers" from the principal aquifer layer [aquifrp025] AND, for the last two only, are defined as areas of karst in the Engineering Aspects of Karst layer [karst0p075]

B.3.3 Data Processing

One or more of the 12 hydrogeological environments was assigned to each WMU footprint or two-kilometer region surrounding a facility, as appropriate, and the percentages of each assigned environment within the data collection area was determined and included with the assignments. When there was more than one environment assigned to a WMU (in cases where the assignment or location was uncertain), the hydrogeological environment was varied probabilistically based on these percentages during each Monte Carlo iteration for a particular WMU. **Table B-3** summarizes these assignments, showing the number of CCR facilities, surface impoundments and landfills for each hydrogeologic environment sent to EPACMTP.

Table B-3. Number of Facilities and WMUs in Each Hydrogeologic Environment

Hydrogeologic Environment		Facilities (2-km radius)	Impoundments (Boundary)	Landfills (Boundary)
1)	Metamorphic and igneous	20	46	19
2)	Bedded sedimentary rock	85	198	93
3)	Till over sedimentary rock	18	48	28
4)	Sand and gravel	47	94	43
5)	Alluvial basins valleys and fans	7	27	5
6)	River valleys and floodplains with overbank deposits	141	335	86
7)	River valleys and floodplains without overbank deposits	119	259	70
8)	Outwash	17	44	16
9)	Till and till over outwash	16	31	13
10)	Unconsolidated and semi-consolidated shallow aquifers	43	100	64
11)	Coastal beaches	2	0	4
12)	Solution limestone	42	92	34

Once the hydrogeologic environments were assigned, a preprocessing run of EPACMTP was conducted to construct a set of randomly generated but correlated hydrogeologic parameter values (i.e., depth to ground water, aquifer thickness, hydraulic gradient, and saturated hydraulic conductivity) for each occurrence of the hydrogeologic environments in the source data files. Missing values in the HGDB data set were filled using correlations during EPACMTP execution, as described in U.S. EPA (1997).

B.4 Climate Data

EPACMTP uses the climate station, along with soil texture, to select both the HELP-modeled infiltration rates in the landfill source model and the recharge rates to use in EPACMTP. Thus, the CCR risk assessment selected HELP meteorological (or climate) stations for each CCR disposal site to collect the climatic data necessary for fate and transport modeling.

To assign the EPACMTP/HELP climate centers to each facility, GIS software was used to determine the three climate centers closest to the facility and to get the long-term (1961–1990) annual average precipitation rate at each facility from a USGS coverage for the contiguous U.S.

(www.nationalatlas.gov; **Figure B-1**). The long-term average precipitation for each of the three closest EPACMTP climate centers was then compared with the precipitation for each facility location to select the climate station with the closest precipitation to the facility. **Attachment B-3** lists the climate center assigned to each CCR disposal facility along with the five-year average precipitation and HELP soil-specific infiltration/recharge rates for each station.

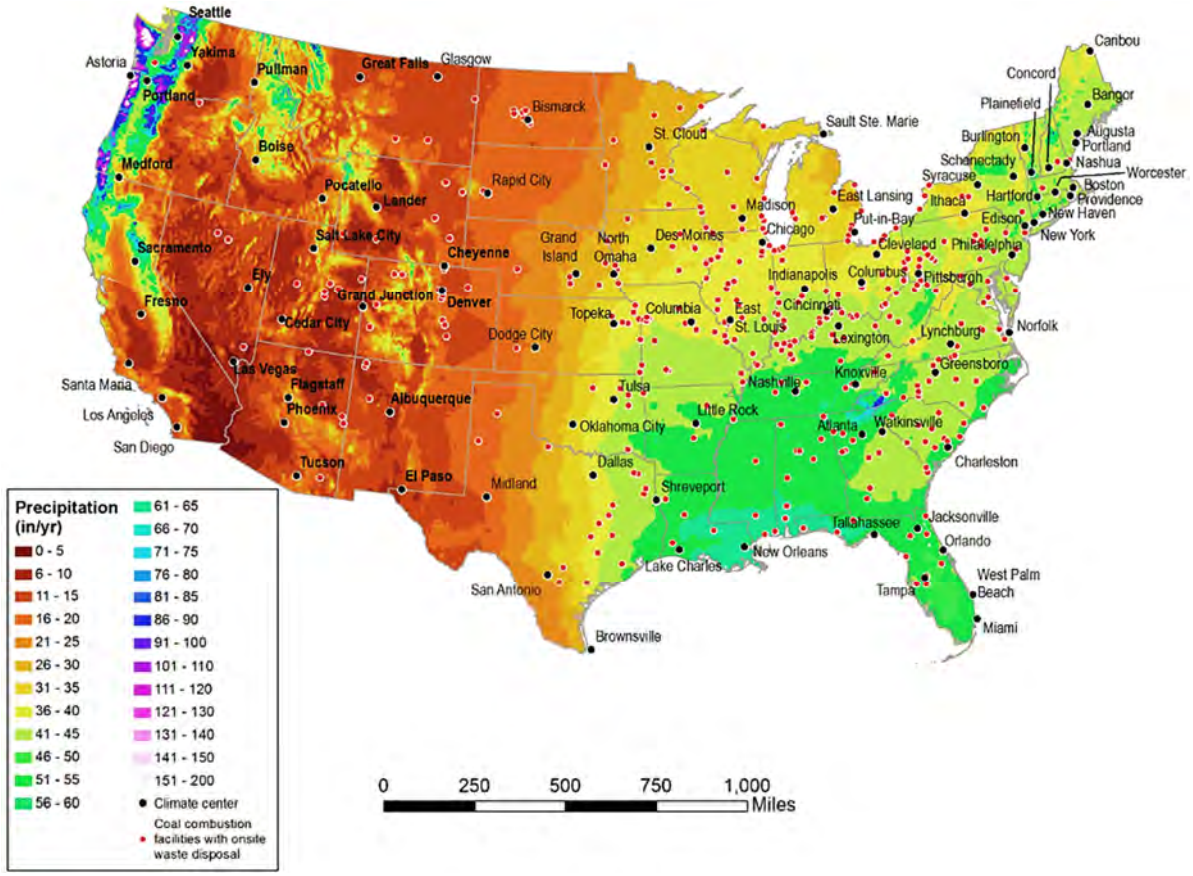

Figure B-1. EPACMTP climate centers, precipitation ranges and CCR disposal facilities.

B.5 Surface Water Data

The surface water model used in the revised risk assessment requires information on the water body type (stream or lake), flow conditions, dimensions and water quality for each surface water body. Data were collected on a site-based, regional or national basis depending on the specific parameter and data availability. Collection methods are discussed in the following subsections.

B.5.1 Data Sources

Data on surface water body characteristics and distances was necessary to calculate the fraction of the ground water plume intercepted by surface water bodies, as well as the resulting constituent concentrations in the surface water. Water body data were collected based on WMU location data, and consisted of the following sources:

- **NHDplus.** NHDplus is a geospatial, hydrologic framework data set that integrates the features of the National Hydrography Dataset (NHD), the Watershed Boundary Dataset (WBD), and the National Elevation Dataset (NED).[3] The NHD represents the drainage network with features such as rivers, streams, canals, lakes, ponds, coastline, dams and stream gauges. The WBD represents drainage basins as enclosed areas in eight different size categories. Both these data sets represent surface waters at a nominal scale of 1:24,000, and use an integer value as a common identifier (COMID) that uniquely identifies the occurrence of each NHD feature. The NED provides basic elevation information for earth science studies and mapping applications in the United States.
- **STORET.** The STORET (STOrage and RETrieval) Data Warehouse is EPA's repository of the water quality monitoring data including total suspended solids (TSS), surface water temperatures, and surface water pH. These data were collected by water resource management groups across the country including states, tribes, watershed groups, other federal agencies, volunteer groups and universities.[4]

B.5.2 Selection of Nearest Water Body

Prior to collecting data on surface water bodies, EPA identified the nearest water bodies and associated ComIDs for each WMU. This was done for the purpose of evaluating ground water flow direction for discharge into a surface water body. EPA notes that topography often controls general shallow ground water flow. Thus, EPA used surface topography as a proxy for the direction of ground water flow in the shallow aquifers modeled in the revised risk assessment. The NHD*Plus* Flow Direction Grid (U.S. EPA and USGS, 2007) provided the foundation for evaluating the probable topographical course of overland runoff. EPA utilized an application of this grid, known as the "Raindrop Tool," to trace the downhill path a hypothetical raindrop is likely to follow as it flows overland until it intersects with the nearest surface water body, as defined by NHD features.[5]

This tool is useful for evaluating the path of a raindrop from a single point. However, WMUs were often large enough that different points within a given WMU may result in runoff to different surface water bodies. Thus, water bodies and ComIDs were identified in the following steps:

- The area of the WMU was idealized as a circle centered at the WMU longitude/latitude.
- Eight points were placed around the circumference of each WMU at equally spaced angles of 0°, 45°, 90°, 135°, 180°, 225°, 270°, and 315°.
- For each of the eight points, the Raindrop Tool selected the surface water body/ComID pair to which the runoff discharged. Each of the eight starting points were assigned an equal probability of occurrence.

[3] Further detail on NHDPlus is available online at: www.horizon-systems.com/nhdplus/

[4] Additional information on STORET is available online at: www.epa.gov/storet/

[5] Further discussion is available online at: www.epa.gov/waters/doc/rad/raindrop.html

- Where multiple points discharged to the same water body/ComID pair, the probabilities for that pair were aggregated.

For each surface water body/ComID pair identified, EPA collected the waterbody type, mean recharge rate, area, length, mean annual flow, and mean annual velocity from the NHDPlus.

Example results of this process are illustrated in **Figure B-2**. The dashed red lines represent the modeled raindrop pathlines, while the straight black lines represent the corresponding shortest straight-line distances from the WMUs to the surface water body. In cases where the projected rain drop flow path overlapped with the WMU footprint, an adjusted distance from where the straight-line distance exited the WMU footprint to the surface water body was used. In cases where the surface water body overlapped with the interior WMU footprint as a result of the idealized boundary, the distance from the water body to the WMU boundary was taken as representative. EPA notes that, since the actual boundary of the WMU already falls so close to the surface water body, the short distances resulting from this approach are believed to be representative. In addition to flow lines, the NHDPlus maintains a data set of polygons that represent larger water bodies, such as lakes and wide rivers. In some cases, the NHDPlus flow lines are located within the middle of the water body, while the polygon outlines the perimeter of the water body. In these cases, the distances to the NHDPlus polygons were used.

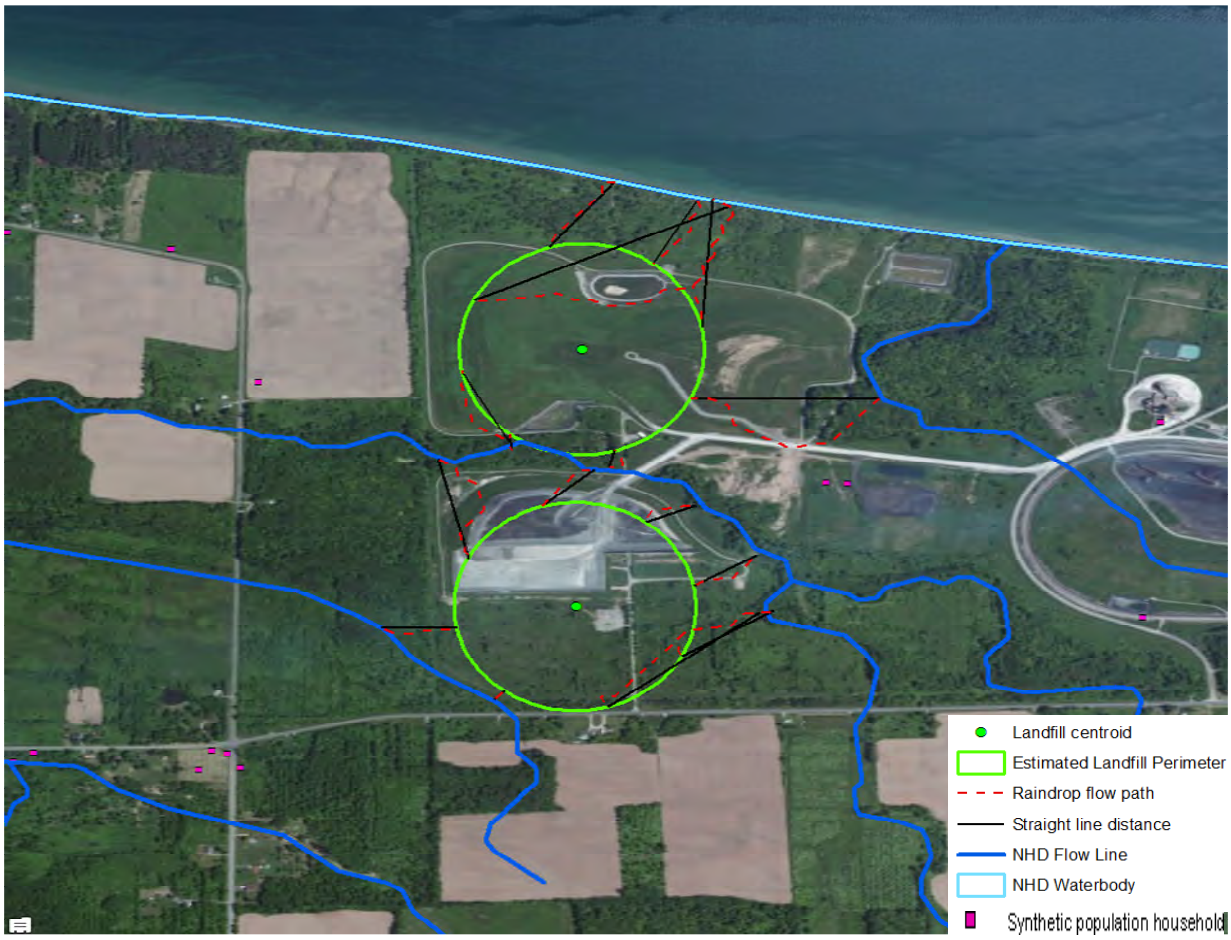

Figure B-2. Examples of surface water body identification results.

Some WMUs did not have location data to permit identification of the nearest water bodies. These units were probabilistically assigned distances and water bodies during the Monte Carlo analysis based on the distributions developed from data available for other impoundments or landfills. The resulting probability distributions are shown in **Figure B-3**. To minimize the potential for outliers at small distances to be selected for facilities without location data, minimum values were set at the first percentile for both surface impoundments (9.3 m) and landfills (19 m).

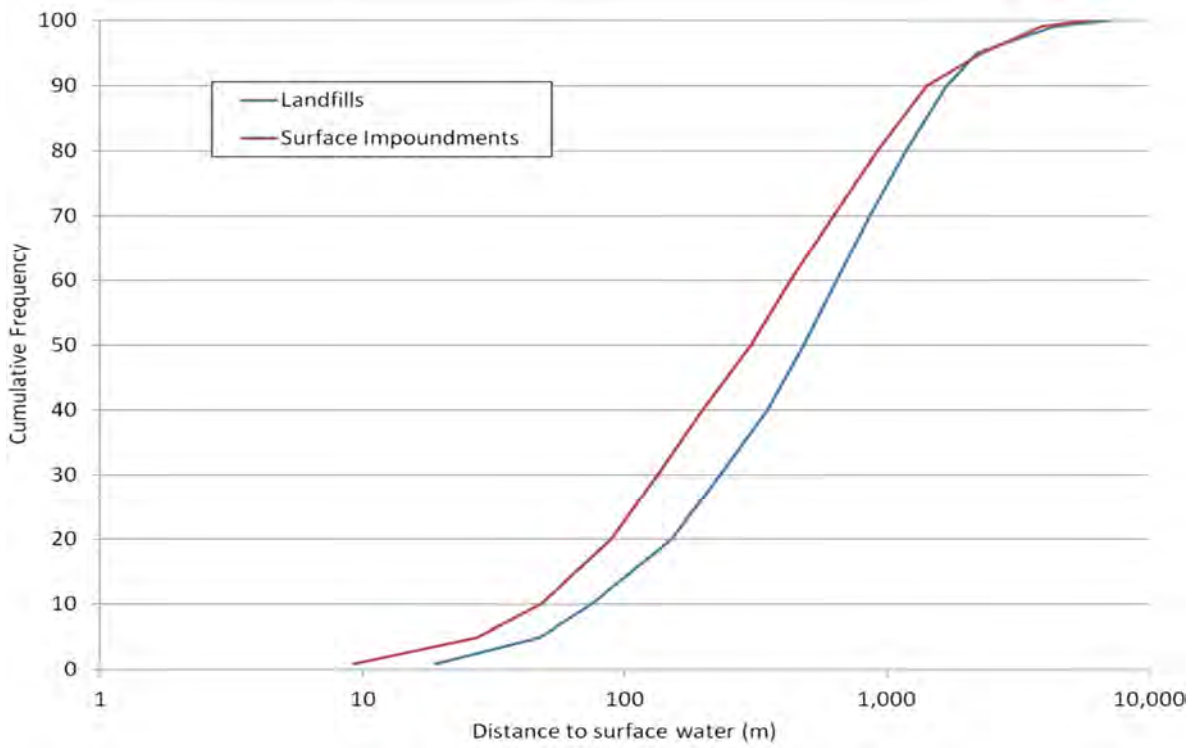

Figure B-3. Cumulative probability distributions for distance to surface water bodies.

B.5.3 Water Body Type

While there are several water body types in NHDplus, EPA only identified surface water models for streams and lakes. Thus, each of the NHDplus water body types needed to be designated as either a stream or a lake. Streams and rivers were designated as streams due to their measurable flow rates, while all other types were designated as lakes due to their negligible flow rates. **Table B-4** lists the NHDplus water body types identified near CCR WMUs and facilities, along with a crosswalk to the stream or lake designation assigned to that type.

Table B-4. NHDplus Water Body Types Assigned to CCR Disposal Facilities

NHDplus Water Body Type	Reach Model Type	Number of CCR Facilities	Surface Impoundments	Landfills
Connector	Stream	3	4	2
CanalDitch		11	11	6
ArtificialPath		173	372	148
Stream/River		264	540	416
Reservoir	Lake	3	2	2
Playa		2	11	0
Coastline		24	51	15
Lake/Pond		82	183	79

Stream Flow Conditions and Dimensions

NHDplus includes estimates of the mean annual stream flow rates for all flowing reaches, as well as the velocities that correspond to these mean flows. Stream dimensions were calculated from the NHDplus flow data as follows. First, the length of the modeled stream segment was set equal to the width of the ground water plume as it enters the water body, which was determined by EPACMTP. The stream width was then derived from the flow rate using an equation derived from empirical data by Kocher and Sartor (1997):

(B-1) $$W = 5.1867Q^{0.4559}$$

Where:

W = Stream width (L); and

Q = Mean annual stream flow rate (L^3/T)

The water column depth was then derived using the continuity equation, which assumes that a stream's flow rate is equal to the product of its cross-sectional area occupied by flow and mean flow velocity:

(B-2) $$Q = Av$$

Where:

A = Cross-sectional area occupied by flow (L^2); and

v = Mean annual stream flow velocity (L/T)

Rearranging and solving for water column depth (with dwc = A/W):

(B-3) $$dwc = \frac{Q}{vW}$$

Where:

dwc = Water column depth (L)

Lake Flow Conditions and Dimensions

Exact areas and depths were not readily available for many of the lakes located near facilities from either NHDplus or other sources. In addition, some facilities were located on very large water bodies (e.g., the Great Lakes) where applying the simple steady-state, single-compartment model used in this analysis to the entire water body would not be appropriate because contamination would be localized to a specific portion of that water body. Thus, a single, small lake (or model lake) was used to represent all lake water body types assigned to the CCR disposal facility. This was considered appropriate because it captures the impact of localized effects through a conservative approximation of much larger lakes. The model lake chosen was Shipman City Lake in Illinois, which is a well characterized 13-acre lake previously selected by EPA as the index reservoir for modeling drinking water exposures to pesticides (Jones et al., 1998). The parameter values for Shipman City Lake are shown in **Equation B-4**.

(B-4) $$V = \frac{A(dwc)}{HRT}$$

where:

V = Annual flow mixing volume (L3/T);
A = Area (13 acres);
dwc = Water column depth (9 ft); and
HRT = Hydraulic residence time [1 month (min), 6 months (mean), 24 months (max)].

B.5.4 Stream and Lake Water Quality Data

EPA's STORET system is the largest single source of water quality data in the country, containing over 275 million analyses performed on more than 45 million samples collected from 800,000 stations across the United States between the years of 1960 and 1998. Data on raw surface water temperature, TSS and pH were collected from the legacy STORET database based on the assigned USGS hydrologic region for use in the surface water model. However, the STORET website states:

> *"The EPA does not change or filter incoming data. This means that when pulling data out of the Warehouse, users must be aware that they are responsible for screening the data for their use."*[6]

EPA notes that there is a high degree of variability in the data due to differences in quality assurance/quality control testing , bias towards samples collected at site locations known to have contamination problems, and bias towards samples collected during critical periods (e.g., summer low flows). To account for these factors, EPA used the STORET data as discussed below.

Surface Water Temperature

Median surface water temperatures were collected for each hydrologic region and assigned to each facility centroid using GIS. Median values were selected in order to capture an appropriate annualized value while minimizing the impact of variability. These temperatures are provided for

[6] Available online at: www.epa.gov/storet/about.html

each hydrologic region in **Table B-5**, as well as the number of modeled facilities and WMUs assigned to each region.

Table B-5. Regional Surface Water Temperatures: CCR Disposal Facilities

Hydrologic Region	Median Surface Water Temperature (°C)	Number of CCR Facilities	Number of CCR Surface Impoundments	Number of CCR Landfills
1	14	5	19	8
2	16	25	36	32
3	21	60	130	51
4	14	36	71	40
5	17	81	244	87
6	18	8	29	7
7	15	51	119	38
8	20	5	13	4
9	10	1	0	7
10	13	49	118	78
11	17	22	50	21
12	21	15	56	30
13	16	1	5	1
14	9	14	31	18
15	17	5	22	5
16	9	3	6	2
17	11[a]	2	3	2

Data source: Legacy STORET database.

[a] Legacy STORET data were not available for Hydrologic Region 17 at the time of this CCR data collection effort. A median temperature of 11 was assigned to be representative of the cooler surface water temperatures anticipated in the mountainous Pacific northwest region.

Total Suspended Solids

Median annual TSS values were collected for each hydrologic region and assigned to each facility centroid using GIS. Medians were selected in order to capture an appropriate annualized value while minimizing the impact of variability. Data were collected separately for streams and lakes because the latter grouping tends to have lower TSS levels as a result of reduced sediment disturbance from moving water.

Minimum, maximum and weighted geometric means of these collected values were used to define log triangular distributions regionally for streams, but only nationally for lakes due to more limited data. The triangular distribution was selected because it is typically used to describe a population for which there is only limited sample data, but there is sufficient knowledge to determine that the

distribution is modal, rather than uniform, as was the case here. Geometric means weighted by the annual number of measurements were used because the actual distribution around the median is unknown. Once developed, these distributions were sampled during the preparation of the input data files. **Table B-6** provides the TSS values used to define the distribution for each region, along with the number of the modeled facilities assigned to that region.

Table B-6. Surface Water Total Suspended Solids (TSS) Distributions

Hydrologic Region	Number of CCR Facilities	Number of Samples	Number of Annual Median Values	Annual Median TSS (log-triangular distribution)		
				Minimum	Maximum	Weighted Geometric Mean
1	5	9,007	33	3.2	40	8
2	25	47,202	38	10	316	32
3	54	43,395	36	6.3	79	25
4	21	29,577	37	6.3	794	25
5	77	39,900	38	4	100	25
6	5	4,137	28	5	316	16
7	49	34,494	37	32	1,585	63
8	4	46,231	38	50	316	158
9	1	3,254	35	13	3,162	32
10	49	62,791	38	10	398	126
11	21	48,969	38	25	794	200
12	12	7,280	35	40	1,995	79
13	1	13,974	37	32	79,433	200
14	13	26,699	38	16	5,012	158
15	4	9,162	37	20	19,953	200
16	3	19,965	33	4	2,512	16
17	2	173,136	37	2	316	6
Lakes	109	4,360	99	1	398	25

Data source: Legacy STORET database.

Note: Because both lakes and streams can be modeled for the same facility, the total count of facilities in this table exceeds 383.

Surface Water pH

Median annual pH values were collected for each hydrologic region and assigned to each facility centroid using GIS. Median values were selected in order to capture an appropriate annualized value while minimizing the impact of variability. Because pH data are already log scale, the minimum, maximum and weighted averages of these collected values were used to define triangular distributions for each hydrologic region. The triangular distribution was selected

because it is typically used to describe a population for which there is only limited sample data, but there is sufficient knowledge to determine that the distribution is modal, rather than uniform, as was the case here. Once developed, these distributions were sampled during the preparation of the input data files. **Table B-7** provides the pH values used to define the distribution for each region, along with the number of the modeled facilities assigned to that region.

Table B-7. Regional Surface Water pH Distributions

Hydrologic Region	Number of CCR Facilities	Number of Samples	Number of Annual Median Values	Annual Median pH (triangular distribution)		
				Minimum	Maximum	Weighted Average
1	5	232,025	38	5.9	7.7	6.5

B.6 National Drinking Water Well Distribution

Residents that use ground water from private wells as a source of potable water may be exposed to COPCs through the GW→DW pathway. Therefore, the location of these wells relative to the surface impoundments and landfills is an important parameter for the risk assessment. Since the human population is not evenly distributed across the landscape, EPA used synthetic population data to place each household and its occupants as discrete points. Synthetic populations are a

representation of households and individual residents in a given area based on methods to identify realistic locations.

Synthesized households and residents are placed to match the population distribution estimated by the LandScan USA 90-meter gridded population data set (Bhaduri, 2007), which distributes the U.S. population across a grid of 90-meter square cells using a combination of satellite imagery and other geographic data layers, including 2000 Census boundaries. The placement of synthesized households is constrained to match the population within a given 2000 Census block. Once a set of households is selected for a particular 90-meter grid cell, they are placed randomly within that 90-meter area. As a result, LandScan USA provides estimates of household locations at a finer resolution than is available from the 2000 Census data alone.

Figure B-4 provides an example CCR landfill and the corresponding synthetic household placement. The WMU centroid and estimated perimeter are shown, as well as a series of dashed-line buffers spaced at 0.2-mile (~ 300 meters) intervals from the WMU perimeter up to one mile away for an idea of scale. Synthetic population households are shown primarily along roadways. Although the household locations do not necessarily coincide with actual house locations, their locations are representative of typical dwelling location distributions as can be seen in the figure.

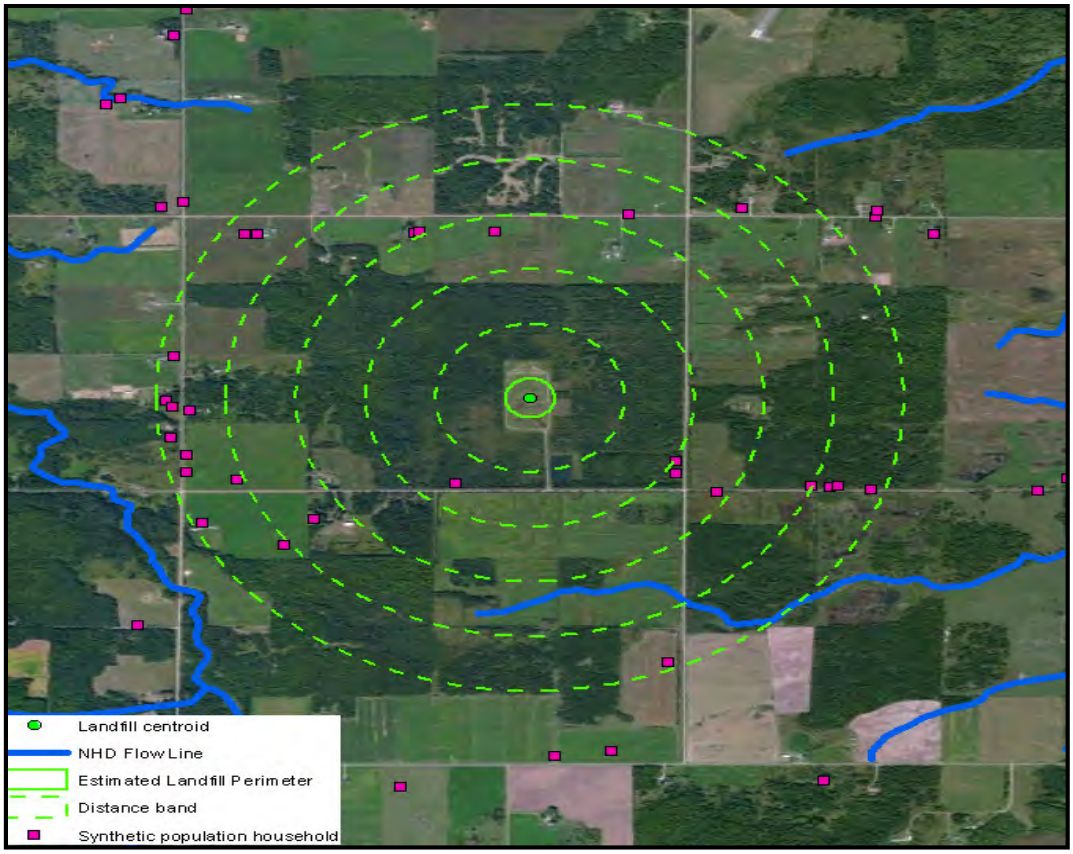

Figure B-4. Synthetic population locations in the vicinity of an example CCR landfill.

The GW→DW pathway considers residential exposure from the use of well water as a source of potable water. The revised risk assessment considered potential risks to highly exposed individuals, which are hypothetical receptors that represent an upper bound of the range of realistic exposures that may occur within the modeled population. Therefore, a GIS algorithm was applied to identify the nearest household from the edge of the WMU. Since houses were randomly placed within a 90 m grid, aerial photographs were visually inspected for all distances less than 150 m (approximately 1.5 grid lengths) to ensure that the location assigned aligned with the location of an actual residence. The associated receptor distances were corrected as necessary.

Figure B-5 shows the cumulative probability distributions for the distance to nearest receptors for CCR impoundments and landfills. Also included for comparison are the well distances used in the 2010 Risk Assessment, which were drawn from an earlier survey of municipal solid waste landfills (U.S. EPA, 1988). As these comparisons indicate, the three distributions are similar, but residents tend to be located somewhat further away from CCR WMUs. Among the CCR WMUs, residents tend to live closer to landfills (minimum of 20 m) than surface impoundments (minimum of 50 m), though much of the distinction between the two disappears at greater distances.

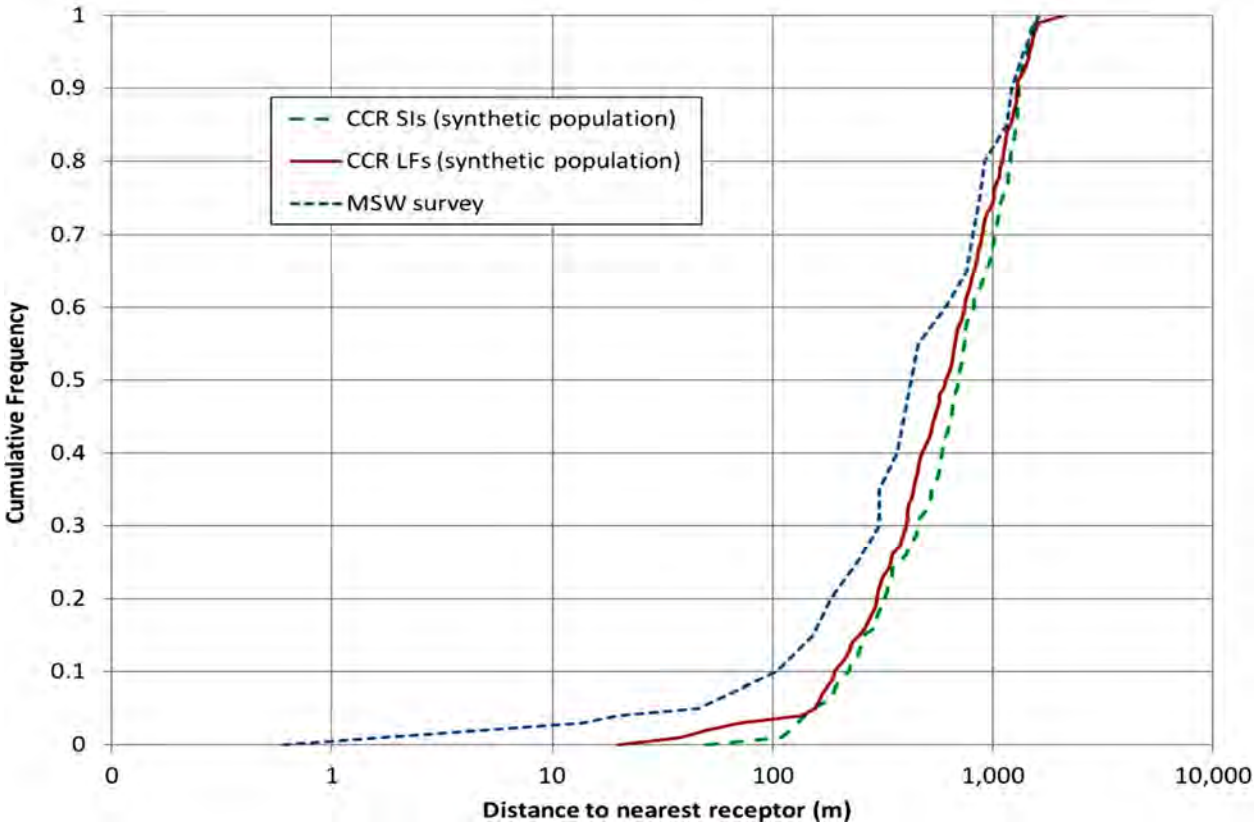

Figure B-5. Cumulative probability distributions for the distance to nearest receptor.

Appendix C.

Constituent Data

[This Page Intentionally Left Blank]

C.1 CCR Constituent Database

This risk assessment addresses metallic and other inorganic constituents identified as constituents of potential concern (COPCs) in coal combustion residuals (CCRs). The CCR constituent database contains data collected over a series of CCR-related regulatory activities from 1998 through 2010, as follows:

- CCR and CCR leachate data used in the 1998 Risk Assessment (U.S. EPA, 1998a,b) and documented in the 1999 Report to Congress ("1999 RTC") (U.S. EPA, 1999);
- Data submitted to EPA through public comments on the 1999 RTC;
- Data submitted to EPA through public comments on the 2000 Regulatory Determination;
- Data submitted to and collected by EPA after the close of the public comment period for the 2000 Regulatory Determination;
- Data submitted to EPA through public comments on the 2010 Proposed CCR Rule;
- Data developed by EPA's Office of Research and Development using the Leaching Evaluation Assessment Framework (LEAF) test methods (U.S. EPA, 2009); and

Attachment C-1 provides a complete list of the data sources contained in the updated 2014 database that were considered in this risk assessment. The data in the CCR constituent database characterizes the concentrations of COPCs present in and released from CCRs. In addition to COPC concentrations, this database also provides information, as available, on the coal burned at the facility and the type of CCR(s) analyzed. The CCR constituent database includes CCRs generated from the major coal ranks: bituminous, sub-bituminous, and, to a lesser degree, lignite and anthracite. In some cases, the coal rank associated with samples in the database is not specified, partly because many facilities mix coals from different sources over time based on a number of factors, such as fuel cost and the need to reduce sulfur levels. The CCR constituent database also includes data on all major types of CCRs, which include fly ash, bottom ash, boiler slag, and flue gas desulfurization (FGD) waste. Similar to coal type, many of the available samples reflect the practice of codisposal, such as fly ash with bottom ash or CCRs with coal refuse. Thus, the CCR constituent database provides a snapshot of current management practices across a broad cross-section of the regulated universe, with a large number of samples collected from sites in 30 states. **Table C-1** lists the data evaluated in this risk assessment, along with the number of sites representing each waste type in the CCR constituent database.

Table C-1. Waste Types in the 2014 CCR Database

CCR Type	Number of Sites by Waste Type		
	Impoundment Wastewater	Impoundment Pore Water	Total Waste
Combined Ash	9	18	67
Ash and Coal Refuse	0	5	1
FGD Waste	2	7	6

C.2 Intra-site Variability

The 2010 Risk Assessment (U.S. EPA, 2010) averaged all of the samples collected at each site for each constituent and waste stream (impoundment surface water, impoundment pore water and whole waste) to create a single concentration for each site, constituent, and waste stream. EPA initially chose this approach in order to avoid the potential to bias the evaluation results toward sites with more samples. However, that approach was found to not adequately account for intra-site variability. Therefore, in the revised risk assessment, EPA relied on a quartile approach to retain more of the intra-site variability lost through the use of site averages. To develop the site quartiles, EPA first separated the data for each site, constituent, and waste stream by waste type (i.e., combined ash, ash and coal waste, FGD waste). Combining the data for the different waste types into a single set of quartiles for a site might bias concentrations toward the most sampled waste types. Therefore, quartiles were calculated for each waste type at each sample site for each waste stream and constituent. Where only one sample was available for a waste type at a sample site, all of the quartiles were set to this value to ensure equal weighting.

Nondetect analytical results were included using a value of half the reported detection limit. For the screening analysis, the 90th percentile of these quartiles across all sites and waste streams was calculated and used. For the full-scale probabilistic analysis, the Monte Carlo simulation sampled from the site-specific quartiles for each constituent and waste stream. **Attachments C-2** through **C-4** provides the quartiles used (sampled) in the full-scale CCR risk assessment by waste type/WMU scenario for CCR impoundment wastewater, pore water and whole waste, respectively. **Attachment C-5** provides a list of the constituents that have concentration data and notes which types of concentration are available (pore water, impoundment wastewater or whole waste).

C.3 LEAF Data

For surface impoundments, the revised risk assessment applied the data from the CCR constituent database in the same way as the 2010 Risk Assessment. For landfills, the 2010 Risk Assessment relied on a hierarchy of dissolved concentration data, ranging from field leachate data to toxicity characteristic leaching procedure. Since that time, new data have been made available through a series of EPA reports (U.S. EPA 2006, 2008, 2009) that examined the effects of coal rank and changes in air pollution control technologies on CCR leaching behavior. The leaching test methods used to evaluate leaching behavior are from the EPA SW-846 LEAF methods. The interlaboratory validation for these methods are described in U.S. EPA (2012a,b), while Kosson et al. (2002) provides the detailed test methodology for Methods SR02 and SR03.[1] These data were collected with three of the LEAF test methods, specifically SW-846 Methods 1313, 1314 and 1316. The data from these three methods were used together to develop the source term to characterize leaching from landfills considering geographically distributed, site-specific conditions and uncertainties to form a set of disposal scenarios that were used in the risk assessment. All three of these methods are briefly summarized in the following text.

[1] Methods SR02 and SR03 are predecessor methods to SW-846 Methods 1313 and 1316.

C.3.1 Summary of LEAF Methods Used

Method 1313: Liquid-Solid Partitioning as a Function of Eluate pH using a Parallel Batch Extraction Procedure

Method 1313 is a leaching test designed to estimate constituent concentrations in eluate as a function of pH. This procedure consists of nine separate parallel batch extractions, which involve placing a given mass of ash in a container with a specific volume of eluent to achieve a L/S ratio of 10 mL/g-dry. Each eluent is buffered using a dilute acid or base to achieve different target pH values ranging between 2.8 and 13. One of these values is the natural pH of the material (also referred to as "own pH"), which is achieved by allowing the material to equilibrate with deionized water. The extraction contact time ranges somewhere between 24 and 72 hours, based on the grain size of the material "as tested." This may be distinct from the grain size of the material "as received," because particle size reduction or air drying may be required either to improve handling and to achieve equilibrium between the liquid eluent and solid sample within a reasonable extraction timeframe. Solid and liquid phases are separated by either vacuum- or pressure-assisted filtration and prepared for chemical analysis. The measured eluate concentrations are plotted as a function of final pH for each batch. Eluate concentrations may be interpolated between these measured concentrations to provide a uniform basis for comparison, as the final measured eluate pH values are likely to differ marginally from the target values. The data collected with Method 1313 were used to characterize the leaching behavior of different CCRs as a function of pH and total leachable content. **Figure C-1** compares example concentration profiles for four constituents as a function of pH for three duplicate samples of the same ash (Sample ID: EaFA). For this waste, the arsenic (As) leachate concentrations ranged over about two orders of magnitude, with peak concentrations at the highest and lowest pH, and a minimum concentration at a pH of approximately 5.6. Chromium (Cr) concentrations varied by over four orders of magnitude across the same range, with a minimum at a pH of 5.6, while molybdenum (Mo) and calcium (Ca) ranging over a little more than an order of magnitude. Additional information on this subject can be found at U.S. EPA (2009).

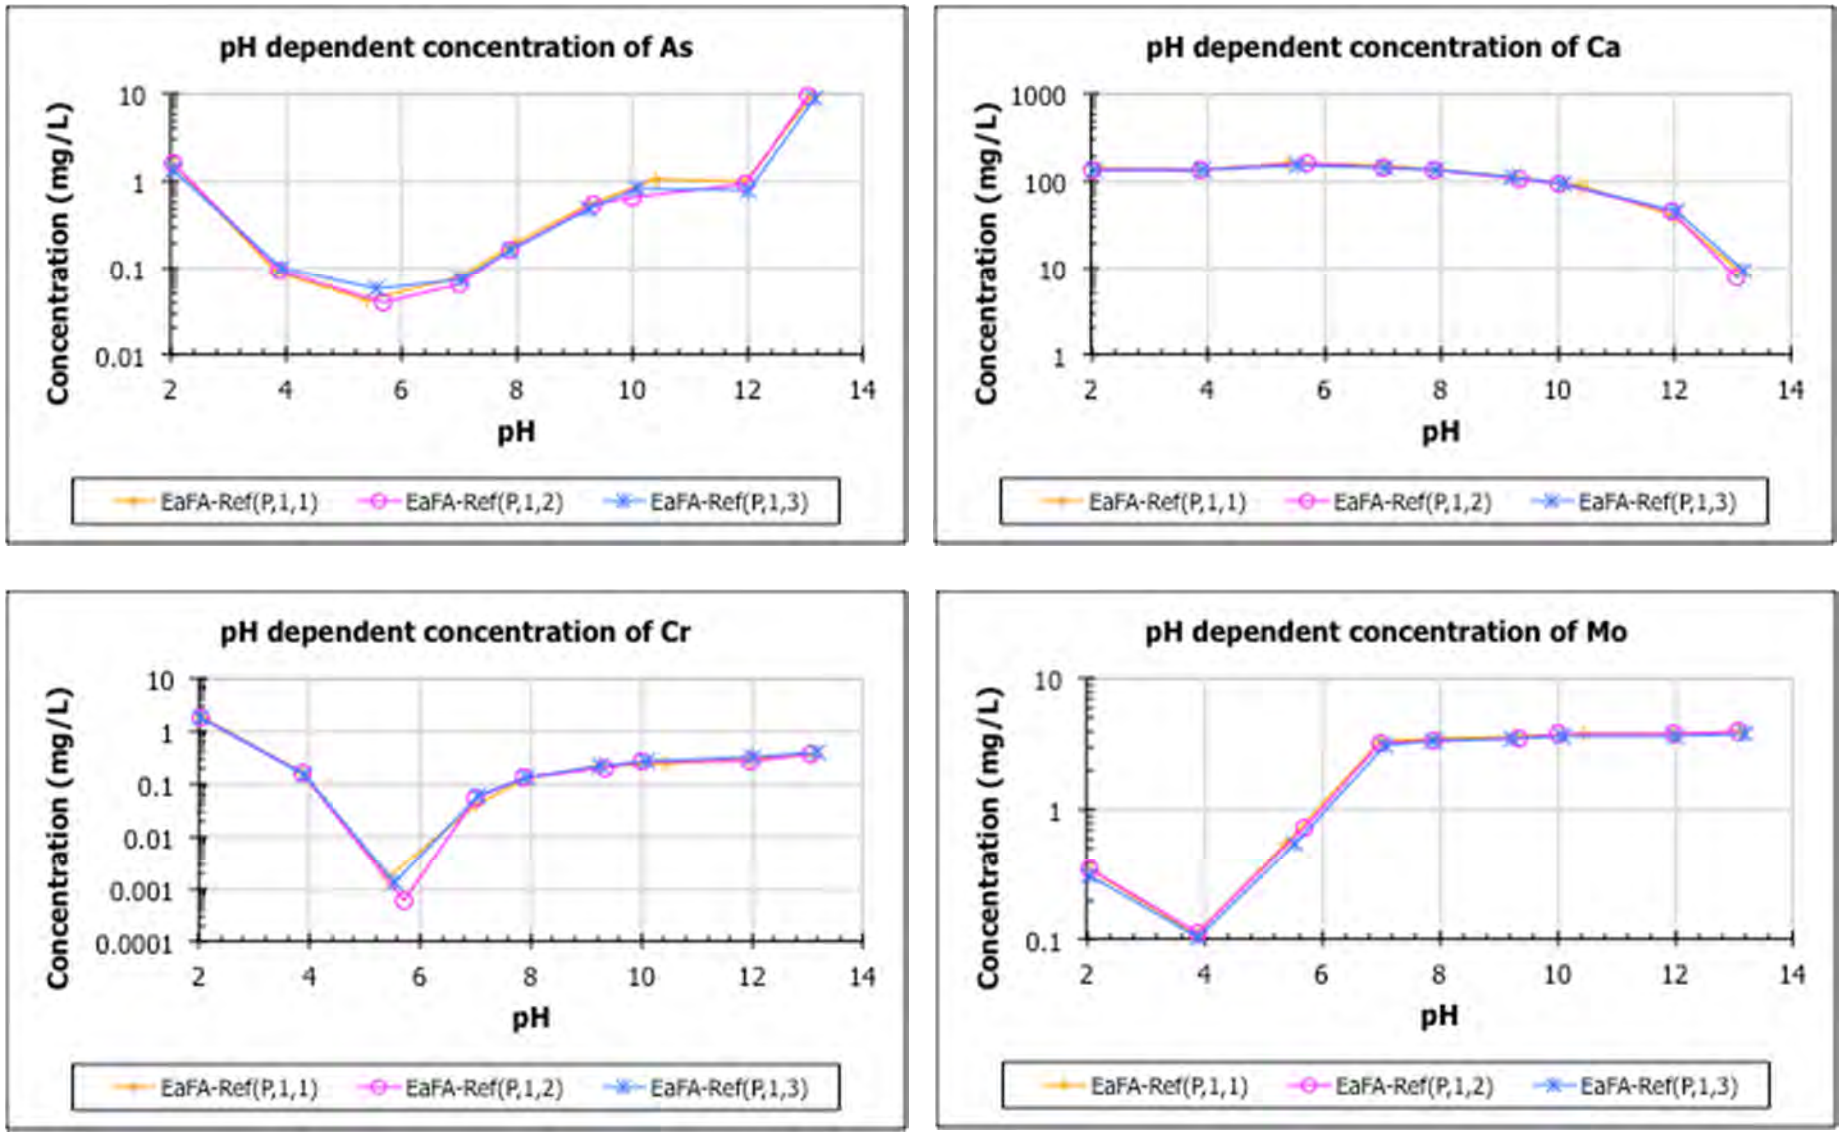

Figure C-1. Example eluate concentrations as a function of pH as obtained from Method 1313 on coal fly ash sample EaFA (Adapted from data in U.S. EPA, 2012a).

Method 1314: Liquid-Solid Partitioning as a Function of Liquid-to-Solid Ratio (L/S) for Constituents in Solid Materials Using an Up-Flow Percolation Column Procedure

Method 1314 is a leaching test designed to estimate constituent concentrations in eluate as a function of the cumulative L/S ratio. This procedure consists of five separate, parallel upflow percolation columns, which involves percolating deionized water through a given mass of moderately compacted ash against the force of gravity. The upflow percolation is intended to minimize air entrainment and preferential flow channeling. The flow rate is maintained at a level corresponding to in an increase of the L/S ratio between 0.5 and 1.0 mL/g-day in order to increase the likelihood of local equilibrium developing between the liquid eluate and solid ash. Samples are collected each time a specified cumulative L/S ratio has been reached. For the purposes of chemical speciation modeling, the entire eluent volume up to 10 mL/g of dry sample is collected in nine specific aliquots of varying volume. The data collected with Method 1314 were used together with those from Method 1316 to verify that the application of the Method 1313 data, which is collected at a single (10 mL/g) L/S ratio, provides a conservative estimate for peak leachate concentrations. **Figure C-2** shows example results of eluate concentrations as a function of the L/S ratio. Both arsenic and chromium show highest concentrations at the lowest and highest L/S ratio tested, while calcium and molybdenum leachate concentrations peak at just less than an L/S of 1 mL/g (L/kg).

Method 1316: Liquid-Solid Partitioning as a Function of Liquid-to-Solid Ratio using a Parallel Batch Extraction Procedure

Method 1316 is a leaching test designed to estimate constituent concentrations in eluate as a function of L/S ratio. This procedure consists of five separate parallel batch extractions, which involve placing a given mass of ash in a container with a specific volume of eluent. Each batch is set to a different, constant L/S ratio ranging between 0.5 and 10 mL/g-day. Particle size reduction of the solid material may be required in order to facilitate the approach to liquid-solid equilibrium. The extraction contact time ranges somewhere between 24 and 72 hours, based on the grain size of the material "as tested." This may be distinct from the grain size of the material "as received," because particle size reduction or air drying may be required either to improve handling and to achieve equilibrium between the liquid eluent and solid sample within a reasonable extraction timeframe. Solid and liquid phases are separated by either vacuum- or pressure-assisted filtration and prepared for chemical analysis. The measured eluate concentrations are plotted as a function of L/S ratio. This method provides data on the changes in equilibrium chemistry (i.e., ionic strength, constituent concentrations) as the L/S ratio value approaches values found within the solid phase pore solution. The data collected with Method 1316 were used together with those from Method 1314 to verify that the application of the Method 1313 data, which is collected at a single L/S ratio, provides a conservative estimate for peak leachate concentrations. **Figure C-3** shows example results of eluate concentrations as a function of the L/S ratio as obtained from parallel batch extractions using Method 1316.

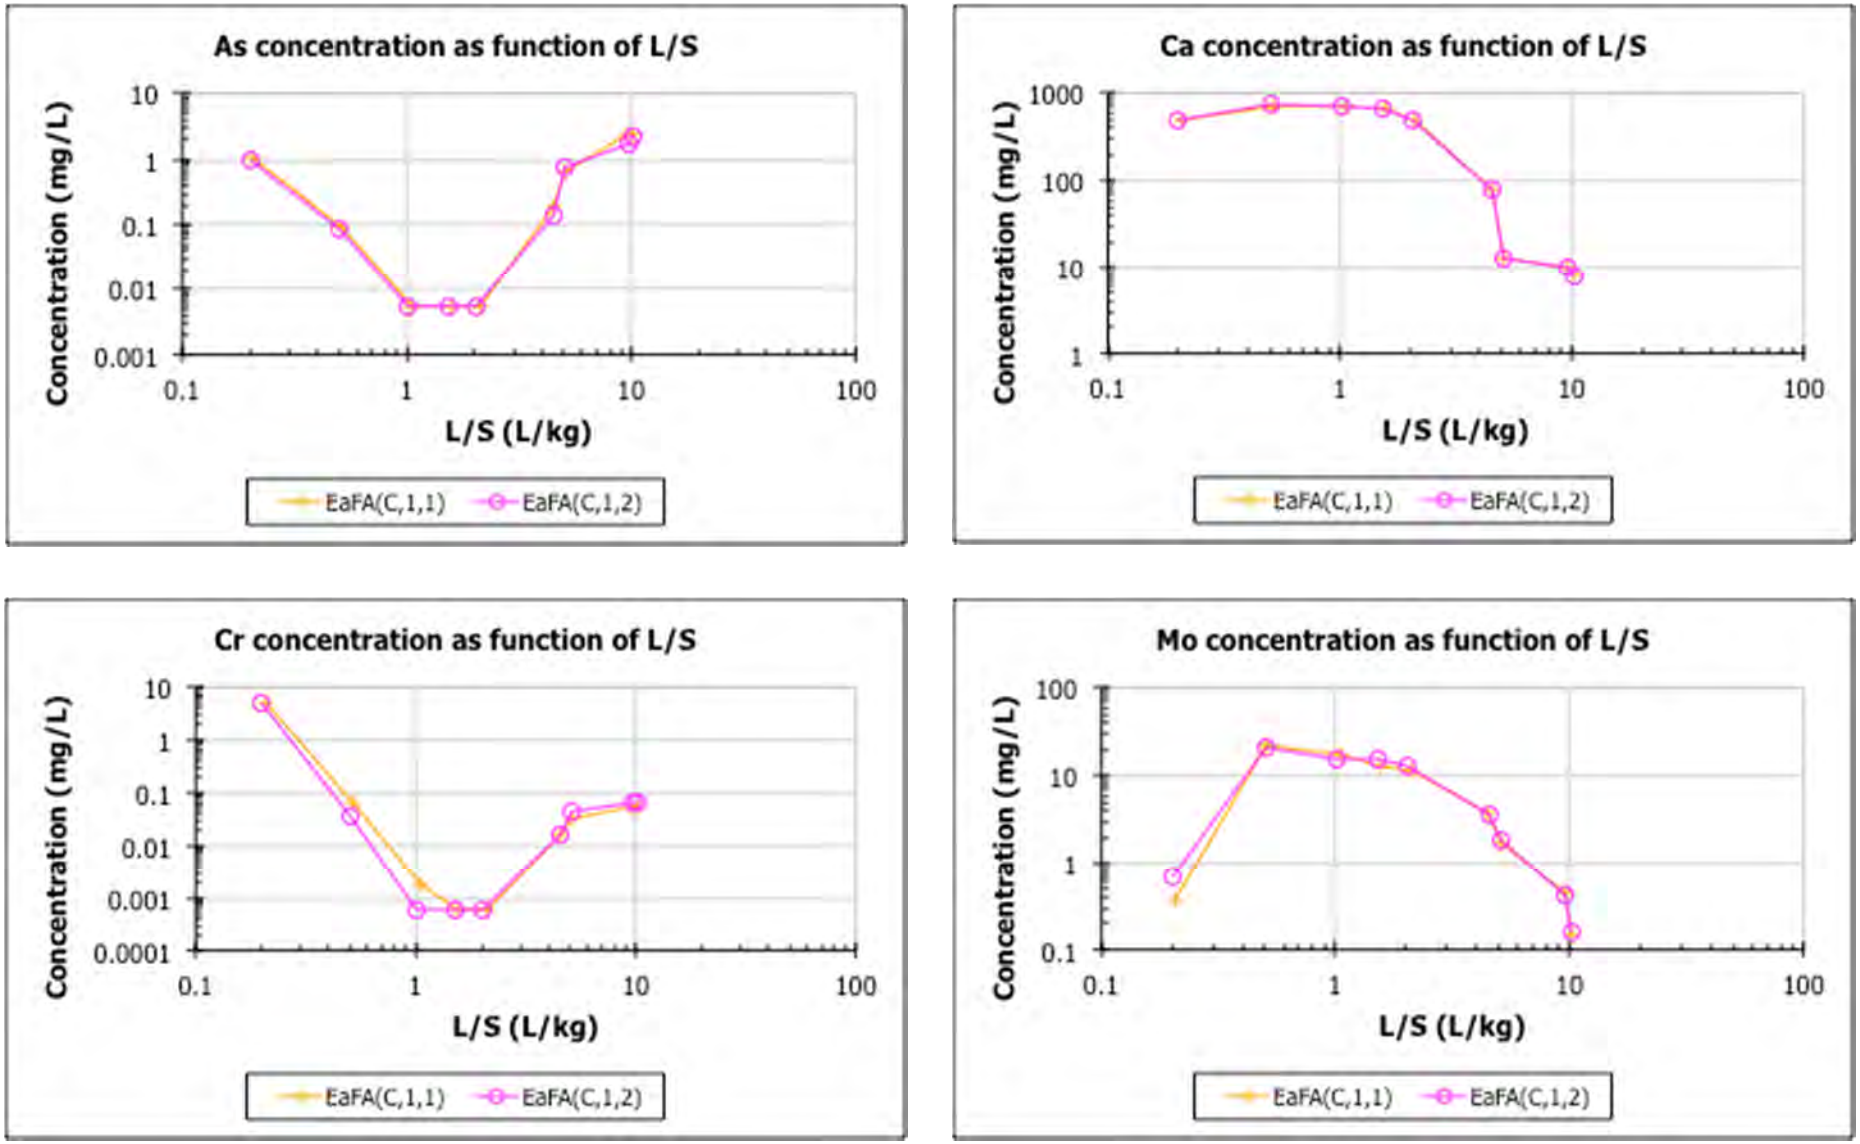

Figure C-2. Eluate concentrations as a function of L/S ratio as obtained from Method 1314 applied to coal fly ash sample EaFA (Adapted from data in U.S. EPA, 2012a).

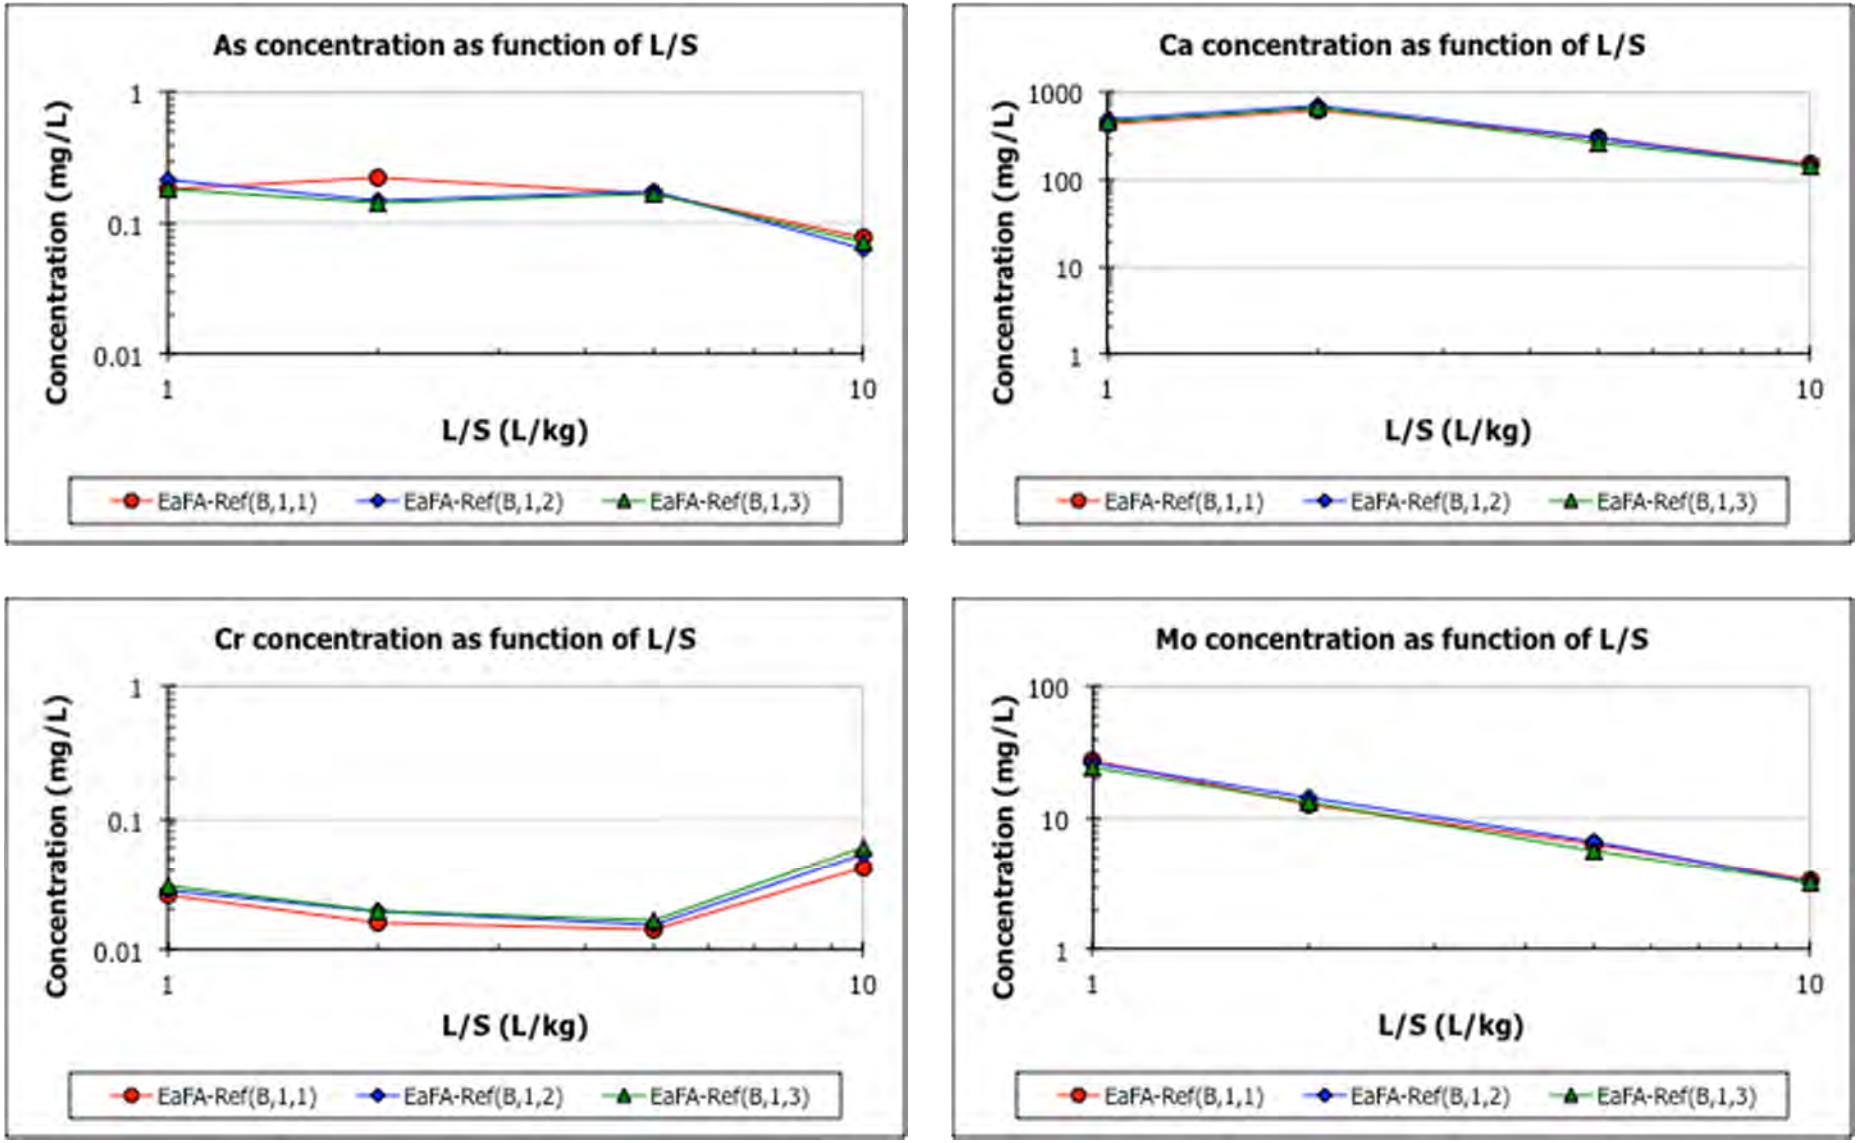

Figure C-3. Eluate concentrations as a function of L/S ratio as obtained from Method 1316 applied to coal fly ash sample EaFA (Adapted from data in U.S. EPA, 2012a).

C.3.2 Constituent Leaching Behavior

The leaching behavior of constituents, as defined by the Method 1313 data, can be divided into the following categories: washout-controlled and solubility-controlled. A single constituent may alternate between the two categories over the relevant pH range (e.g. some constituents may be washout-controlled at a low pH and solubility-controlled at a high pH, while other constituents display the opposite behavior). In addition, this behavior profile is not constant for a constituent across all CCR types. A given constituent may fall entirely into the washout-controlled zone when leached from ash generated by one combination of coal type and pollution control technology, but enter the solubility-controlled zone when leached from ash generated by a different combination. With these considerations in mind, the two leaching categories are briefly described below.

The washout-controlled zone is characterized by the quick dissolution and release of the more soluble species (e.g., sodium, potassium) from the ash into the pore water. In Method 1313 data, this behavior is characterized by a generally constant leachate concentration over a pH range. **Figure C-4** shows an example of an ash (Sample ID: AaFA) for which boron falls in the washout-controlled zone over the entire pH range evaluated and leachate concentrations are almost constant.

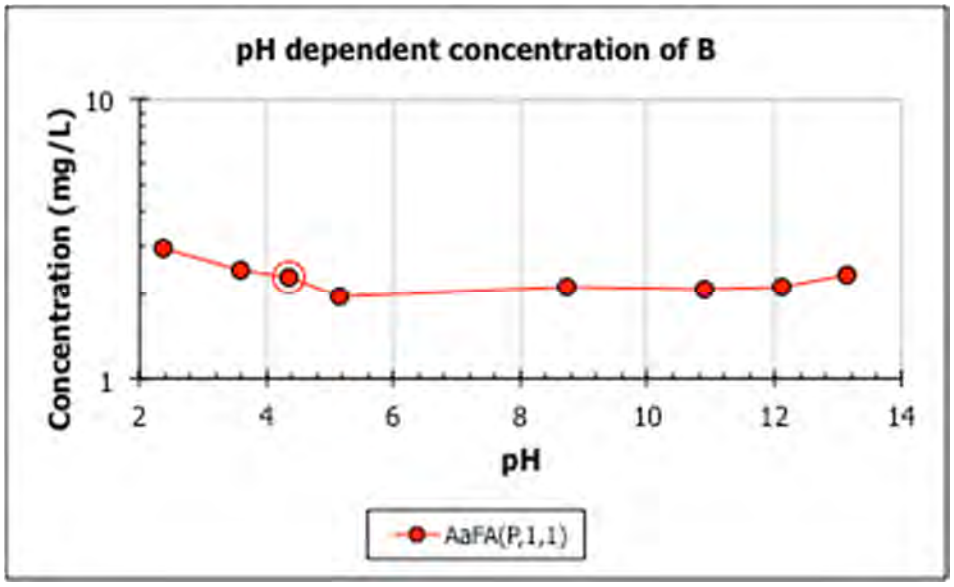

Figure C-4. Example of a washout-controlled species over the full experimental pH domain for sample AaFA (Adapted from data in U.S. EPA, 2009).

The solubility-controlled zone is characterized by a slower release of less soluble species (e.g., calcium, aluminum) where the leachate concentration is controlled by solubility of the species at a specific pH value. In Method 1313 data, this is characterized by variable leachate concentrations over the pH range. **Figure C-5** shows an example of an ash (Sample ID: AaFA) for which chromium falls within the solubility-controlled zone over the entire pH range. Note that concentrations vary by almost two orders of magnitude over the pH range evaluated.

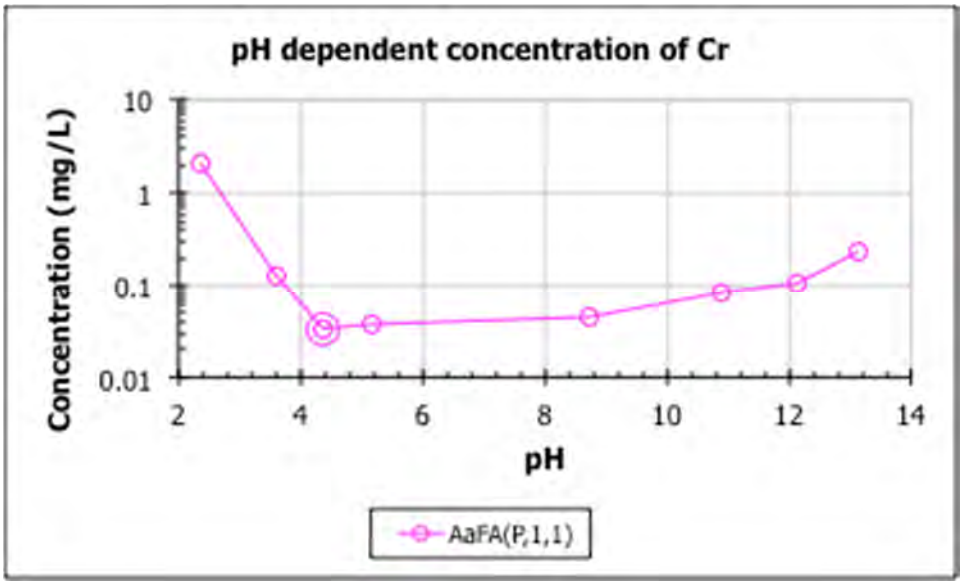

Figure C-5. Example of a solubility-controlled species over the full experimental pH domain for sample AaFA (Adapted from data in U.S. EPA, 2009).

In some cases, a constituent may be washout-controlled over one part of the pH range and solubility-controlled over another. **Figure C-6** shows an example of an ash (Sample ID: AFA) for which boron is washout-controlled, with an almost constant leachate concentration for pH values less than eight, and solubility-controlled for pH values above eight.

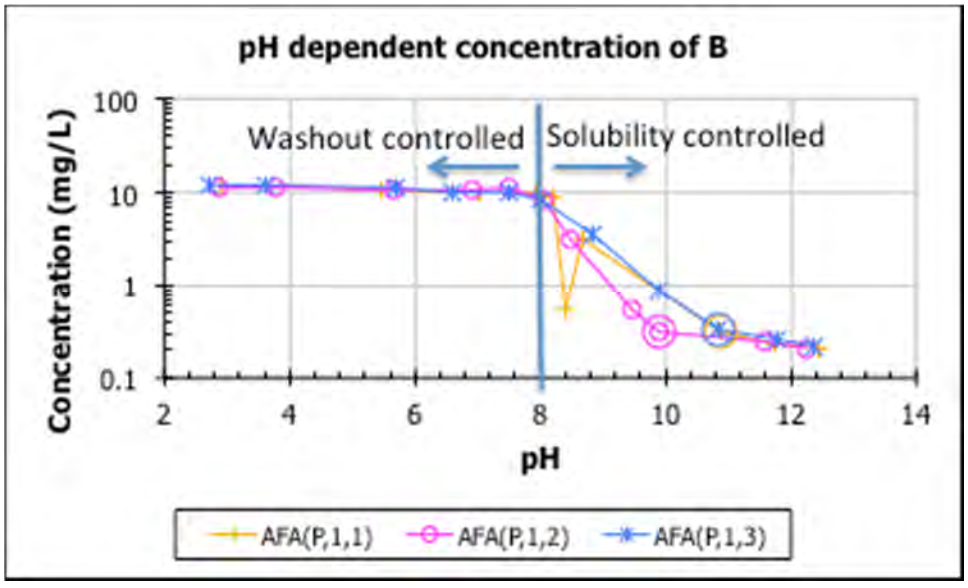

Figure C-6. Example of a part washout- and part solubility-controlled species triplicate measurements of sample AaFA (Adapted from data in U.S. EPA, 2009).

C.3.3 Data Preparation

During the waste sampling and LEAF analysis conducted to develop constituent concentrations for landfills, EPA determined that the range and variability of different waste chemistry was best represented by a single pH distribution for all waste types (U.S. EPA, 2009). Even though on a single distribution, it still effectively captures the different waste types. For example, low pH conditions were used to represent codisposal of CCR with coal refuse.

To accommodate this single distribution within the CCR Metal Speciation Equilibrium Model for Surface and Ground Water (MINTEQA2) modeling construct, the waste types for landfills were modeled using a single combined ash isotherm, and risk results were evaluated across all landfill waste types. To select a MINTEQA2 isotherm for each iteration of the Monte Carlo analysis for landfills, a leachate pH was randomly selected from the distribution, a combined ash waste type was assumed, and aquifer type was assigned based on the location of the landfill being modeled (see **Appendix B, Section B.3)**. Iron oxide, natural organic matter, and leachate ionic strength were then randomly selected based on the combined ash waste type to identify the unsaturated and saturated zone isotherms to be used for a particular model run. How these data were prepared for and used by EPA's Composite Model For Leachate Migration With Transformation Products (EPACMTP) is described in **Appendix I**.

The LEAF-generated landfill leachate data were consolidated into a single data set for the revised risk assessment. The Method 1313 data were organized into a series of tables, each containing the data collected for each ash sample, as described in U.S. EPA (2009). The landfill leachate data tables also included a measured availability (in mg/kg) for each constituent and waste that was used by the EPACMTP landfill model to provide a limit in the constituent mass that can be leached from a particular CCR waste at a particular leachate concentration. **Attachment C-7** provides each of these generated tables. Availability data, by constituent, are at the bottom of each table.

Appendix D.

Human Exposure Factors

[This Page Intentionally Left Blank]

D.1 Introduction

Exposure factors are data that quantify human behavior patterns (e.g., ingestion rates of drinking water and fish) and physiological characteristics (e.g., body weight) that affect an individual's exposure to environmental contaminants. These data can be used to construct realistic assumptions concerning the magnitude of exposure to and subsequent intake of a contaminant in the environment. The exposure factors data also enable the U.S. Environmental Protection Agency (EPA or the Agency) to differentiate the exposures of individuals of different ages. The derivation of human exposure factors used in both the screening and probabilistic analyses are described below.

D.1.1 Data Sources

The Agency relied primarily on the *Exposure Factors Handbook* (*EFH*) (U.S. EPA, 1997a,b,c) for data on adult receptors and the *Child-Specific Exposure Factors Handbook* (*CSEFH*) (U.S. EPA, 2008) for data on child receptors. Where sufficient data were available, the percentiles and corresponding data points obtained from these two sources were used to develop a cumulative distribution in order to capture variability within the U.S. population. Otherwise, EPA relied on point values selected based on the recommendations of the EFH, CSEFH or established Agency guidance (U.S. EPA, 1991).

EPA acknowledges that the 2011 *Exposure Factors Handbook* (U.S. EPA, 2011) has been completed and updates some of the data from the 1997 EFH and 2008 CSEFH. During the finalization of this risk assessment, EPA released *Office of Solid Waste and Emergency Response Directive 9200.1-120* (U.S. EPA, 2014). Although this document provides protective, default exposure factors to use as point estimates, EPA is still in the process of updating the full distributions necessary for a probabilistic analysis. Therefore, this risk assessment does not incorporate the data from the 2011 EFH and instead relies on the 1997 EFH and 2008 CSEFH, referred to simply as the "EPA exposure factor data" throughout the remainder of this appendix.

D.1.2 Age Cohorts

There has been considerable effort across the Agency to improve the accuracy and consistency of childhood exposure assessments. In the *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (U.S. EPA, 2005), EPA recommended specific age cohorts (i.e., groups) intended to better capture the large variability in physiological and behavioral characteristics of child receptors during different stages of development. Narrower age cohorts were identified where rapid developmental changes occur, while broader age groups were identified where the rate of development decreases. These age groupings and the supporting rationale for their selection have been subjected to internal and external scientific peer review. In total, receptors were divided into the eight distinct age cohort groupings recommended by U.S. EPA (2005). **Table D-1** below presents a comparison between the age groups used in the 2010 Risk Assessment and those used in the revised risk assessment. As seen in this table, this risk assessment adopts the notation proposed in U.S. EPA (2005), where

age groupings are described in terms of "X to < Y." For example, the age cohort of "3 to < 6 years" represents a 3-yr time interval from a child's third birthday up until the day before the child's sixth birthday.

Table D-1. Age Cohorts Used in the 2010 and Revised Risk Assessments

2010 Age Cohorts	Revised Age Cohorts
Not Evaluated	Infant (< 1 year)
1 to 5 years	1 to < 2 years
	2 to < 3 years
	3 to < 6 years
6 to 11 years	6 to < 11 years
11 to 20 years	11 to < 16 years
	16 to < 21 years
Adult (> 20 years)	Adult (> 21 years)

D.2 Exposure Factors for Screening Analysis

EPA conducted a deterministic screening analysis by using point estimates for all exposure factors. The majority of the exposure factors were set to median values in this analysis because the purpose was to streamline the evaluation and identify the constituents of potential concern most likely to pose risk to receptors. Where available distributions were not comprehensive enough to allow identification of a median value, high-end values were used instead. In addition, averaging time (i.e., anticipated lifetime over which cancer may occur) was set to a high-end because of the dependency between this exposure factor and many toxicity values used to calculate cancer risks. In instances where data were not available for a specific age cohort, the data fit to the closest age cohort available was used instead. Consistent with the regional screening tables used in the Superfund program, EPA screened risks using children and adult age cohorts, but not infants. The specific values used in the screening analysis are presented in **Table D-2**. These values are point estimates selected from the distributions developed for the probabilistic analysis, as described in **Section D.3**.

Table D-2. Exposure Data Used in the Screening Analysis

Parameter		Age Cohort	Value	Units	Basis
Averaging Time		All Cohorts	70	yr	Agency Policy U.S. EPA, 1989
Body Weight		1 to < 2 yrs	11.3	kg	50th Percentile from CSEFH, Table 8-3
		2 to < 3 yrs	13.6		
		3 to < 6 yrs	17.8		
		6 to < 11 yrs	29.3		
		11 to < 16 yrs	54.2		
		16 to < 21 yrs	67.6		
		Adult	69.3		50th Percentile from EFH, Table 7-4 & 7-5
Total Exposure Duration **Note:** Total exposure durations longer than the duration of the cohort indicate that the cohort will age into each subsequent cohort until the specified total duration has elapsed.		1 to < 2 yrs	5	yr	50th Percentile from EFH, Table 15-168
		2 to < 3 yrs	5		
		3 to < 6 yrs	5		
		6 to < 11 yrs	7.7		
		11 to < 16 yrs	8.5		
		16 to < 21 yrs	7		
		Adult	10*		50th Percentile from EFH, Table 15-164
Exposure Frequency		All Cohorts	350	days/yr	Agency Policy U.S. EPA (1991)
Fraction Contaminated	All media and foods	All Cohorts	1	fraction	Agency Policy U.S. EPA (1991)
Fraction Of Fish Consumed	Trophic Level 3 (TL3)	All cohorts	0.36	fraction	Calculated from EFH Table 10-66
	Trophic Level 4 (TL4)	All cohorts	0.64	fraction

Event Duration		Adult	0.58	hr	

* Used data for households that farm (not broken out by age) to capture highly exposed individuals.
\+ Weighted (by number of observations) average of 20-39 and 40-69.

D.3 Exposure Factors for Probabilistic Analysis

The general methodology for collecting human exposure data for the probabilistic analysis relied on the EPA data from the 1997 EFH or 2008 CSEFH in one of three ways:

1. When the available data were adequate (as for most input variables), nonparametric approaches were used to fit distributions to the cumulative distribution (percentiles) of the data using @Risk software (available at www.palisade.com/risk/). Fitting nonparametric distributions removed parameter uncertainty associated with the fitting of specific parametric distributions (U.S. EPA, 2000).
2. When the available data were not adequate to support the statistical fitting for a specific age cohort, the data fit to the closest age cohort available was used instead.
3. When available data were not adequate for either of the above methods, variables were fixed at values recommended in the EFH or CSEFH or according to established EPA policy.

D.3.1 Variable Parameters

This section describes how the various distributions of exposure factor data were collected and processed for use in the probabilistic analysis. Probabilistic exposure analyses involve sampling values from a distribution with the same characteristics as the data using the values to estimate risk. For most variables for which distributions were developed, EPA exposure factor data were analyzed to fit nonparametric models. Steps in the development of distributions included preparing data, fitting models, assessing fit, and preparing parameters to characterize distributional uncertainty in the model inputs.

For many exposure factors, the data from the EFH and CSEFH include sample sizes and estimates of the following parameters for specific receptor types and age groups: mean, standard deviation, standard error, and percentiles corresponding to some subset of the following probabilities: 0.01, 0.02, 0.05, 0.10, 0.15, 0.25, 0.50, 0.75, 0.85, 0.90, 0.95, 0.98, and 0.99. These percentile data, where available, were used as a basis for fitting distributions. Although in no case are all of these

percentiles provided for a single factor, seven or more are typically available. Therefore, using the percentiles provided a better representation of the available information than fitting distributions simply based on the method of moments (i.e., selecting models that agree with the data mean and standard deviation).

Neither the EFH nor the CSEFH makes use of the standardized age cohorts recommended in U.S. EPA (2005). Different exposure factors are reported for different age categories based on the information available in the scientific literature. Therefore, to obtain the percentiles for fitting the eight standardized age cohorts used for the revised risk assessment, each cohort-specific value for a given exposure factor was assigned to one of the cohorts. When multiple cohorts fitted into a single CCR cohort, the percentiles from the EFH or CSEFH were averaged within each CCR cohort (e.g., data on 6 year olds and 9 year olds were averaged for the 6 to <11 age cohort). If sample sizes were available, weighted averages were used, with weights proportional to sample sizes. If sample sizes were not available, equal weights were assumed (i.e., the percentiles were simply averaged).

Nonparametric distributions were used to characterize the data. The nonparametric approach fits an optimal smooth curve to the cumulative distribution (percentiles) of the data. The best nonparametric fit is selected as the one that minimized the distance between the smooth curve and the empirical curve generated by the percentiles of the data. The maximum, minimum are used to specify the range of the simulated values. Depending on the data set, there could be more than one distribution (parametric or nonparametric) that could be considered a good fit for the data. Selecting an incorrect exposure distribution model may bias the risk assessment results, producing incorrect conclusions. Therefore, the application of goodness-of-fit statistics was required to select between competing distributions and to reduce model uncertainty. One goodness-of-fit statistic available was the root mean squared error, defined as the root of the average of the squared differences between the predicted percentile and the observed percentile. The other goodness-of-fit statistic available was the Chi-square based comparison of the empirical cumulative distribution (derived from the cumulative data) or the nonparametric cumulative distribution. Graphical displays were also used to evaluate the appropriateness of the selected distribution. A plot of the observed percentiles (from the cumulative data) vs. the nonparametric cumulative distribution was created. In some cases, exposure distributions are highly skewed, and there is a probability, although small, that a combination of extreme values might be selected from the tails of the distributions.

Drinking Water Intake

Drinking water intake data were obtained from Table 3-19 of the *CSEFH* and Table 3-6 of the *EFH* (U.S. EPA, 1997a), for children and adults, respectively. Weighted averages of percentiles and means were calculated for the 0 to < 1 yr infant (based on birth to < 1 month, 1 to < 3 months, 3 to < 6 months and 6 to < 12 months), the 16 to < 21 years age group (based on 16 to < 18 years and 18 to < 21 years) and adults (based on 20 to 44, 45 to 64, and 64 to 74 years), using the number of observations in each subcohort as weights. **Table D-3** presents drinking water intake data used

to prepare Monte Carlo simulations (note that the infant and child values are normalized by body weight and reported in mL/kg-day, while the adult ones are not and are reported in mL/day).

Table D-3. Drinking Water Consumption Rate Data (mL/kg-day)(1)

Age Group (Years)	N	Mean	Percentile						
			P10	P25	P50	P75	P90	P95	P99
Infant(2)	948	71	7	25	66	104	140	164	217
1 to < 2	880	27	4	9	20	36	56	75	109
2 to < 3	879	26	4	9	21	36	52	62	121
3 to < 6	3,703	24	3	8	19	33	49	65	97
6 to < 11	1,439	17	3	6	13	23	35	45	72
11 to < 16	911	13	2	5	10	17	26	34	54
16 to < 21	700	13	2	5	10	17	27	34	61
Adult	13,394	1,384	607	900	1,275	1,741	2,260	2,682	3,737

Source: Table 3-19, CSEFH for child cohorts and Table 3-6, EFH (U.S. EPA, 1997b) for adults.

1) Adult values are mL/day.

2) Weighted average based on subcohorts presented in the CSEFH or EFH.

Drinking water consumption rate data for infants (birth to < 1 month, 1 to < 3 months, 3 to < 6 months and 6 to < 12 months) are available from the CSEFH (U.S. EPA, 2008). **Table D-4** presents the water ingestion data used for infants. As drinking water concentrations are provided by the model as annual averages, the infant consumption rates were averaged to estimate a 0 to < 1 year infant. The data were weighted by sample size because the small sample sizes did not meet minimum requirements as described in the *Third Report on Nutrition Monitoring in the United States* (FASEB, 1995) for numerous percentiles in numerous subcohorts.

Table D-4. Drinking Water Consumption Rates for Infant Subcohorts (mL/kg-day)

Age Group (Months)	N	Mean	Percentile						
			P10	P25	P50	P75	P90	P95	P99
Birth to < 1	37	137	11	65	138	197	235	238	263
1 to < 3	108	119	12	71	107	151	228	285	345
3 to < 6	269	80	7	27	77	118	148	173	222
6 to < 12	534	53	5	12	47	81	112	129	186
Infant	948	71	7	25	66	104	140	164	217

Source: Table 3-19, *CSEFH*.

Body Weight

Weighted averages of percentiles and means were calculated for the infant age group (based on birth to < 1 month, 1 to < 3 months, 3 to < 6 months and 6 to < 12 months) and adults (based on male and female data). **Table D-5** presents body weight data. Body weight data were obtained from Table 8-8 of the CSEFH and Tables 7-4 and 7-5 of the EFH (U.S. EPA, 1997a). Data in the EFH tables were presented by race, age, gender. The female and male distributions for "all races" were weighted based on sample size to develop the percentile data presented in Table D-5 for all adults.

Table D-5. Body Weight Data (kg)

Age Group (Years)	N	Mean	Percentile								
			P05	P10	P15	P25	P50	P75	P85	P90	P95
Infant	1,858	7.8	6	6.4	6.7	7.1	7.8	8.6	9.0	9.3	9.7
1 to < 2	1,176	11.4	8.9	9.3	9.7	10.3	11.3	12.4	13	13.4	14
2 to < 3	1,144	13.8	10.9	11.5	11.9	12.4	13.6	14.9	15.8	16.3	17.1
3 to < 6	2,318	18.6	13.5	14.4	14.9	15.8	17.8	20.3	22	23.6	26.2
6 to < 11	3,593	31.8	19.7	21.3	22.3	24.4	29.3	36.8	42.1	45.6	52.5
11 to < 16	5,297	56.8	34	37.2	40.6	45	54.2	65	73	79.3	88.8
16 to < 21	4,851	71.6	48.2	52	54.5	58.4	67.6	80.6	90.8	97.7	108
Adult	12,504	71.4	52.9	56.0	58.2	61.7	69.3	78.5	84.9	89.8	97.6

Sources: Table 8-3 *CSEFH* (U.S. EPA, 2008) for children and Table 7-4 and 7-5 *EFH* (U.S. EPA, 1997a) for adults.

Fish Consumption

Fish consumption data were obtained from Table 10-64 of the EFH (U.S. EPA, 1997b). These data originate from a fish consumption study of recreational anglers conducted in Maine, one of four freshwater angler studies recommended in the 1997 EFH. Fish consumption rates for subsistence anglers were not considered, in part because fish ingestion rates for Native American subsistence anglers are currently limited and can vary widely among individual tribes. EPA selected the Maine data because it was the most complete of the data sets available and because it agrees most closely with the mean intake rates reported in a separate U.S. Department of Agriculture study of national fish consumption (USDA, 1992). The Maine study provides percentile data necessary to develop a distribution that were not available in the USDA study. **Table D-6** presents fish consumption rate data used to prepare Monte Carlo simulations. Age-specific data for children were not available; children were assumed to consume the same amount of fish as adults.

Table D-6. Fish Consumption Rates for All Ages (g/day)

Age Group	N	Mean	Percentile				
			P50	P66	P75	P90	P95
All	1,053	6.4	2	4	5.8	13	26

Source: Table 10-64, *EFH* (U.S. EPA, 1997b)

Exposure Duration

Exposure durations for adult and child residents were determined using data on residential occupancy from Tables 15-164 and 15-168 of the EFH (U.S. EPA, 1997c). The data represent the total time a person (both male and female) is expected to live at a single location, based on age. For adult residents, data reported for farm residents were used to capture highly exposed receptors within the population. For child residents, data reported for the 3-yr age group were used to represent infants to < 6 yrs. Data reported for ages 6 and 9 were averaged to represent 6 to < 11 yrs. Data on ages 12 and 15 were averaged to represent 11 to < 16 yrs. Data reported for age 18 were used to represent 16 to < 21 yrs. **Table D-7** presents exposure duration data. The underlying source for the recommended EFH distribution was a Monte Carlo simulation that estimated a probability distribution function for residential occupancy period based on the probability of moving and dying. There are no sample sizes, as these data do not derive from a survey.

Table D-7. Human Exposure Durations for All Ages (yr)

Age Group (Years)	Mean	Percentile					
		P25	P50	P75	P90	P95	P99
Infant	6.5	3	5	8	13	17	22
1 to < 2	6.5	3	5	8	13	17	22
2 to < 3	6.5	3	5	8	13	17	22
3 to < 6	6.5	3	5	8	13	17	22
6 to < 11	8.45	4.5	7.7	11	15.5	18	22
11 to < 16	9.2	5	8.5	12.5	16	18	23
16 to < 21	8.2	4	7	11	16	19	23
Adult	N/A	2.4	10.0	26.7	48.3	58.4	N/A

Adult farmer: Table 15-164, EFH (U.S. EPA, 1997c)
N/A – Not Available

D.3.2 Fixed Parameters

Certain parameters were fixed because the available data were not adequate to generate distributions. These parameters are shown in **Table D-8** along with the value selected for the risk analysis and the data source. For fraction of fish consumed that is trophic level 3 (TL 3) vs. trophic level 4 (TL 4), EFH Table 10-66 presents grams of fish consumed per year by species and type of fishing (ice fishing, lakes and ponds, and rivers and streams). The fraction of TL3 and TL4 fish consumed were calculated from these data using all fishing types and categorizing the fish species as either TL3 (i.e., carp, smelt, perch, catfish, sucker, bullhead, perch, and white fish) or TL4 (i.e., salmon, trout, bass, chub, and other).

Table D-8. Summary of Human Exposure Factor Data Used in Modeling: Constants

Description		Value	Units	Source
Averaging Time for Carcinogens		70	yr	EPA Policy (U.S. EPA, 1989)
Exposure Frequency		350	d/yr	EPA Policy (U.S. EPA, 1991)
Fraction Contaminated: All media and food items		1	Fraction	EPA Policy (U.S. EPA, 1991)
Fraction of Fish Consumed that is:	Trophic Level 3	0.36	Fraction	Calculated from EFH, Table 10-66
	Trophic Level 4	0.64

Appendix E.

Human Health and Ecological Benchmarks

[This Page Intentionally Left Blank]

E.1 Introduction

This appendix provides the benchmarks for human and ecological receptors used in the coal combustion residuals (CCR) risk assessment, and describes the data sources.

E.2 Human Health Benchmarks

Human health benchmarks are based on the specific adverse effects that may occur. Adverse effect is a broad term for any abnormal, harmful, or undesirable change that results from exposure to a stressor. Adverse health effects are divided into two main categories: carcinogenic and noncarcinogenic. Carcinogenic effects are those that result in the development of cancer somewhere in the organism. Noncarcinogenic effects are those that result in any adverse health effect other than cancer. Some stressors may result in both carcinogenic and noncarcinogenic effects, depending on the route through which the receptor is exposed and the magnitude of the exposure. Benchmarks were collected for ingestion and inhalation because these are the primary routes through which residential receptors who live close to CCR surface impoundments and landfills may be exposed.

E.2.1 Chronic Human Health Benchmarks

Reference doses (RfDs) and reference concentrations (RfCs) are used to evaluate noncancer effects from oral and inhalation exposures, respectively. RfDs and RfCs are estimates of a daily exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious noncancer effects. However, an average lifetime exposure above the RfD (or RfC) does not imply that an adverse health effect will necessarily occur.

Oral cancer slope factors (CSFo's) and inhalation unit risk factors (URFs) are used to evaluate carcinogenic effects. The CSFo is an upperbound estimate (approximating a 95% confidence limit) of the increased human cancer risk from a lifetime of exposure. The URF is a cancer benchmark for inhalation exposures, where the air concentrations are used as a threshold.

The Office of Solid Waste and Emergency Response 2003 Directive 9285.7-53 encourages prioritization of sources that are most current, those for which the basis is transparent and publicly available and those that have been peer reviewed (U.S. EPA, 2003). Accordingly, a three-tiered approach was followed to use higher priority data sources based on availability.

Tier I

Integrated Risk Information System (IRIS): IRIS (U.S. EPA, 2012a) provides the highest quality science-based chronic human health assessments to support EPA regulatory activities. IRIS assessments have been peer-reviewed and represent Agency-wide consensus. Thus, EPA used values from IRIS whenever available. IRIS contains RfDs and RfCs for chronic noncarcinogenic health effects, and oral CSFs and inhalation URFs for carcinogenic effects.

Tier II

Provisional Peer-Reviewed Toxicity Values (PPRTVs): When a value is not available in IRIS, the Superfund Program may derive a PPRTV after a review of the relevant scientific literature using the methods, sources of data and guidance for value derivation used by the EPA IRIS Program. All provisional peer-reviewed toxicity values receive internal review by EPA scientists and external peer review by independent scientific experts. However, PPRTVs do not reflect Agency-wide consensus, because PPRTVs are developed specifically for the Superfund Program. PPTRVs included cancer and noncancer benchmarks for both oral and inhalation exposure.

Tier III

Agency for Toxic Substances and Disease Registry (ATSDR) Chronic Minimal Risk Levels (MRLs): The ATSDR MRLs (ATSDR, 2013) are substance-specific health guidance levels for noncarcinogenic effects. An MRL is intended to be an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse noncancer health effects over a specified duration of exposure. MRLs are derived for oral and inhalation routes of exposure in a manner similar to RfDs and RfCs, respectively. MRLs have undergone both internal and external peer review.

California EPA (CalEPA) Cancer Potency Factors and Reference Exposure Levels: CalEPA has developed cancer potency factors (CalEPA, 2011) for chemicals regulated under California's Hot Spots Air Toxics Program. The cancer potency factors are analogous to the EPA's oral and inhalation CSFs. CalEPA has also developed chronic inhalation RELs, analogous to the EPA's RfC (CalEPA, 2014). The cancer potency factors and inhalation RELs have undergone peer review by various California agencies and have been made available for public comment.

Other Health Benchmarks: Some other organizations have also developed human health benchmarks. In limited cases where no other benchmarks from the above sources were available, such benchmarks were used:

- An oral cancer benchmark for chromium (VI), developed by the New Jersey Department of Environmental Protection for their soil cleanup program (NJDEP, 2009) based on information from a study by the National Toxicity Program (NTP, 2008).
- An RfD for lanthanum carbonate, compiled for the International Toxicity Estimates for Risk database, that was developed by National Sanitation Foundation (NSF) International (NSF, 2010).
- For lead, EPA currently has no consensus on the development of an RfD or CSFo because of the difficulty associated with identifying an effect threshold needed to develop these benchmarks. Therefore, the maximum contaminant level (MCL) for drinking water was used as an alternative method of approximating human health risk.

Health Effects Assessment Summary Tables: HEAST (U.S. EPA, 1997a) is a listing of provisional noncarcinogenic and carcinogenic health toxicity values (RfDs, RfCs, URFs and CSFos) derived by the EPA. Although the health toxicity values in HEAST have undergone review and have the concurrence of individual EPA program offices, the values have not been externally reviewed as extensively as those in IRIS. Values for chemical exposures are not updated at this time.

The chronic human health benchmarks used in the CCR risk assessment are summarized in **Table E-1** (cancer benchmarks) and **Table E-2** (noncancer benchmarks). These tables provide the constituent name, Chemical Abstract Service Registry Number (CASRN), CSFo and inhalation URF (**Table E-1**) or RfD and RfC (**Table E-2**), and the reference for each benchmark. A key to the references cited is provided at the end of the tables. All values are current as of May 2014.

* RfD for ammonia was provided as a concentration in drinking water of 34 mg/L, which was converted to mg/kg-day assuming a drinking water consumption rate of 2 L/day (approximately 90th percentile for adults) and a body weight of 70 kg (approximately 50th percentile for adults). Thus, 34 mg/L × 2 L/day ÷ 70 kg = 9.7E-1 mg/kg-day.

E.2.2 Acute Inhalation Human Health Benchmarks

In addition to chronic exposures, another exposure scenario of potential concern for the screening analysis is acute inhalation. The *Human Health Risk Assessment Protocol for Hazardous Waste Combustion Facilities* (HHRAP, U.S. EPA, 2005i) recommends evaluating an acute exposure scenario to ensure that an assessment evaluates all receptors that may be significantly exposed to emissions from facility sources. However, short-term emissions are unlikely to cause an adverse impact through the indirect exposure pathways (as compared to impacts from long-term emissions through those pathways). Therefore, HHRAP recommends evaluating acute effects only through the short-term (maximum 1-hour) inhalation of vapors and particulates.

Acute inhalation exposure guidelines and criteria are designed to protect a variety of exposure groups, including occupational workers, military personnel, and the general public. Acute guidelines are based on varying exposure durations up to 24 hours (e.g., 10, 30 and 60 minutes; 4 and 8 hours; and 1 day). Acute exposure guidelines are based on adverse health effects reflecting a wide range of severity, from mild, transient effects (e.g., respiratory irritation) to irreversible or serious effects, to potentially life threatening effects. Reflecting the conservative nature of a screening assessment, EPA used guidelines based on the mild, transient effects, as those would also be protective of more severe effects.

To identify acute inhalation guidelines, EPA used the hierarchy established by HHRAP (U.S. EPA, 2005i). Preference is given to sources and values that 1) have undergone rigorous scientific review, 2) address intermittent exposures (as opposed to one-time exposures), 3) are based on one-hour exposures, and 4) apply to the general population, including susceptible individuals. The hierarchy is as follows:

1. **CalEPA Acute Reference Exposure Levels (RELs):** concentration in air at or below which no adverse health effects are anticipated in the general population, including sensitive individuals, for a specified exposure period (1 and 8 hours). CalEPA Acute RELs are meant to address routine short-term emissions rather than industrial accidents, another reason they are the most preferred source. They are peer-reviewed by the State's Scientific Review Panel on Toxic Air Contaminants and have been made available for public comment.
2. **U.S. EPA Acute Exposure Guideline Levels (AEGL-1):** the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic non-sensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure (10 and 30 minutes and 1, 4 and 8 hours). AEGLs are intended to protect against rare, typically accidental or once-in-a-lifetime exposures. AEGL values and methods undergo peer review by the National Advisory Committee for AEGLs and the National Research Council of the National Academy of Sciences, and also receive public comment.

3. **American Industrial Hygiene Association Level 1 Emergency Response Planning Guidelines (ERPG-1):** the maximum concentration in air below which it is believed nearly all individuals could be exposed for up to one hour without experiencing other than mild transient adverse health effects or perceiving a clearly defined objectionable odor (1 hour). ERPGs are meant to anticipate adverse health effects from chemical release emergencies. ERPG-1 values are peer reviewed.
4. **U.S. Department of Energy Temporary Emergency Exposure Limits (TEEL-1):** the maximum concentration in air below which it is believed nearly all individuals could be exposed without experiencing other than mild transient adverse health effects or perceiving a clearly defined odor. TEELs are meant to fill in where ERPGs are not available, until ERPGs are developed. The TEEL-1s are based on 15 minute exposures. Although individual TEELs are not peer reviewed, they are developed based on a peer-reviewed process.

Two constituents, chromium III and chromium VI, did not have values in any of the above sources on HHRAP's hierarchy. For these, EPA used the National Institute for Occupational Safety and Health Immediately Dangerous to Life or Health Values (IDLH) and, following the same process as EPA's Air Toxics Program, divided by 10 to more closely match the milder effect levels developed by the other sources; this approach is consistent with the methodology used to develop levels of concern under Title III of the Superfund Amendments and Reauthorization Act, and their use in the accidental release prevention requirements under section 112(r) of the Clean Air Act (see www.epa.gov/ttn/atw/toxsource/acutesources.html).

The acute inhalation health benchmarks used in the CCR risk assessment are summarized in Table E-3. All values were current as of May 2014, except the TEELs, which were current as of January 2012, when the acute benchmark data were collected. The TEELs were updated in February 2012, but those have not been incorporated here, as they occurred after the CCR modeling was completed.

E.3 Ecological Benchmarks

Ecological benchmarks used in this assessment are medium-specific constituent concentrations that are intended to protect ecological receptors from adverse effects. Depending on the medium (surface water, sediment, or soil), the benchmarks may represent a class-specific value (e.g., an EPA Ecological Soil Screening Level for mammals) or it may represent a higher level of biological organization (e.g., National Water Quality Criteria are developed to protect a generalized aquatic community). In either case, the ecological benchmarks are considered to be environmental quality criteria and do not provide information on the likelihood or severity of the effects on the ecosystem. Ecological receptors may be exposed through the ingestion and/or direct contact with a contaminated medium, or they may be exposed through the food chain (i.e., consuming plants and prey that have, themselves, become contaminated). The ecological benchmarks presented in this section assume that the receptors are exposed to the constituent concentration over a significant portion of their life cycle (i.e., the exposure is assumed to be chronic in nature) or, for aquatic receptors, the exposure can be assumed to be indefinite. This appendix describes the ecological benchmarks used in the revised risk assessment.

E.3.1 Data Sources and Methodology

For this assessment, concentration-based ecological benchmarks for surface water, sediment and soil receptors were used to characterize the potential for adverse ecological effects. For each medium, EPA established a hierarchy for the selection of ecological benchmarks. In instances where multiple benchmarks were available at the same level of the hierarchy, EPA selected the lowest benchmark to ensure that the most sensitive ecological receptors were protected. The following sections summarize the benchmark derivation methods for each medium included in the modeling scenarios.

E.3.2 Surface Water Benchmarks

Surface water benchmarks were selected to protect animals in water bodies that may be exposed through direct contact with surface water or through ingestion of other biota that live in the water body. EPA chose aquatic criteria appropriate for species living in the freshwater bodies because brackish and coastal waters were not modeled in this risk assessment. The hierarchy for these benchmarks was originally defined during the development of the Multimedia, Multipathway, and Multireceptor Risk Assessment Modeling System (3MRA; U.S. EPA, 2003c). The hierarchy is as follows, with the selected values presented in **Table E-4**:

- Criterion Continuous Concentration (CCC) developed by the EPA Office of Water as part of the National Ambient Water Quality Program.
- Final Chronic Value (FCV) developed using the methods Stephan et al. (1985), and implemented under the Great Lakes Water Quality Initiative (U.S. EPA, 1993; 1995a,b),
- Secondary Chronic Value (SCV) as presented in Suter and Tsao (1996).

Thallium	7440-28-0	0.01	SCV	Suter and Tsao (1996)
Uranium	7440-61-1	—	—	—
Vanadium	7440-62-2	0.02	SCV	Suter and Tsao (1996)
Zinc	7440-66-6	0.12	CCC	U.S. EPA (1995)

+ Data sources for CCC are discussed online at: water.epa.gov/scitech/swguidance/standards/criteria/current/index.cfm#A.

* Public commenters (EPA-HQ-RCRA-2009-0640-06526) noted that the units in the fish study from which the SCV was derived (Hamilton, 1995) had been erroneously transcribed in Suter and Tsao as µg/L instead of mg/L. The SCV was recalculated using the corrected units, resulting in a boron SCV of 1.1 mg/L. The revised value has been corroborated by EPA.

E.3.3 Sediment Benchmarks

Sediment benchmarks were selected to protect animals in sediment that may be exposed through direct contact with sediment or through ingestion of other biota that live in the sediment. The hierarchy for these benchmarks was originally defined during the development of 3MRA (U.S. EPA, 2003c). Since the completion of the 3MRA database, NOAA has updated their methodology, making this information available for national analyses. The hierarchy is as follows, with the selected values presented in **Table E-5**:

- Threshold Effect Level (TEL) from Buchman (2008), geometric mean of the 15th percentile in the effects data set and the 50th percentile in the no effects data set.
- Effects Range Low (ERL), the lower 10th percentile concentration estimated to correspond with adverse effects as identified in alternate literature sources including, for example, Long et al. (1995); Long and Morgan (1991); Jones, Suter and Hull (1997); MacDonald (1994); and U.S. EPA (1995c, 1997b).

Table E-5. Ecological Benchmarks for Sediment (Sediment Community)

E.3.4 Soil Benchmarks

The soil benchmarks are developed to be protective of plants, animals and soil invertebrates that may be chronically exposed to constituents in soil through direct contact, as well as the ingestion of biota that live in or on the soil. The hierarchy is as follows, with the selected values presented in **Table E-6**:

- Ecological Soil Screening Levels (Eco-SSLs) (U.S. EPA, 2005a–h; 2006c; 2007a–e; 2008b) derived through a collaborative effort of a multi-stakeholder workgroup consisting of federal, state, consulting, industry and academic participants led by the EPA Office of Emergency and Remedial Response, as documented in *Guidance for Developing Soil Screening Levels* (U.S. EPA, 2005).
- Oak Ridge National Lab (ORNL) screening benchmarks developed for the U.S. Department of energy (Efroymson et al., 1997; Efroymson, Will, and Suter, 1997; Sample, Opresko, and Suter 1996),

Appendix F.

Air Modeling for Screening Analysis

[This Page Intentionally Left Blank]

F.1 Introduction

Modeling was performed to estimate ambient air concentrations (for inhalation pathways) and deposition rates (for food chain pathways) for particulates released from landfills and landfill operations. Particulate emissions were estimated, and then air dispersion modeling was used to estimate air concentrations and deposition rates at off-site receptor locations.

F.2 Particulate Emissions

Particulate emission estimates were developed and evaluated for windblown emissions, as well as for vehicular activity, unloading operations and compacting operations, using established methods published by the U.S. Environmental Protection Agency (EPA or the Agency), specifically *AP-42: Compilation of Air Pollutant Emission Factors* and windblown emission equations (U.S. EPA, 1985a). The applied approach is consistent with the landfill model methodology reviewed by EPA's Science Advisory Board in 2003 (U.S. EPA, 2003). Modifications to this methodology were made to reflect coal combustion residual (CCR)–specific releases focusing on particulate matter (PM) 10 micrometers or less in diameter or smaller (PM_{10}) and fine particles or particles 2.5 micrometers or less in diameter or smaller ($PM_{2.5}$). The emissions modeling approach is described in more detail in **Attachment F-1**. The following inputs were used for the emissions modeling:

- **Meteorological Parameters:** Meteorological parameters associated with each of the 57 meteorological stations in the EPA's Industrial Waste AIR model (IWAIR; U.S EPA, 2002) were used. The IWAIR meteorological stations are described in **Section F.3**. Particulate emissions were calculated for each station to capture national variability in meteorological conditions.
- **Landfill Operations:** CCR-specific data were used to characterize landfill dimensions. **Table F-1** shows five landfill surface areas ranging from 35 to 126 acres that were modeled. These represent the 50th to the 90th percentile of the distribution of landfill areas. For other data elements, default parameter values were applied as shown in **Attachment F-1**.

Table F-1. Distribution of Landfill Sizes (acres)

Percentile	50th	60th	70th	80th	90th
Surface Area	35.3	48.3	59	85	126

- **Particle Size Distribution:** Data on particle size range mass fractions for coal ash are limited for different CCR types. EPA made the assumption that all particulate releases would have the characteristics of fly ash. Based on a literature review and data presented in Moreno et al. (2005), a profile consisting of 15 percent fine particles or $PM_{2.5}$ (< 2.5 microns) was applied.

- **Dust Controls:** EPA considered various control options such as covering or otherwise managing CCR waste to control wind dispersal of dust. Control efficiencies applied under the "controlled scenario" were based on the above particle size profile and the collection efficiencies from AP-42 (Appendix B.2; U.S. EPA, 2006) for dust suppression by wet spray or by chemical stabilization or wetting agents and are shown in **Table F-2**. Based on these data, a uniform control efficiency of 40 percent was assumed for the $PM_{2.5}$ releases. In the absence of an overall reported control efficiency for $PM_{10,}$ a CCR-specific value was calculated. The $PM_{2.5}$ control efficiency shown in the table was weighted as 15% and the efficiencies for the two size bins greater than 2.5 were averaged and weighted as 85%, reflecting the percentage of coarse particles. This results in in a control efficiency of approximately 70 percent for particulates less than 10 micrometers in diameter.

Table F-2. EPA's AP-42 Collection Efficiencies*

Type of Control	Particle Size		
	0–2.5 µm	2.5–6 µm	6–10 µm
Dust suppression by wet spray	40%	65%	90%
Dust suppression by chemical stabilizer or wetting agents	40%	65%	90%

* These efficiencies reflect ideal operating conditions with appropriate application rates and frequencies.

- **Percent Silt:** EPA assumed that fugitive dust emissions were 80 percent silt, consistent with the previous fugitive dust CCR analysis and based on the value for fly ash presented in AP-42 Chapter 13, Table 13.24-1. Although this value is potentially conservative, EPA deemed it appropriate for screening purposes in the absence of sufficient data to support a lower percent silt value.
- Other source parameters were characterized as shown in **Attachment F-1**, **Table F-1-2**.

F.3 Air Dispersion Modeling

EPA conducted dispersion modeling to estimate ambient air concentrations. Modeling was performed with the American Meteorological Society/Environmental Protection Agency Regulatory Model (AERMOD) and its screening model AERSCREEN (U.S. EPA, 2011). Modeling was performed using a phased approach starting with AERSCREEN to estimate conservative maximum air concentrations for each landfill size/location combination discussed above. AERSCREEN also calculates maximum air concentrations for other averaging times (e.g., 3-hour, annual) by scaling the estimated 1-hour maximum air concentrations. In the case of an area source, such as a landfill, a scaling factor of 1 is applied producing very conservative short-term and long-term concentrations that are identical to the 1-hour maximum values. Thus, the 1-hour AERSCREEN results were used as an initial screen of the inhalation pathway.

Subsequent modelling was performed with AERMOD to produce results for the refined inhalation screen and to develop deposition rates to evaluate ingestion exposures (AERSCREEN does not

produce deposition estimates). Modeling was performed using 5 years of meteorological from the weather station associated with the 90th percentile landfill PM_{10} emissions. Weather stations whose natural characteristics lead to high fugitive dust concentrations in AERSCREEN (e.g., dry, high wind speeds) are likely to also lead to high short term and long term concentrations in AERMOD especially in close proximity to the area source as was considered in this analysis. These more refined air modeling results were considered if an AERSCREEN modeled COPC concentration was above the inhalation health benchmark.

Both AERSCREEN and AERMOD modeling was conducting based on a unitized emission rate (e.g., 1 g/m^2-s). The resulting air concentrations and deposition rates are called unitized air concentrations (e.g., $\mu g\ m^{-3}$ per unit emission rate of 1 g/m^2-s) and unitized deposition rates (e.g., g/m^2-yr per unitized emission rate of 1 g/m^2-s), and these are multiplied by the constituent-specific emission rates and appropriate conversion factors to calculate chemical-specific particle-phase air concentrations and deposition rates.

Chronic exposures to specific constituents were evaluated using outputs averaged over 1 year. Acute exposures to specific constituents were evaluated using outputs averaged over 1 hour. Exposures to $PM_{2.5}$ and PM_{10} were evaluated by comparing EPA's National Ambient Air Quality Standards (NAAQS) to ambient air concentration estimates reflecting appropriate averaging times (i.e., 24-hour and annual for $PM_{2.5}$ and 24-hour for PM_{10}). Because the NAAQS for lead reflects a rolling 3-month average, which is not an available output from AERSCREEN or AERMOD, EPA evaluated those exposures using monthly concentrations.

For this screening, total particulate concentrations output by the model were adjusted with constituent-specific 90th percentile whole waste concentrations to predict corresponding constituent-specific ambient air concentrations. The total particulate concentrations were also apportioned to $PM_{2.5}$ using the particle size distribution discussed in **Section F.1**. **Attachment F-2** summarizes the inputs needed for AERSCREEN; two critical inputs are receptor distance and meteorological data. These are discussed below:

- **Receptor Distances:** Air concentrations were evaluated at a range of distances included in previous EPA analyses and models, such as the Multimedia, Multiple Exposure Pathway, Multiple Receptor Risk Assessment (3MRA) modeling system (U.S. EPA, 2003) and the solvent wipes risk assessment (U.S. EPA, 2009). The specific distances (25 m, 50 m, 75 m, 150 m, 300 m, 500 m, 1,000 m, and 2,000 m) were selected to ensure complete coverage in the air estimates, particularly near the source of the emissions.
- **Meteorological Data:** To capture national variability in the estimates, the air dispersion modeling used representative meteorological and land use data associated with the 57 IWAIR meteorological regions where coal combustion facilities are located. The IWAIR model and meteorological regions have been subjected to extensive peer review. **Figure F-1** shows the coal combustion facilities cross-referenced to the IWAIR meteorological regions (U.S. EPA, 2002). As part of the initial screening, EPA performed AERSCREEN modeling using meteorological and land use data for all of the IWAIR meteorological regions where coal

combustion facilities are located. Because it was not feasible to run AERMOD (to obtain results for longer averaging times) for all of the 57 meteorological stations, EPA selected the location with the 90th percentile particulate air concentration (which accounts for meteorological and land use effects on both emissions and dispersion) and performed AERMOD modeling for that location. AERMOD outputs were generated for the range of receptor distances (i.e., 25 m, 50 m, 75 m, 150 m, 300 m, 500 m, 1,000 m, and 2,000 m) and included unitized 1-, 3-, 8, and 24-hour, monthly, and annual average air concentrations for $PM_{2.5}$ and PM_{10} and yearly average wet and dry deposition rates from particle phase. EPA then used those meteorological conditions to calculate emissions and used the associated dispersion factors and deposition rates as representative of the 90th percentile meteorological conditions for the chronic screening.

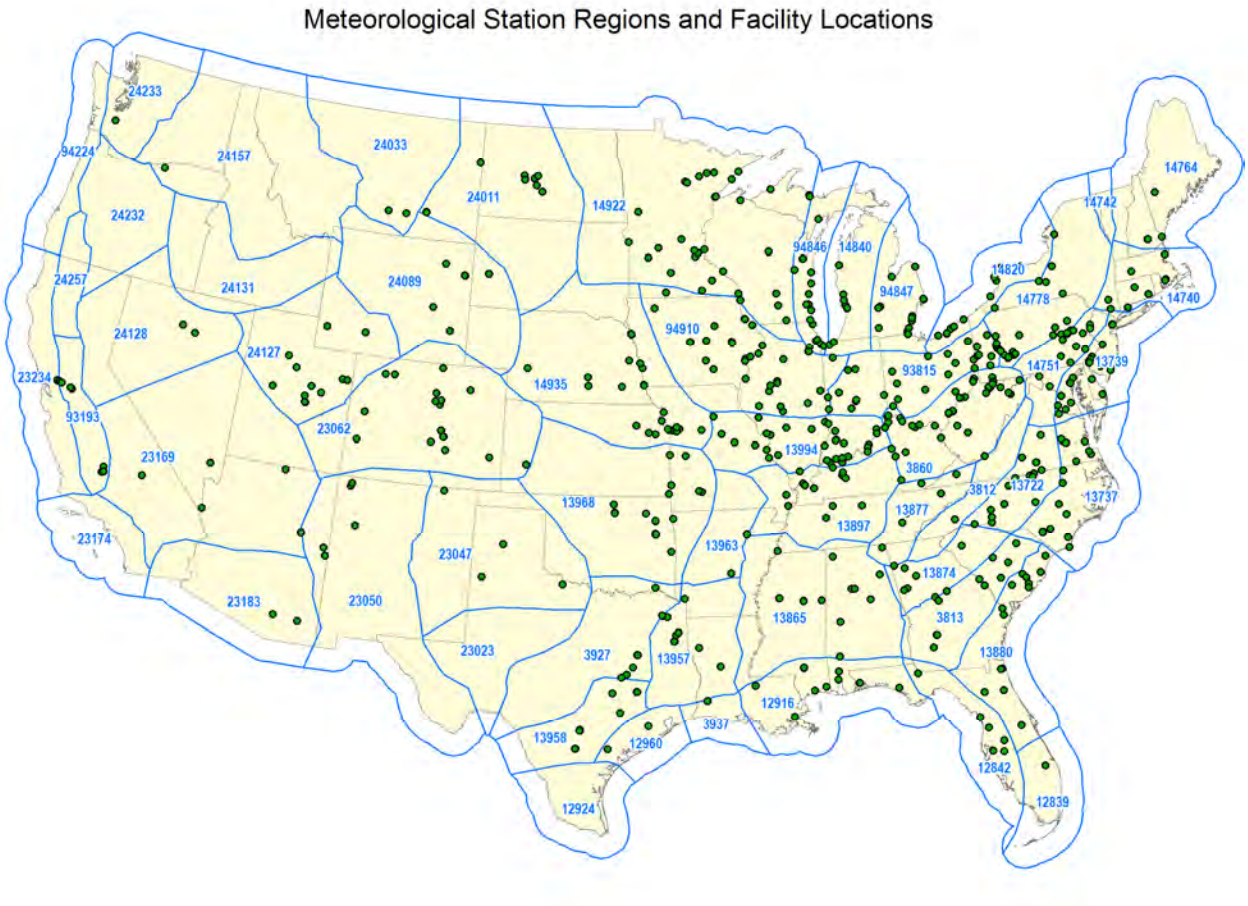

Figure F-1. IWAIR meteorological regions and coal combustion sites.

Attachment F-1.
Particulate Emissions Equations

F-1.1 Introduction

The following release mechanisms are considered: wind erosion, vehicular activity, unloading operations and spreading/ compacting operations. The sources for each of these mechanisms are summarized in **Table F-1-1**.

Table F-1-1. Mechanisms of Release of Particulate Emissions for Active Landfills

Mechanism of Release	Ei Subscript	Algorithm Reference
Wind Erosion from Open Area	wd	U.S. EPA, 1985a
Vehicular Activity	ve	AP-42 (U.S. EPA, 2006, Chapter 13.2.2: Unpaved Roads)
Unloading	un	AP-42 (U.S. EPA, 2006, Chapter 13.2.4: Aggregate Handling and Storage Piles)
Spreading/Compacting	sc	AP-42 (U.S. EPA, 1985b)*

* This equation was removed from the most recent (5th) edition of AP-42 but is still widely used, including, for example, in the 3MRA landfill model (U.S. EPA, 1999) and in Western Regional Air Partnership (see MRI, 2006). It can be found in the cited 4th edition.

This attachment describes the algorithms and assumptions used to estimate emissions for each landfill:

- Ei (g of PM/m^2-d), the annual average PM emission rate due to each release mechanism i (wind erosion, vehicular activity, unloading, and spreading and compacting)
- $\sum$Ei (g/m^2-d), the total annual average PM emission rate due to all release mechanisms, and
- CE (g/m^2-d), the annual average emission rate of contaminant as PM.

The equations all estimate emissions of PM_{10}, which are adjusted to $PM_{2.5}$ using the particle size distribution described in **Section F-1.3**. **Table F-1-2** presents the landfill-specific values used as inputs to these algorithms.

Table F-1-2. Emissions Equation Inputs

Variable	Units	Variable Name	Value	Comments
Waste-Specific Parameters				
Fly ash bulk density	g/cm^3	BD	1.19	U.S. EPA (1998)
Fraction $PM_{2.5}$	unitless	$PM_{2.5}$frac	0.15	See Section F-1.3
Fraction PM_{10}	unitless	PM_{10}frac	1	Reflects respirable releases*
Wind Erosion				
Mode of aggregate size distribution	mm	asdm	0.5	Based on the Soil Screening Guidance (U.S. EPA, 1996)
Silhouette area ratio	unitless	Lc	0.0003	Mean value (U.S. EPA, 1999b)
Fraction vegetative cover	frac	Veg	0	Assumed worst case
Surface roughness height	cm	z_0	1	Value of zruf for active landfill (U.S. EPA, 1999b)
Silt content (wind erosion)	%	S	80	AP-42, Chap. 13, Table 13.2.4-1 (fly ash) (U.S.EPA, 2006)
Frequency of disturbances (active)	1/mo	fd'	30	Consistent with worst case U.S. EPA, 1985a
Surface area	m^2	A	510,000	126 acres based on 90th percentile size; see Table F-2
Vehicular Emissions				
Silt content of roads	%	S_{roads}	24	Based on value from AP-42 for western surface coal mining–haul road (freshly graded) (U.S. EPA, 2006, Table 13.2.2-1). Maximum value in range of source conditions tested to develop Eqn 1a (U.S. EPA, 2006, p. 13.2.2.2-1) was 25.2%.
Mean vehicle weight	Short tons	V_w	40	Assumes trucks weigh 30 tons empty. Mean weight during travel equals half payload (i.e., approximately 10 tonsbased on truck volume and waste bulk density). Applied value is a combined weight of 40 tons.
Mean no. vehicles per day	1/day	N_v	88	Estimated based on 90th percentile loading rate, truck volume of 21 cubic yards, and waste bulk density
Meters traveled per vehicle	m	M_t	714	Length of landfill (truck travels to center of unit and back)
Dust suppression control efficiency (roads)	unitless	$EFF_{DustRoads}$	0	Assumed worst case of no controls

(continued)

Table F-1-2. Emissions Equation Inputs

Variable	Units	Variable Name	Value	Comments
Unloading Operations				
Waste moisture content	%	mcW	27	AP-42, Chap. 13, Table 13.2.4-1 (fly ash) (U.S. EPA, 2006)
Annual average waste loading rate	Mg/y	L	612,000	90th percentile value from DOE EIA-923 form data on landfill disposal in 2009 (161 plants; 675,000 sh. ton/yr; converted to Mg/yr using 0.907 Mg/sh. ton)
Surface area	m^2	A	510,000	90th percentile unit size (126 acres)
Spreading/Compacting/Tilling				
Silt content (spreading)	%	$S_{spreading}$	80	AP-42, Chap. 13, Table 13.2.4-1 (fly ash) (U.S. EPA, 2006)
No. of tilling/ spreading operations/day	1/day	NopC	3	Assumes spreading occurs once per 8-hour shift
Surface area/day	m^2	A	1,400	Estimated from daily loading rate & waste bulk density.

* EPA's Office of Air and Radiation considers PM_{10} and smaller to be respirable; available online at: www.epa.gov/airquality/particulatematter

F-1.2 Particulate Emission Rate (E_i) Algorithms

F-1.2.1 Wind Erosion from Open Fields (E10wd)

The algorithm for the estimation of PM_{10} emissions due to wind erosion from an open field is based on the procedure developed by U.S. EPA. (1985a). The input parameters are summarized in **Table F-1-3**.

Table F-1-3. Input Parameter Units and Definitions for $E10_{wd}$

Symbol	Units	Definition
asdm	mm	Mode of the aggregate particle size distribution
Lc	—	Ratio of the silhouette area of roughness elements too large to be included in sieving to total base area
veg´	—	Fraction of surface covered with vegetation (see Table F-2-2)
z´0	cm	Surface roughness height (see Table F-2-2)
S	w/w, %	Silt content of surface material
U+	m/s	Observed or probable fastest mile of wind between disturbances
PE	—	Thornthwaite Precipitation Evaporation Index
u	m/s	Mean annual wind speed
p	d/yr	Mean number of days per year with ≥0.01 in precipitation
fd´	1/mo	Frequency of disturbance per month where a disturbance is defined as an action that exposes fresh surface material

*Step 1: Calculate U*t*

Calculate the threshold friction velocity, U_{*t} (m/s), the threshold wind speed for the onset of wind erosion:

(F-2-1a) $$U_{*t} = 0.65(cf)(asdm)^{0.425}$$

Where:

(F-2-1b) $$cf = \begin{cases} 1.0 & \textbf{for } Lc < 2 \times 10^{-4} \\ 1.05 + 50.18(Lc) - 647.89(Lc)^2 + 6{,}863.5(Lc)^3 & \textbf{for } 2 \times 10^{-4} \le Lc \le 1 \times 10^{-1} \end{cases}$$

Table F-1-2 provides definitions of asdm and Lc. Lc is measured by inspection of a representative 1-m^2 transect of the site surface. Lc can range from zero to 0.1. High Lc ($\geq 2 \times 10^{-4}$) increases the threshold friction velocity, which results in a relatively low or zero particulate emission rate due to wind erosion. Low Lc ($<2 \times 10^{-4}$) is indicative of a bare surface with homogeneous finely divided material (e.g., an agricultural field). Such surfaces have a relatively low threshold friction velocity and increased particulate emissions. Equations (F-2-1a) and (F-2-1b) were derived from U.S. EPA. (1985a, Figures 3-4 and 3-5).

Step 2: Calculate U_t

U_t (m/s) is the threshold wind velocity at a height of 7.0 m (7.0 m is the typical weather station anemometer height). It is calculated using U.S. EPA. (1985a; Equation, 4-3, with z = 700 cm):

(F-2-2) $$U_t = \frac{U_{*t}}{0.4} \ln\left(\frac{700}{z'_0}\right) \qquad \textbf{for } z'_0 < 700$$

Where z'_0 is the roughness height in cm. Values for z'_0 for various surface conditions are provided in U.S. EPA. (1985a, Figure 3-6).

Step 3: Calculate $E10_{wd}$

$E10_{wd}$ is the annual average emission rate of particulate matter less than 10 μm in diameter per unit area of the contaminated surface.

For Sites with Limited Erosion Potential ($U_{*t} > 0.75$ m/s), the following equation was derived by using U.S. EPA. (1985a, Equations 4-1 to 4-3), converting units to g/m^2-d:

(F-2-3) $$E10_{wd} = \begin{cases} \dfrac{5.56(U^+ - U_t)(1 - veg')(24 \cdot fd')}{10^3 \cdot \left(\frac{PE}{50}\right)^2} & \textbf{for } U^+ \ge U_t \\ 0 & \textbf{for } U^+ < U_t \end{cases}$$

Data for peak gust wind velocities, which can be converted to U^+, and PE for locations throughout the United States can be found in the *Climatic Wind Data for the United States* (U.S. Department

of Commerce, 1998) and U.S. EPA (1985a, Figure 4-2), respectively. U.S. EPA (1985a) advises that, in the worst case, f_d should be assumed to be 30 per month. When $U_{*t} \leq 0.75$ m/s, the site is considered to have unlimited erosion potential and $E10_{wd}$ is calculated using U.S. EPA (1985a, Equation 4-4):

(F-2-4a) $$E10_{wd} = 0.036(1 - veg')\left(\frac{u}{U_t}\right)^3 g(x) \cdot 24\frac{h}{d}$$

Where:

(F-2-4b) $$x = 0.886\left(\frac{U_t}{u}\right)$$

(F-2-4c) $$g(x) = \begin{cases} 1.91 & \textbf{for } 0 \leq x < 0.5 \\ 2.2 - 0.6x & \textbf{for } 0.5 \leq x \leq 1.0 \\ 2.9 - 1.3x & \textbf{for } 1.0 < x \leq 2.0 \\ 0.18(8x^3 + 12x)e^{(-x^2)} & \textbf{for } x > 2.0 \end{cases}$$

Where g(x) was derived from U.S. EPA (1985a, Figure 4-3). Data for u for locations throughout the United States can be found in the *Climatic Wind Data for the United States* (U.S. Department of Commerce, 1998).

F-1.2.2 Vehicular Activity (E_{ve})

To estimate E_{ve} (g/m^2/d), the quantity of particulate emissions from vehicular travel on the surface of the landfill, the following equation for vehicles traveling on unpaved surfaces at industrial sites from AP-42 (updated November 2006) was used, adapted to convert from lb/VMT (vehicle mile traveled) to g/m^2/d:

(F-2-5) $$E_{ve} = 281.9k\left(\frac{S}{12}\right)^a \left(\frac{W}{3}\right)^b nv \left(\frac{mt}{A}\right)\left(\frac{km}{10^3 m}\right)$$

Where k, a and b are empirical constants that depend on particle size desired (see **Table F-1-4**) and the other parameter definitions are provided in **Table F-1-5**.

Table F-1-4. Coefficient Values for E_{ve} Equation

Symbol	Units	PM_{10}
k	lb/VMT	1.5
a	unitless	0.9
b	unitless	0.45

Table F-1-5. Parameter Units and Definitions for E_{ve}

Symbol	Units	Definition
S	w/w, %	Surface silt material content
W	tons	Mean vehicle weight
nv	1/d	Mean annual number of vehicles per day
A	m^2	Contaminated surface area
mt	m	Meters traveled per vehicle (nv) on contaminated surface

F-1.2.3 Unloading Operations (E_{un})

The equation for estimating E_{un} ($g/m^2/d$), the PM emission rate due to unloading operations at landfills, was adapted from U.S. EPA. (2006, Equation 1, p. 13.2.4-4). The EPA equation was adapted by multiplying it by the average annual loading rate (L, Mg/yr) and normalizing the emissions for the contaminated surface area:

(F-2-6) $$E_{un} = 0.0016k\frac{\left(\frac{u}{2.2}\right)^{1.3}}{\left(\frac{mcW}{2}\right)^{1.4}}\left(\frac{L}{A}\right)\left(\frac{10^3 g}{kg}\right)\left(\frac{yr}{365d}\right)$$

Where k is an empirical constant that depends on particle size desired (see **Table F-1-6**), and the other parameter definitions are provided in **Table F-1-7**.

Table F-1-6. Coefficient Values for E_{un} Equation

Symbol	Units	PM_{10}
k	Unitless	0.35

Table F-1-7. Parameter Units and Definitions for $E10_{un}$

Symbol	Units	Definition
U	m/s	Mean annual wind speed
mcW	Volume %	Waste moisture content
L	Mg/yr	Annual average waste loading rate
A	m2	Contaminated surface area

F-1.2.4 Spreading/Compacting or Tilling Operations (E_{sc})

As in the 3MRA landfill model (U.S. EPA, 1999), the equation for estimating E_{sc} ($g/m^2/d$), the rate of PM emissions due to spreading and compacting or tilling operations, was adapted from an equation in U.S. EPA (1985b, Equation 1, p. 11.2.2-1) that was developed for estimating emissions due to agricultural tilling in units of kilogram of particulate emissions per hectare per tilling (or spreading/compacting) event.

(F-2-7) $$E_{sc} = 5.38k(S^{0.6})(N_{op})\left(\frac{ha}{10^4 m^2}\right)$$

Where k is an empirical constant that depends on particle size desired (see **Table F-1-8**), and the other parameter definitions are provided in **Table F-1-9**.

Table F-1-8. Coefficient Values for E_{sc} Equation

Symbol	Units	PM_{10}
k	Unitless	0.21

Table F-1-9. Parameter Units and Definitions for E_{sc}

Symbol	Units	Definition
S	w/w, %	Silt content of surface material
Nop	1/d	Number of spreading and compacting operations per day

F-1.3 Particle Size Distribution for $PM_{2.5}$

To calculate $PM_{2.5}$ emissions of fly ash for the $PM_{2.5}$ NAAQS, EPA conducted a literature search for particle size distributions for fly ash. EPA did not find any data for U.S. coal-fired power plant sites. However, Moreno et al. (2005) provide distributions for 23 pulverized coal-fired power plant sites in Europe. These sites were selected to cover most of the fly ash types produced in the European Union. The range of coal types in this study is similar to the range used in the United States, and electrostatic precipitators are used in over 90 percent of facilities in the United States (Bein et al., 2007). Therefore, EPA used these data to estimate a particle size distribution.

Moreno et al. (2005) list the particle sizes for the 10th, 50th and 90th percentiles for selected fly ash samples from each of the listed power plants (see **Table F-1-10**. EPA omitted one plant (the power station As Pontes) because its sample was a mixture of fly ash and molten slag. All other samples were collected at the ESP. EPA plotted the 10th and 50th percentiles on log-probability paper and determined the probabilities for particle sizes 2.5 and 10 µm, and then calculated the ratio of the PM_{10} to $PM_{2.5}$ percentiles for each power plant. The overall mass ratio of PM_{10} to $PM_{2.5}$

has a mean of 6.8 and a median of 6.2. Using the mean, this suggests a particle size distribution in which $PM_{2.5}$ account for about 15 percent of the total PM_{10}.

Table F-1-10. Particle Size Distributions for Selected Power Stations in the European Union

Power Station	Location	Size Percentile			Percentile		Ratio
		10th	50th	90th	PM_{10}	$PM_{2.5}$	$PM_{10}/PM_{2.5}$

Attachment F-2.
AERSCREEN Inputs

In general, AERSCREEN provides added capabilities that allow refinement of the screen estimates based on environmental setting and location. **Table F-2-1** shows the inputs needed. Not all input options presented in this table apply to this assessment, given that the sources that were modeled are ground-level area sources (so inputs specific to elevated point sources, such as building parameters and terrain, will not apply). However, these inputs were included in the table to allow for a comprehensive listing of the parameters. The following key components of the AERSCREEN model allow for the refinement of the CCR high-end dispersion estimates, as follows:

- AERSCREEN executes MAKEMET to generate a site-specific matrix of meteorological conditions, interfaces with AERMAP to process terrain, interfaces with BPIPPRM (Building Profile Input Program for PRIME) to process building information and executes AERMOD with special screening options. One of its postprocessing functions is to search for and isolate the receptor distance with the highest impact.
- MAKEMET takes into account many factors when creating the matrix of meteorological conditions. These include wind speeds, cloud covers, ambient temperatures, solar elevation angles and convective velocity scales for user-specific surface characteristics (albedo, Bowen ratio and surface roughness length). MAKEMET calculates mechanical mixing height and convective mixing height for convective conditions and includes AERMET subroutines for boundary layer calculations.
- As part of its screening function, MAKEMET eliminates sets of conditions that are not necessary for identifying worst-case impacts.
- The surface characteristics can be specified using three methods: constants input by the user (i.e., no spatial or temporal variation), seasonally varying for generic land use classifications or output from AERSURFACE.

Table F-2-1. Inputs Needed for AERSCREEN

Parameter	Units*	Values or Options Available
Model basis	—	AERMOD
Averaging time options	—	1-hour, 3-hour, 8-hour, 24-hour, annual
Emission rate	Model specific	g/s
Emission type	—	Vapor and particles
Source types	—	Point, flare, capped stack, horizontal stack, volume, rectangular area, circular area
Source release height above ground	m	Set to zero
Length of larger side of the rectangular area	m	Based on modeled unit size
Length of smaller side of the rectangular area	m	Based on modeled unit size
Radius of circular source	m	Based on modeled unit size
Receptor height above ground (flagpole receptor)	m	Set to zero
Initial vertical dimension of plume	m	Not applicable
Urban/rural option	U or R	Location specific
Urban population (if urban)	Count	Location specific
Wind direction search option (yes/no)	—	Set to yes
Wind direction angle (if wind direction search option set to no)	Degrees	(0° from N; long side is x-axis)
Meteorology option	—	Site-specific matrix of screening meteorological conditions (MAKEMET)
Minimum ambient air temperature	°K	Default available
Maximum ambient air temperature	°K	Default available
Minimum wind speed	m/s	Default available

(continued)

Table F-2-1. Inputs Needed for AERSCREEN

Parameter	Units*	Values or Options Available
Anemometer height	m	Default available
Land use type for surface characteristics	—	0=user-entered, 1=water, 2=deciduous forest, 3=coniferous forest, 4=swamp, 5=cultivated land, 6=grassland, 7=urban, 8=desert shrub land, 9=external file
Seasonally varying surface characteristics (option)	—	Not applied
Detailed temporally and spatially explicit surface characteristics (option)	—	AERSURFACE results
Climatology type	—	1=average, 2=wet, 3=dry
Albedo	—	Location-specific
Bowen ratio	—	Location-specific
Surface roughness	—	Location-specific
Distance to receptor	m	Minimum
Building parameters for wake effects	—	Executes BPIPPRM; not for area or volume sources
Terrain impacts	—	Automates AERMAP; not for rectangular area source
Geographic coordinates	—	Latitude/longitude, or UTM (UTM required for automated mode), NAD 1927 or NAD 1983

* AERSCREEN can accommodate either metric or English units; metric are shown here.

Appendix G.

Food Chain Equations and Data

[This Page Intentionally Left Blank]

G.1 Introduction

The equations used to calculate concentrations in food chain items and total intake for human receptors are shown in this section.

- **Attachment G-1** provides each of the chemical-specific bioconcentration and biotransfer factors needed.

G.2 Food Chain Equations

G.2.1 Concentrations in Fish

This section contains the equations for contaminant concentrations in fish:

- **Table G-1.** Concentration in Fish at Different Trophic Levels
- **Table G-2.** Average Fish Fillet Concentration Ingested by Humans.

Table G-1. Concentration in Fish at Different Trophic Levels (mg/kg)

C_{fish}	
For Nonvolatile Metals:	**For Mercury:**
$C_{fish} = C_{wTot} \times BCF_i$	$C_{fish} = 0.15 \times C_{dw} \times BCF_i$

Name	Description	Value
BCF_i	Bioconcentration factor for specified trophic level (L/kg)	See **Table G-1-1**
C_{dw}	Dissolved waterbody concentration (mg/L)	Calculated
C_{wTot}	Total waterbody concentration from loading (g/m^3 or mg/L)	Calculated
0.15	Fraction of dissolved mercury assumed to be methyl mercury (unitless)	Source: HHRAP (U.S. EPA, 2005)

Table G-2. Average Fish Fillet Concentration Ingested by Humans (mg/kg)

C_{fish_fillet}

$$C_{fish_fillet} = F_{T3} \times C_{fishT3F} + F_{T4} \times C_{fishT4F}$$

Name	Description	Value
$C_{fishT3F}$	Concentration of contaminant in fish at different trophic levels (mg/kg)	Calculated
$C_{fishT4F}$	Concentration of contaminant in fish at different trophic levels (mg/kg)	Calculated
F_{T3}	Fraction of trophic level 3 intake (unitless)	See **Appendix D**
F_{T4}	Fraction of trophic level 4 intake (unitless)	See **Appendix D**

G.2.2. Concentrations in Produce

This section contains the equations for contaminant concentration in produce, forage, silage, grain, and animal products:

- **Table G-3.** Concentration in Aboveground Produce Due to Soil Uptake
- **Table G-4.** Concentration in Root Vegetables Due to Soil Uptake
- **Table G-5.** Concentration in Aboveground Produce due to Deposition
- **Table G-6.** Concentration in Exposed Fruits and Vegetables Due to Deposition
- **Table G-7.** Concentration in Protected Fruits and Vegetables Due to Deposition
- **Table G-8.** Concentration in Forage and Silage
- **Table G-9.** Concentration in Grain.

Table G-3. Concentration in Aboveground Produce Due to Soil Uptake (mg/kg DW)

Pr_i

$$Pr_i = C_{soil} \times Br_i$$

Name	Description	Value
C_{soil}	Soil concentration (mg/kg)	Calculated
Br_i	Plant-soil bioconcentration factor for aboveground produce type i ([mg/kg DW plant]/[mg/kg soil]) (chemical specific)	See **Table G-1-1**

Table G-4. Concentration in Root Vegetables Due to Soil Uptake (mg/kg WW)

Pr_{bg}

$$Pr_{bg} = C_{soil} \times Br_{root} \times \frac{(100 - MAF_{root})}{100}$$

Name	Description	Value
C_{soil}	Soil concentration (mg/kg)	Calculated
Br_{root}	Plant-soil bioconcentration factor for root vegetables ([mg/kg DW plant]/[mg/kg soil]) = RCF (root concentration factor) divided by K_d of soil (chemical specific)	See **Table G-1-1**
MAF_{root}	Moisture adjustment factor for root vegetables (% water)	See Table G-15

Table G-5. Concentration in Aboveground Produce due to Deposition (mg/kg DW)

Pd_i

$$Pd_i = \frac{Dp \times Rp_i \times (1 - e^{-KpPart \times Tp_i})}{Yp_i \times KpPar}$$

Name	Description	Value
Dp	Deposition term for plants (mg/m^2-yr)	Calculated
Rp_i	Interception fraction for aboveground produce type i (unitless)	See **Table G-15**
KpPar	Plant surface loss coefficient for particulates (1/yr)	Mercury: 40.41* Other constituents: 18.07*
Tp_i	Length of plant exposure to deposition per harvest of edible portion of plant for aboveground produce type i (yr)	See **Table G-15**
Yp_i	Yield or standing crop biomass of the edible portion of the plant (productivity) for aboveground produce type i (kg DW/m^2)	See **Table G-15**

* Source: U.S. EPA (1997b)

Table G-6. Concentration in Exposed Produce Due to Deposition (mg/kg DW)

P_{exp}

$$P_{exp} = (Pd_i + Pr_i) \times \frac{(100 - MAF_i)}{100}$$

Name	Description	Value
Pdi	Concentration in aboveground produce type i due to deposition (mg/kg DW)	Calculated
Pri	Concentration in aboveground produce type i due to soil uptake (mg/kg DW)	Calculated
MAFi	Moisture adjustment factor for aboveground produce type i (unitless)	See **Table G-15**

Table G-7. Concentration in Protected Produce Due to Deposition (mg/kg DW)

P_{pro}

$$P_{pro} = Pr_i \times \frac{(100 - MAF_i)}{100}$$

Name	Description	Value
Pr_i	Concentration in aboveground produce type i due to soil uptake (mg/kg DW)	Calculated
MAF_i	Moisture adjustment factor for aboveground produce type i (unitless)	See **Table G-15**

Table G-8. Concentration in Forage and Silage (mg/kg DW)

P_{forage}, P_{silage}

$$P_{forage} = (Pd_{forage} + Pr_{forage})$$

$$P_{silage} = (Pd_{silage} + Pr_{silage})$$

Name	Description	Value
Pd_i	Concentration in aboveground produce type i due to deposition (mg/kg DW)	Calculated
Pr_i	Concentration in aboveground produce type i due to soil uptake (mg/kg DW)	Calculated

Table G-9. Concentration in Grain (mg/kg DW)

P_{grain}

$$P_{grain} = Pr_i$$

Name	Description	Value
Pr_i	Concentration in aboveground produce type i due to soil uptake (mg/kg DW)	Calculated

G.2.3. Concentrations in Animal Products

This section contains the equations for contaminant concentration animal products:

- **Table G-10.** Concentration in Beef
- **Table G-11.** Concentration in Dairy.

Table G-10. Concentration in Beef (mg/kg)

A_{beef}

$$A_{beef} = Ba_{beef} \times [(F_{grain} \times Q_{gbs} \times P_{grain}) + (F_{forage} \times Q_{fbs} \times P_{forage}) + (F_{silage} \times Q_{sbs} \times P_{silage}) + (Q_{soilbs} \times C_{soil})]$$

Name	Description	Value
Ba_{beef}	Biotransfer factor from soil or feed to beef ([mg/kg-WW]/[mg/day])	See **Table G-1-1**
P_{forage}	Concentration in forage (mg/kg DW)	Calculated
P_{silage}	Concentration in silage (mg/kg DW)	Calculated
P_{grain}	Concentration in grain (mg/kg DW)	Calculated
F_{forage}	Fraction of forage that is contaminated (unitless)	See **Table G-15**
F_{silage}	Fraction of silage that is contaminated (unitless)	See **Table G-15**
F_{grain}	Fraction of grain that is contaminated (unitless)	See **Table G-15**
Q_{fbs}	Quantity of forage consumed by beef cattle (kg-DW/day)	See **Table G-15**
Q_{gbs}	Quantity of grain consumed by beef cattle (kg-DW/day)	See **Table G-15**
Q_{sbs}	Quantity of silage consumed by beef cattle (kg-DW/day)	See **Table G-15**
Q_{soilbs}	Quantity of soil consumed by beef cattle (kg/day)	See **Table G-15**
C_{soil}	Concentration in soil (mg/kg)	Calculated

Table G-11. Concentration in Dairy (mg/kg)

Amilk

$$A_{milk} = Ba_{milk} \times [(F_{grain} \times Q_{gds} \times P_{grain}) + (F_{forage} \times Q_{fds} \times P_{forage}) + (F_{silage} \times Q_{sds} \times P_{silage}) + (Q_{soilds} \times C_{soil})]$$

Name	Description	Value
Ba_{milk}	Biotransfer factor from soil or feed to dairy ([mg/kg-WW]/[mg/day])	See **Table G-1-1**
P_{forage}	Concentration in forage (mg/kg DW)	Calculated
P_{silage}	Concentration in silage (mg/kg DW)	Calculated
P_{grain}	Concentration in grain (mg/kg DW)	Calculated
F_{forage}	Fraction of forage that is contaminated (unitless)	See **Table G-15**
F_{grain}	Fraction of grain that is contaminated (unitless)	See **Table G-15**
F_{silage}	Fraction of silage that is contaminated (unitless)	See **Table G-15**
Q_{fds}	Quantity of forage consumed by dairy cattle (kg-DW/day)	See **Table G-15**
Q_{gds}	Quantity of grain consumed by dairy cattle (kg-DW/day)	See **Table G-15**
Q_{sds}	Quantity of silage consumed by dairy cattle (kg-DW/day)	See **Table G-15**
Q_{soilds}	Quantity of soil consumed by dairy cattle (kg/day)	See **Table G-15**
C_{soil}	Concentration in soil (mg/kg).	Calculated

G.2.4. Intake Rates

This section contains the equations for intake of drinking water, soil, produce, animal products, and fish:

- **Table G-12.** Contaminant Intake from Drinking Water
- **Table G-13.** Daily Intake of Contaminant from Fish Ingestion
- **Table G-14.** Daily Intake of Contaminant from Produce or Animal Product Ingestion.

Table G-12. Daily Intake from Drinking Water (mg/kg-day)

I_{dw}

$$I_{dw} = \frac{C_{dw} \times CR_{dw} \times F_{dw}}{1{,}000}$$

Name	Description	Value
C_{dw}	Dissolved waterbody concentration (mg/L)	Calculated
CR_{dw}	Consumption rate of water (mL/kg-day)	See **Appendix D**
F_{dw}	Fraction of drinking water ingested that is contaminated (unitless)	See **Appendix D**

Table G-13. Daily Intake from Fish Ingestion (mg/kg-day)

I_{fish}

$$I_{fish} = \frac{C_{fish_fillet} \times CR_{fish} \times F_{fish}}{1000 \times BW}$$

Name	Description	Value
BW	Body weight (kg)	See **Appendix D**
C_{fish_fillet}	Average fish fillet concentration ingested by humans (mg/kg)	Calculated
CR_{fish}	Consumption rate of fish (g WW/day)	See **Appendix D**
F_{fish}	Fraction of fish intake from contaminated source (unitless)	See **Appendix D**

Table G-14. Daily Intake from Produce or Animal Product Ingestion (mg/kg-day)

$I_{produce}$, I_{beef}, I_{milk}

$$I_i = \frac{C_i \times CR_i \times F_i}{1{,}000}$$

Name	Description	Value
C_i	Average concentration in plant or animal product *i* ingested by humans (mg/kg)*	Calculated
CR_i	Consumption rate of plant or animal product *i* (g/day) [a]	See **Appendix D**
F_i	Fraction of plant or animal product *i* intake from contaminated source (unitless)	See **Appendix D**

* Concentrations and consumption rates must be in dry weight for aboveground plants (so mg/kg DW or g DW/day) and whole weight for root vegetables and animal products (so mg/kg WW or g WW/day).

G.3 Biota Data

The biota data needed for the above equations are presented in **Table G-15**. These values are all constants and were all drawn from the U.S. Environmental Protection Agency's (EPA's or the Agency's) *Parameter Guidance Document* (U.S. EPA, 1997b).

Table G-15. Biota Data

Model Code	Description	Value
F_forage	Fraction of pasture grasses grown on contaminated soil and eaten. (unitless)	1
F_grain	Fraction of grain grown on contaminated soil and eaten (unitless)	1
F_silage	Fraction of silage grown on contaminated soil and eaten (unitless)	1
MAF_exfruit	Moisture adjustment factor for exposed fruits (% water)	85
MAF_exveg	Moisture adjustment factor for exposed vegetables (% water)	92
MAF_profruit	Moisture adjustment factor for protected fruits (% water)	90
MAF_proveg	Moisture adjustment factor for protected vegetables (% water)	80
MAF_root	Moisture adjustment factor for root vegetables (% water)	87
Rp_exfruit	Interception fraction for exposed fruit (unitless)	0.052
Rp_exveg	Interception fraction for exposed vegetation (unitless)	0.052
Rp_forage	Interception fraction for forage (unitless)	0.47
Rp_silage	Interception fraction for silage (unitless)	0.44
Tp_exfruit	Length of plant exposure to deposition for exposed fruit (yr)	0.123
Tp_exveg	Length of plant exposure to deposition for exposed vegetables (yr)	0.123
Tp_forage	Length of plant exposure to deposition for forage (yr)	0.123
Tp_silage	Length of plant exposure to deposition for silage (yr)	0.164
Yp_exfruit	Crop yield for exposed fruit (kg DW/m^2)	0.09
Yp_exveg	Crop yield for exposed veg (kg DW/m^2)	0.18
Yp_forage	Crop yield for forage (kg DW/m^2)	0.31
Yp_silage	Crop yield for silage (kg DW/m^2)	0.31
Q_{fbs}	Quantity of forage consumed by beef cattle (kg-DW/day)	8.8
Q_{gbs}	Quantity of grain consumed by beef cattle (kg-DW/day)	0.47
Q_{sbs}	Quantity of silage consumed by beef cattle (kg-DW/day)	2.5
Q_{soilbs}	Quantity of soil consumed by beef cattle (kg/day)	0.39
Q_{fds}	Quantity of forage consumed by dairy cattle (kg-DW/day)	11
Q_{gds}	Quantity of grain consumed by dairy cattle (kg-DW/day)	2.6
Q_{sds}	Quantity of silage consumed by dairy cattle (kg-DW/day)	3.3
Q_{soilds}	Quantity of soil consumed by dairy cattle (kg/day)	0.41

G.4 Bioconcentration and Biotransfer Data

Data on certain chemical-specific factors were used to estimate the degree to which constituents of potential concern (COPCs) may accumulate in exposed plants and animals. In turn, this information is used to calculate residential exposures from consumption of produce, livestock, and fish. Available data was gathered for each of the following 25 COPCs identified during hazard identification (**Section 2**):

- Aluminum
- Antimony
- Arsenic
- Barium
- Beryllium
- Boron
- Cadmium
- Chromium
- Cobalt
- Copper
- Fluoride
- Iron
- Lanthanum
- Lead
- Lithium
- Manganese
- Mercury
- Molybdenum
- Nickel
- Nitrate
- Selenium
- Silver
- Strontium
- Thallium
- Uranium
- Vanadium
- Zinc

Bioconcentration factors (BCFs) and biotransfer factors (BTFs) are based on the compilation of field and laboratory study results to develop a single factor or ratio for estimating the amount of constituent transferred into specific plant or animal tissue. EPA estimated fish tissue concentrations for trophic level 3 (TL3) and trophic level 4 (TL4) fish filets to account for the variability in fish likely consumed by human receptors. The following source hierarchy was used for fish BCFs:

- **Primary literature:** These are generally papers that may focus on a single chemical (Eisler, 1989; Kumada et al., 1973; Lemly, 1985; Murphy et al., 1978) or may contain data on multiple chemicals (Barrows et al., 1980; Stephan, 1993).
- **U.S. EPA databases/publications:** These included ECOTOX (U.S. EPA, 2009) and the Mercury Report to Congress (U.S. EPA, 1997a).
- **Other government agency resources:** These included Agency for Toxic Substances and Disease Registry (ATSDR) Toxicological Profiles (ATSDR, 2008) and the Hazardous Substances Data Bank (HSDB; U.S. NLM, 2011).

Where data for only one trophic level of fish were available, those data were used as a surrogate for the other trophic level. Where data were only available for whole fish, those were used as a surrogate for filet. Whole fish values from the correct trophic level were preferred as surrogates to filet values from the other trophic level. So, given a TL3 whole fish value and a TL4 filet value, the TL3 whole value would be preferred to the TL4 filet as a surrogate for TL3 filet. Similarly, EPA evaluated different categories of produce and animal products to capture the variability in farm-raised foods consumed by human receptors. The key source for biotransfer factors for animal products and plants was Baes et al. (1984).

Attachment G-1. Bioconcentration and Biotransfer Factors

Table B-1-1 lists all of the chemical-specific parameters collected for this analysis, presented in alphabetical order based on the name of the constituent. In some instances, adequate data was not available on one or more of the parameters for a given constituent. In these cases, the analysis could not quantitatively consider exposures through the associated pathway. The factor abbreviations are defined below as follows:

- **Ba_{Beef} & Ba_{Milk}:** Biotransfer factor for beef or milk (day/kg-wet weight); primary data source is Baes et al. (1984).
- **BCF_{T3F} & BCF_{T4F}:** Bioconcentration factor for trophic level 3 (TL3) and trophic level 4 (TL4) fish filet (L/kg); data mostly drawn from primary literature or ECOTOX (U.S. EPA, 2009)
- **Br_i:** Soil-to-plant bioconcentration factor for plant type *i* (µg/g-plant dry weight)/(µg/g soil); primary data source is Baes et al. (1984), but some factors are calculated based on U.S. EPA (2009) if not available in Baes et al. Plant types are:
  - **ExFruit:** Exposed fruits eaten by human receptors;
  - **ExVeg:** Exposed vegetables eaten by human receptors;
  - **Forage:** Forage eaten by cattle;
  - **Grain:** Grains eaten by cattle;
  - **ProFruit:** Protected fruits eaten by human receptors;
  - **ProVeg:** Protected vegetables eaten by human receptors;
  - **Root:** Root vegetables eaten by human receptors; and
  - **Silage:** Silage eaten by cattle.

When the reference is a compilation, the original paper from which the value was drawn is also shown, if available. For example, "ECOTOX Wright, 1977" means the value was obtained from ECOTOX, which cites Wright (1977). Similarly, "ATSDR Hope 1996" means we obtained it from the ATSDR toxicological profile, which cites Hope (1996).

Estimation of Contaminant Partition Coefficients for the CCR Risk Assessment

[This Page Intentionally Left Blank]

H.1 Introduction

The following appendix details the development of soil-water partitioning coefficients used to model COPC concentrations in ground water.

- **Attachment H-1** provides a report developed for EPA by Allison Geoscience Consultants. This report summarized the statistical analysis of the concentrations of major ions in the pore water that was conducted to identify distinct waste types. This report has been reformatted by EPA for consistency; however, no substantive changes have been made to the content.
- **Attachment H-2** provides plots of the nonlinear sorption isotherms used in the CCR risk assessment, organized by waste management unit type (landfill or surface impoundment), constituent, soil/aquifer environment (carbonate or noncarbonate), and saturated (aquifer) or unsaturated (soil) zone.
- **Attachment H-3** tabulates, by constituent, K_d percentiles for the saturated and unsaturated zones from the inputs of the probabilistic modeling described in **Section 4** of this document.

Executive Summary

This report describes the development of concentration-dependent partition coefficients for use in modeling subsurface leaching of Coal Combustion Residues (CCR) using the fate and transport model EPACMTP (EPA Composite Model with Transformation Products). EPACMTP incorporates the option of using nonlinear contaminant-specific tables of partitioning values in which the contaminant partitioning is presented over a range of contaminant concentration levels (isotherms) for particular settings of environmental variables that control partitioning. These tables of sorption isotherms reflect the tendency of Kd to decrease as the total contaminant concentration in the system increases. The isotherms were estimated using the geochemical speciation model MINTEQA2. For a particular contaminant, Kd values in a soil or aquifer are dependent upon the contaminant concentration and various geochemical characteristics of the soil or aquifer and the associated porewater.

Geochemical parameters that have the greatest influence on the magnitude of Kd include the pH of the system and the nature and concentration of sorbents associated with the soil or aquifer matrix. In the subsurface beneath a disposal facility, the concentration of leachate constituents may also influence Kd. This is especially true of some CCR leachates that may have high concentrations of calcium, sulfate, and other inorganic constituents. The use of a speciation model allows Kd values to be estimated for a range of total contaminant concentrations in various model systems designed to depict natural variability in those geochemical characteristics that most influence contaminant partitioning.

The CCR constituents whose partition coefficients have been estimated using MINTEQA2 correspond to those that failed the screen of CCR wastes (discussed in Appendix K of the risk assessment document) through the groundwater exposure pathways: aluminum, antimony (V), arsenic (III and V), barium, beryllium, boron, cadmium (II), chromium (III and VI), cobalt (II), copper (II), fluoride ion, iron (II), lead (II), manganese (II), mercury (II), molybdenum (VI), nickel (II), selenium (IV and VI), silver (I), thallium(I), vanadium (V), and zinc (II). Expected natural variability in Kd for a particular contaminant was included in the MINTEQA2 modeling by including variability in important input parameters upon which Kd depends.

The input parameters for which variability was incorporated include groundwater chemical composition, pH, concentration of aquifer sorbents, composition and concentration level of CCR leachate, and concentration of the contaminant. Two groundwater compositions were used: carbonate and noncarbonate. The natural pH range for each of these groundwater types is restricted (about 7 to 9 for carbonate terrain waters and 4 to 10 for noncarbonate. However, CCR leachate ranges from very acidic (pH < 2) to highly alkaline (pH > 12) and intrusion of leachate into the soil/aquifer system can impact the groundwater pH. For many contaminants modeled here, the magnitude of the partition coefficient is very much dependent on pH. This dependence was

included in the estimated partition coefficients by equilibrating the leachate/groundwater system at a series of pH values that span the range of expected variability in mixed leachate-groundwater systems. The influence of variability in the sorption capacity of soil and aquifer materials on Kd estimates was included by equilibrating the groundwater systems with various concentrations of two commonly occurring natural sorbents: ferric oxyhydroxide and particulate organic matter (POM). CCR leachate can include elevated concentrations of inorganic constituents such as calcium, sulfate, sodium, potassium, and chloride. Elevated concentrations of leachate constituents may reduce sorption of metals due to competition for sorption sites or complexation with metals in solution. The influence of elevated concentrations of leachate constituents on Kd estimates was included in the modeling by adding leachate components at concentrations representative of CCR leachate. Examination of the major ion concentrations in a database of CCR porewater and leachate samples led to the choice of four representative leachate chemistries: ash codisposed with coal refuse, fluidized bed combustion (FBC) waste leachate, flue gas desulfurization (FGD) waste leachate, and combined ash (primarily non-FBC fly ash) leachate.

Each MINTEQA2 model execution produced an isotherm for a particular contaminant and was defined by the following selections of system variables:

- groundwater type (carbonate or noncarbonate)
- hydrologic zone (unsaturated or saturated)
- ferric oxide (FeOx) sorbent concentration level (low, medium, high)
- POM/dissolved organic matter (DOM) concentration level (low, medium, high)
- equilibrium pH (range depends on groundwater type and leachate type)
- leachate type (ash and coal refuse, FBC waste, FGD waste, or combined ash)
- leachate "richness" or ionic strength

For each constituent modeled, the results of each MINTEQA2 model run were compiled as the equilibrium distribution of the contaminant among dissolved, sorbed, and precipitated fractions. These results were saved in a separate file indexed with the settings of all variables defining the system. Such files were produced for all possible values for the variables defining the system and were compiled into a database of indexed K_d values for use in the EPACMTP fate and transport model. A typical plot of K_d versus total contaminant concentration from a MINTEQA2 output file for arsenic is shown in **Figure 1**.

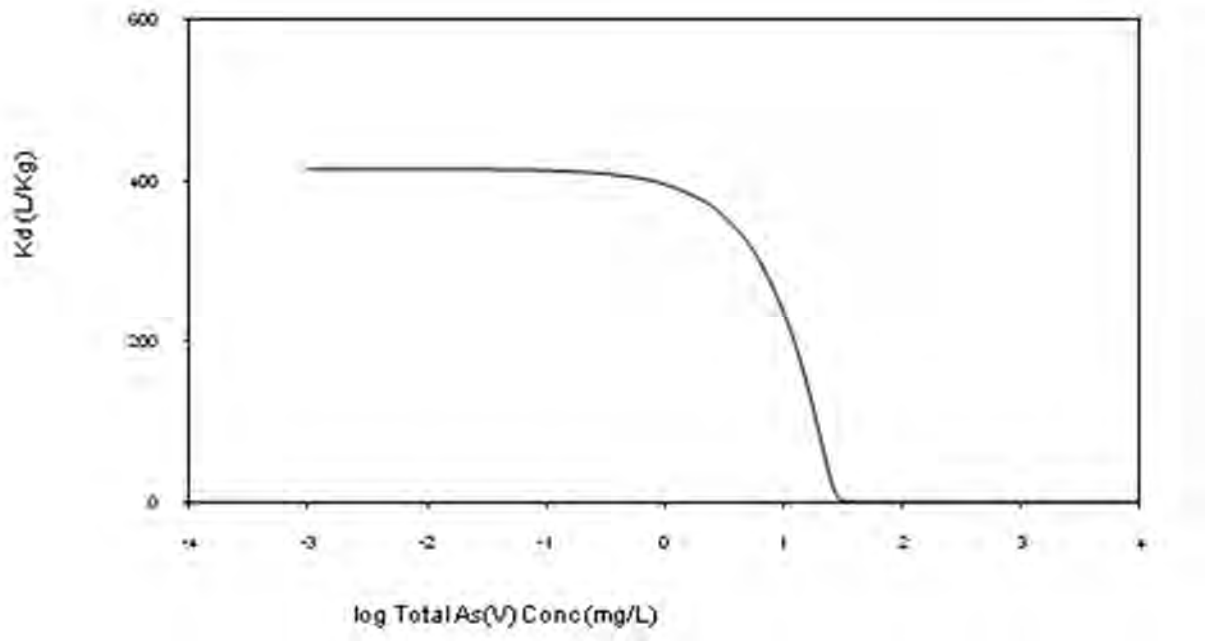

Figure 1. Typical K_d versus total contaminant concentration response curve from MINTEQA2.

1 Introduction

This report describes the development of concentration-dependent partition coefficients for use in modeling subsurface leaching of coal combustion residues (CCR) using the groundwater fate and transport model EPACMTP. In the subsurface, metal and nonmetal contaminants undergo reactions with ligands in the porewater and with surface sites on the solid aquifer or soil matrix material. Reactions in which the contaminant is bound to the solid matrix are referred to as sorption reactions, and a contaminant that is bound to the solid is said to be sorbed. The ratio of the concentration of contaminant sorbed to the concentration in the mobile aqueous phase at equilibrium is referred to as the partition coefficient (K_d). During contaminant transport, sorption to the solid matrix results in retardation of the contaminant front. Transport models such as EPACMTP incorporate the contaminant partition coefficient into the overall retardation factor (the ratio of the average linear particle velocity to the velocity of that portion of the plume where the contaminant is at 50 percent dilution. The use of K_d in EPACMTP transport modeling implies the assumption that local equilibrium between the solutes and the sorbents is attained. This implies that the rate of sorption reactions is fast relative to advective-dispersive transport of the contaminant.

EPACMTP incorporates the option of using contaminant-specific tables of partitioning values in which the contaminant partitioning is presented over a range of contaminant concentration levels for particular settings of environmental variables that control partitioning. These tables of sorption isotherms reflect the tendency of K_d to decrease as the total contaminant concentration in the system increases. Isotherms for use in EPACMTP are specified in terms of the dissolved contaminant concentration and the corresponding sorbed concentration at a series of total contaminant concentrations. The isotherms were estimated using the geochemical speciation model MINTEQA2.

For a particular contaminant, K_d values in a soil or aquifer are dependent upon the contaminant concentration and various geochemical characteristics of the soil or aquifer and the associated porewater. Geochemical parameters that have the greatest influence on the magnitude of K_d include the pH of the system and the nature and concentration of sorbents associated with the soil or aquifer matrix. In the subsurface beneath a disposal facility, the concentration of leachate constituents may also influence K_d. This is especially true of some CCR leachates that may have high concentrations of calcium, sulfate, and other inorganic constituents. Although the dependence of partitioning on the total contaminant concentration and on pH and other geochemical characteristics is apparent from partitioning studies reported in the scientific literature, K_d values for individual contaminants are not available for the range of concentrations or geochemical conditions relevant in the CCR land disposal scenarios. It is for this reason that the U.S. Environmental Protection Agency (EPA) has chosen to use an equilibrium speciation model to estimate partition coefficients for the CCR study. The use of a speciation model allows K_d values

to be estimated for a range of total contaminant concentrations in various model systems designed to depict natural variability in those geochemical characteristics that most influence partitioning.

1.1 Description of MINTEQA2

The nonlinear sorption isotherms for contaminants were produced by using MINTEQA2,[1] a geochemical speciation model maintained and distributed by the U.S. EPA. From input data consisting of total concentrations of chemical constituents, MINTEQA2 calculates the fraction of a contaminant that is dissolved, adsorbed, and precipitated at equilibrium (see **Figure 2**). The total concentrations of major and minor ions, trace metals, and other chemicals are specified in terms of key species known as components. MINTEQA2 automatically includes an extensive database of solution species and solid phase species representing reaction products of two or more of the components. The model does not automatically include sorption reactions, but these can be included in the calculations if supplied by the user. When sorption reactions are included, the dimensionless partition coefficient can be calculated from the ratio of the sorbed contaminant concentration to the dissolved concentration at equilibrium. The dimensionless partition coefficient is converted to K_d with units of liters per kilogram (L/kg) by normalizing by the mass of soil (in kilograms) with which 1 liter of porewater is equilibrated (the phase ratio). An isotherm is generated when the equilibrium distribution between sorbed and dissolved fractions is estimated for a series of total contaminant concentrations.

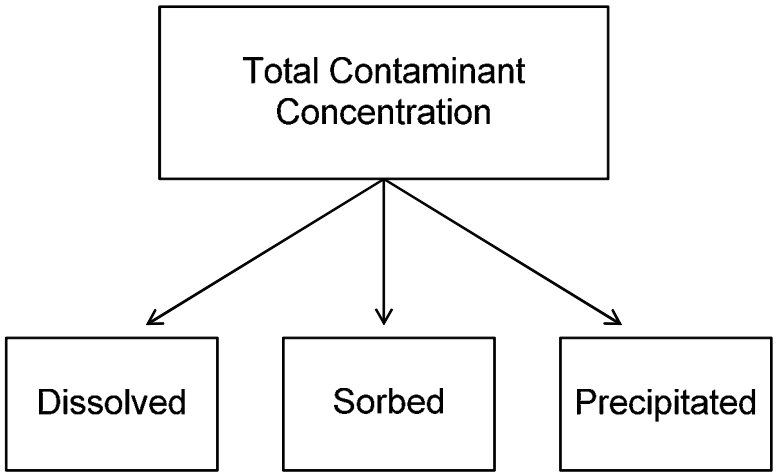

Figure 2. MINTEQA2 computes the equilibrium distribution of contaminant.

Progress in accounting for sorption in equilibrium calculations over the past decade has resulted in the development of coherent databases of sorption reactions for particular sorbents. These databases include acid-base sorption reactions and reactions for major ions in aquatic systems (calcium, magnesium, sulfate [SO_4], etc. Including such reactions along with those representing sorption of the contaminant makes it possible to estimate sorption in systems of varying pH and

[1] The version of MINTEQA2 used in this modeling was modified from version 4.02.

composition. Examples of coherent databases of sorption reactions include that for the hydrous ferric oxide (HFO) surface presented by Dzombak and Morel (1990) and a similar database for goethite presented by Mathur (1995).

1.2 Contaminants of Interest

The contaminants whose partition coefficients have been estimated using MINTEQA2 correspond to those that failed the groundwater pathway screening described in **Section 3**. These contaminants are listed in **Table 1**.

Table 1. Contaminants for which Partition Coefficients Were Computed

Contaminant	Oxidation State(s) Modeled	MINTEQA2 Component
Aluminum (Al)	+3	Al^{3+}
Antimony (Sb)	+5	$Sb(OH)_6^-$
Arsenic (As)	+3, +5	H_3AsO_3, H_3AsO_4
Barium (Ba)	+2	Ba^{2+}
Beryllium	+2	Be+2
Boron (B)	+3	H_3BO_3
Cadmium (Cd)	+2	Cd^{2+}
Chromium (Cr)	+3, +6	$Cr(OH)_2^+$, CrO_4^{2-}
Cobalt (Co)	+2	Co^{2+}
Copper (Cu)	+2	Cu^{2+}
Fluoride (F)	-1	F^-
Iron (Fe)	+2	Fe^{2+}
Lead (Pb)	+2	Pb^{2+}
Manganese	+2	Mn^{2+}
Mercury (Hg)	+2	$Hg(OH)_2$
Molybdenum (Mo)	+6	MoO_4^{2-}
Nickel (Ni)	+2	Ni^{2+}
Selenium (Se)	+4, +6	$HSeO3^-$, SeO_4^{2-}
Silver (Ag)	+1	Ag^+
Thallium (Tl)	+1	Tl^+
Vanadium (V)	+5	VO_2^+
Zinc (Zn)	+2	Zn^{2+}

Several of these contaminants occur naturally in more than one oxidation state. The modeling described here is restricted to the oxidation states that are most likely to occur in waste systems or

most likely to be mobile in groundwater-waste systems. Partition coefficients were modeled for two oxidation states each for arsenic, selenium, and chromium. These were arsenic (III) and (V), selenium (IV) and (VI), and chromium (III) and (VI). For antimony, molybdenum, thallium, copper, iron, and vanadium only one oxidation state was modeled although multiple oxidation states occur. For these metals, the choice of which state to model was dictated by practical aspects such as availability of sorption reactions and by subjective assessment of the appropriate (or predominant) oxidation state. The oxidation states modeled were antimony (V) (there were no sorption reactions available for antimony [III]), molybdenum (VI) (molybdate seems the most relevant form from literature reports), thallium (I) (this form is more frequently cited in the literature as having environmental implications), copper (II) (this oxidation state seemed to be more likely in coal ash leachate), iron (II) (ferric iron is more likely to be precipitated), and vanadium (V) (this seems the most relevant form, and sorption reactions were available for this form only. Table 1 lists the oxidation states modeled for all contaminants.

2 Modeling Approach

Expected natural variability in K_d for a particular contaminant was included in the MINTEQA2 modeling by including variability in important input parameters upon which K_d depends. The input parameters for which variability was incorporated include groundwater composition, pH, concentration of aquifer sorbents, composition and concentration level of CCR leachate, and concentration of the contaminant.

The groundwater chemistry exerts an important influence on partition coefficients. The major ions present in groundwater may compete with trace metals for sorption sites. Also, inorganic ligands may complex with some metals, reducing their tendency to sorb. For the purposes of this modeling, it is assumed that the influence of groundwater composition on sorption of the contaminant can be adequately represented by dividing the universe of groundwater compositional types into two categories: carbonate and noncarbonate. The natural pH range for each of these groundwater types is restricted (about 7 to 9 for carbonate terrain waters and 4 to 10 for noncarbonate. However, CCR leachate ranges from acidic ($pH < 2$) to highly alkaline ($pH > 12$) and intrusion of leachate into the soil/aquifer system can impact the groundwater pH. For many metals, the magnitude of the partition coefficient is very much dependent on pH. This dependence was included in the estimated partition coefficients by equilibrating the leachate/groundwater system at a series of pH values that span the range of expected variability.

The influence of variability in sorption capacity of soil and aquifer materials on K_d estimates was included by equilibrating the groundwater systems with various concentrations of two commonly occurring natural sorbents: ferric oxyhydroxide and particulate organic matter (POM). Although other sorbents such as clay minerals, carbonate minerals, hydrous aluminum and manganese oxides, and silica may sorb metals in the subsurface, representation of ferric oxyhydroxide and

particulate organic matter in the model is sufficient to provide a conservative assessment of the sorption capacity of most natural groundwater systems.

CCR leachate can include elevated concentrations of inorganic constituents such as calcium, sulfate, sodium, potassium, and chloride. Elevated concentrations of iron and manganese also occur in certain types of leachate. Upon mixing with groundwater, elevated concentrations of leachate constituents may reduce sorption of metals due to competition for sorption sites or complexation with metals in solution. The influence of elevated concentrations of leachate constituents on K_d estimates was included in the modeling by adding leachate components at concentrations representative of CCR leachate. In this way, the MINTEQA2 model systems included competitive sorption reactions, metal complexation, and elevated ionic strength effects from CCR leachate in computing the K_d values.

2.1 Characterization of Model Groundwater Systems

The extent of contaminant sorption in a groundwater system is dependent upon the chemical characteristics of the porewater solution and the interactions between all solutes and the sorbing sites present on the exposed surfaces of the soil and aquifer matrix material. Here, partition coefficients were estimated separately for two groundwater compositional types, one with composition representative of a carbonate-terrain system and one representative of a noncarbonate system. The two groundwater compositional types are correlated with the hydrogeologic environment parameter in EPACMTP. In EPACMTP, this parameter may take on 1 of 13 values, each indicative of a particular groundwater type (see **Table 2**). Issues of practicality limit the number of groundwater types for which separate partition coefficients can be estimated to just two. The broadest division that may be made of the 13 groundwater types in EPACMTP is carbonate and noncarbonate. Thus, coefficients were estimated for these two broad types. The carbonate type corresponds to the "solution limestone" hydrogeologic environment setting in EPACMTP (hydrogeologic environment parameter = 12). The other 12 possible hydrogeologic settings in EPACMTP are represented by the noncarbonate groundwater type.

Table 2. Settings for the Hydrogeologic Environment Parameter in EPACMTP

Hydrogeologic Environment Parameter	Environment (Groundwater Type) Represented
1	Metamorphic and Igneous (noncarbonate)
2	Bedded Sedimentary Rock (noncarbonate)
3	Till Over Sedimentary Rock (noncarbonate)
4	Sand and Gravel (noncarbonate)
5	Alluvial Basins Valleys and Fans (noncarbonate)
6	River Valleys and Floodplains with Overbank Deposits (noncarbonate)

(continued)

Table 2. Settings for the Hydrogeologic Environment Parameter in EPACMTP

Hydrogeologic Environment Parameter	Environment (Groundwater Type) Represented
7	River Valleys and Floodplains without Overbank Deposits (noncarbonate)
8	Outwash (noncarbonate)
9	Till and Till Over Outwash (noncarbonate)
10	Unconsolidated and Semi-consolidated Shallow Aquifers (noncarbonate)
11	Coastal Beaches (noncarbonate)
12	Solution Limestone (carbonate)
13	Others (unclassified hydrogeologic environments) (noncarbonate)

2.1.1 Model Groundwater Composition

For both groundwater types, representative charge-balanced groundwater chemistry specified in terms of major ion concentrations and natural pH was selected from the literature. The carbonate system was represented by a well sample reported for a limestone aquifer (Freeze and Cherry, 1979). This groundwater had a natural pH of 7.5 and was saturated with respect to calcite. The noncarbonate system was represented by a sample reported from an unconsolidated sand and gravel aquifer with a natural pH of 7.4 (White et al., 1963). An unconsolidated sand and gravel aquifer was selected to represent the noncarbonate compositional type because it is the most frequently occurring of the 12 (noncarbonate) hydrogeologic environments in EPACMTP. The compositions of both the carbonate and noncarbonate representative groundwater samples are shown in **Table 3**. These compositions were used in MINTEQA2 to estimate partition coefficients for carbonate and noncarbonate groundwater types. When EPACMTP is used in site-specific or Monte Carlo mode, the choice of the hydrogeologic environment by the user (or the Monte Carlo routine) dictates the set of partition coefficients (carbonate or noncarbonate) that should be accessed.

2.1.2 Model Adsorbents

Two types of adsorbents were represented in the MINTEQA2 equilibrium modeling: ferric oxide and POM. FeOx (and hydroxides) and POM are among the most important sorbents in natural systems. The former may be present as amorphous substances or crystalline minerals such as hematite, goethite, or ferrihydrite dispersed in soil as discrete particles or as coatings on particles of other materials. In recent years, databases of equilibrium sorption reactions for HFO and goethite have been compiled from studies described in the literature (Dzombak and Morel, 1990; Mathur, 1995). Both of the databases cited were designed for use with the MIT Two-Layer sorption model, also called the diffuse-layer model (DLM; Dzombak and Morel, 1990).

Owing to the complexity and variability of natural organic substances, the science of modeling surface reactions on POM is less advanced than for sorption onto hydrous metal oxides. The modeling described here assumes that reactions on POM are analogous to those on dissolved organic matter (DOM); a DOM model was adapted for the POM calculation. This model, the Gaussian distribution model (Dobbs et al., 1989), assumes that organic matter is a complex mixture of substances exhibiting highly variable binding affinities for metals. Reactions are represented like conventional pure substance reactions except that the usual single equilibrium constant is replaced by a distribution of constants (log K values). The distribution of log K is assumed to be Gaussian in shape. This model is also supplied with a database of reactions, including acid-base and major ion reactions, each with its mean log K for depicting the Gaussian distribution.

When included in equilibrium models, these databases of sorption reactions provide a means of including competition for sorption sites among major groundwater ions such as calcium, magnesium, and SO_4 and contaminants. More importantly, by including in equilibrium calculations the acid-base reactions for these surfaces, the dependence of trace metal sorption on pH can be reflected in the model.

Goethite Sorbent

Mineralogically, the FeOx sorbent was assumed to be goethite (α-FeOOH). Goethite is a common form of FeOx in soils. The database of sorption reactions for goethite reported by Mathur (1995) was used with the diffuse-layer sorption model in MINTEQA2 to represent the interactions of protons, major ions, and contaminant with the FeOx surface.

The concentration of sorption sites used in the MINTEQA2 model runs was based on a measurement of ferric iron extractable from soil samples using hydroxylamine hydrochloride as reported in EPRI (1986). This method of iron extraction is intended to provide a measure of the exposed FeOx present as mineral coatings and discrete particles and available for surface reactions with solutes in the associated pore water. The variability in FeOx sorbent concentration represented by the variability in extractable iron from these samples was included in the modeling by selecting low, medium, and high extractable iron concentrations corresponding to the 17th, 50th, and 83rd percentiles of the sample measurements. The extractable iron weight percentages used in the modeling are shown in **Table 4**.

Table 4. Concentration Levels for Goethite Sorbent

Concentration Level	Weight Percent Iron (extractable)	Geothite Sorbent Concentration (g/L)
Unsaturated zone		
Low	0.0182	1.325
Medium	0.0729	5.309
High	0.1190	8.667
Saturated zone		
Low	0.0182	1.032
Medium	0.0729	4.136
High	0.1190	6.751

Although the same distribution of extractable iron sorbent was used in modeling the saturated and unsaturated zones, the actual concentration of sorbing sites corresponding to the low, medium, and high FeOx settings in MINTEQA2 was different in the two zones because the assumed ratio of soil mass to solution volume (the phase ratio) was different. For both zones, the phase ratio was calculated as the mean soil bulk density divided by the mean water content (product of mean porosity and mean water saturation). In EPACMTP, the mean soil bulk density and mean porosity are 1.6 kg/L and 45 percent, respectively. The mean water saturation in the unsaturated zone is 77.7 percent. The water saturation in the saturated zone is, of course, 100 percent. Thus, the phase ratio for the unsaturated zone is 4.57 kg/L and that for the saturated zone is 3.56 kg/L. These values and the molar mass ratio of goethite to Fe were used to convert the weight percent extractable iron to the mass of goethite appropriate for 1 liter of porewater solution (see Table 4).

The specific surface area and site density used in the diffuse-layer adsorption model were as prescribed by Mathur (1995) for goethite. These values along with the molar concentration of FeOx sorbing sites are shown in **Table 5**. The complete database of goethite sorption reactions used in MINTEQA2, including acid-base surface reactions and reactions for major ions, is shown in **Table 6**. The reactions shown in Table 6 have been reformulated for use in MINTEQA2. The

reformulation step is necessary in order to present the reaction to MINTEQA2 in a manner consistent with its database conventions and its predetermined set of reactants (components. The MINTEQA2 conventions include the requirement that all reactions be written as formation reactions. In some cases, the reformulation may have involved adding ancillary reactions to those presented by Mathur (1995). The addition of ancillary reactions is necessary if the original reaction is not written in terms of MINTEQA2 components. All ancillary reactions used to reformulate the Mathur (1995) goethite reactions were obtained directly from the MINTEQA2 (v4.02) thermodynamic database.

Table 5. Model Parameters for the Goethite Sorbent

Parameter	Model Value
Specific surface area (m^2/g)	60
Site density (moles of sites per mole Fe)	0.018

$\equiv FeOH^o + F^- = \equiv FeOHF^-$	$\log K_2 = 1.59$

Particulate Organic Matter Sorbent

The concentration of the second adsorbent, POM, was obtained from organic matter distributions already present in EPACMTP. EPACMTP includes frequency distributions for organic matter for three soil types in the unsaturated zone: silty clay loam, sandy loam, and silty loam. The silty loam soil type is intermediate in weight percent organic matter in comparison with the other two and is the most frequently occurring soil type. Therefore, low, medium, and high POM content levels for the MINTEQA2 modeling in the unsaturated zone were established as the 7.5th, 50th, and 92.5th percentiles of the silty loam organic matter distribution. In the saturated zone, the EPACMTP distribution of organic matter is identical to that for the sandy loam soil type of the unsaturated zone. Low, medium, and high POM content levels in MINTEQA2 modeling of the saturated zone were established as the 7.5th, 50th, and 92.5th percentile levels, respectively, of this distribution.

As was the case for the goethite sorbent, the concentration of POM included in the MINTEQA2 modeling was determined from the low, medium, and high content levels (expressed in weight percent POM) and the mass of soil appropriate for 1 liter of porewater solution (see **Section 2.1.2**). Thus, phase ratios of 4.57 kg/L in the unsaturated zone and 3.56 kg/L in the saturated zone were used to compute the POM concentration for MINTEQA2 model runs.

A dissolved organic carbon (DOC) distribution for the saturated zone was obtained from the U.S. EPA STORET database. This distribution is based on 1,343 groundwater samples and is approximated by a log normal distribution with a median $\log_e$ DOC of 1.974 (corresponding to 7.2 mg C per liter) and $\log_e$ standard deviation of 1.092. Assuming DOM is approximately 50 percent

organic carbon, the DOC values are multiplied by two to approximate DOM concentrations. The MINTEQA2 modeling employed low, medium, and high concentrations for DOM corresponding to the 7.5th, 50th, and 92.5th percentiles, respectively, of this approximated DOM distribution. An important point to note is that POM and DOM were not treated as independent variables in the MINTEQA2 modeling: the high DOM value was associated with the high POM value, the medium DOM with the medium POM, etc.

Because no directly measured data were available for describing the variation in DOM concentration in the unsaturated zone, high, medium, and low DOM concentrations were assumed to reflect a constant ratio of POM content (in weight percent) to DOM concentration. The constant ratio was arbitrarily chosen as the ratio of the median DOM (mg/L) from the saturated zone distribution to the median value of POM (weight percent) from the saturated zone distribution. This ratio, 194.6, was applied to the low, medium, and high weight percent POM values of the unsaturated zone to obtain DOM concentrations at the low, medium, and high levels. The weight percent POM and concentration (mg/L) of both POM and DOM are shown in **Table 7** for all three concentration levels in both zones.

Table 7. POM and DOM Concentration Levels

POM Category	POM wt%	POM Concentration (mg/L)	DOM Concentration (mg/L)
Unsaturated zone			
Low	0.034	1,553.8	6.6
Medium	0.105	4,798.5	20.4
High	0.325	14,852.5	63.2
Saturated zone			
Low	0.02	712	3
Medium	0.074	2,634.4	14.4
High	0.275	9,790	69.38

For both POM and DOM, a site density of 1.2 x 10^{-6} moles of sites per mg organic matter was assumed. The site concentrations for organic matter in both zones are listed in **Table 8**.

Table 8. Site Concentrations for POM and DOM Components in MINTEQA2

POM Category	POM Site Concentration (mol/L)	DOM Site Concentration (mol/L)
Unsaturated zone		
Low	1.865 x10-3	7.896 x10-6
Medium	5.758 x10-3	2.439 x10-5
High	1.782 x10-2	7.548 x10-5
Saturated zone		
Low	8.544×10^{-4}	3.600×10^{-6}
Medium	3.161×10^{-3}	1.728×10^{-5}
High	1.175×10^{-2}	8.326×10^{-5}

A specialized submodel within MINTEQA2 was used for calculations involving the POM and DOM. This submodel, called the Gaussian distribution model, assumes that natural organic matter is a mixture of various functional groups having a mean log K for binding protons and metals and a standard deviation in log K (Dobbs et al., 1989). This is in contrast to all other reactants in MINTEQA2, which are implicitly treated as pure substances with a single equilibrium constant for a particular metal. A database of DOM reactions proposed by Susetyo et al. (1991) for the metals barium, cadmium, chromium (III), copper, lead, nickel, and zinc and for protons and various other MINTEQA2 components is included with v4.02 of the model. Adsorption of metals onto POM was included in the model calculations by assuming that the reactions were identical to those for metal complexation with DOM. **Table 9** shows Gaussian organic matter reactions used in MINTEQA2 for this work. Although the Gaussian model was proposed for metal–DOM reactions, it has been used here to account for metal–POM reactions as well. The only difference between the method of calculation for metal–DOM and metal–POM species in MINTEQA2 was that POM species were excluded from contributing to the ionic strength.

For the metals cobalt, mercury, and thallium, it was necessary to estimate the mean log K for DOM and POM binding for use in MINTEQA2. The mean log K values for cobalt and thallium were derived from a linear free-energy relationship based upon the known mean log K values for several metals, their first hydrolysis constants, and their log K values for complexation with acetate. For mercury, the mean log K was estimated from a linear regression based on binding constants for humic and fulvic acid as given by Tipping (1994).

Table 9. POM and DOM Reactions Included in MINTEQA2 Modeling

Organic Matter (OM) Reaction	Mean log K	Standard Deviation	Species Charge
OM+ H^+ = OM-H	3.87	1.7	-1.8
OM+ Ca^{2+} = OM-Ca	2.9	1.7	-0.8

OM+ Tl^+ = OM-Tl	1.0	1.7	-1.8

2.2 Characterization of Model CCR Leachate

Leachate from CCR landfills and impoundments is known to span a broad pH range and to exhibit highly variable concentrations of inorganic ions. Preliminary to the CCR risk assessment modeling, EPA assembled a constituent database with CCR leachate characteristics encompassing many types of CCR wastes. The database includes analyte concentration data for three types of analyses: (1) analysis of landfill leachate from toxicity characteristic leaching procedure (TCLP), synthetic precipitation leaching procedure (SPLP), or other leaching/extraction methods; (2) analysis of surface impoundment and landfill porewater; and (3) analysis of whole waste samples from landfills and other sources. Each of these three analysis types includes waste samples from various locations representing different coal source types (bituminous, subbituminous, lignite, anthracite), different combustion processes (fluidized bed combustion [FBC], flue gas desulfurization [FGD], Na FGD, non-FBC) or combustion product types (fly ash, bottom ash, combined fly ash and bottom ash, slag, mixed ash and coal waste, and ash not otherwise specified). (Please refer to **Appendix C** for a more detailed discussion of the CCR database.)

The analysis type assumed to best represent long-term waste monofill porewater composition is the landfill and surface impoundment porewater data. Accordingly, the porewater analyte concentration data were examined to identify which constituents exhibit significantly elevated concentrations and to identify trends in concentration levels among samples from different coal source types, combustion process types, and combustion product types. MINTEQA2 sensitivity runs using extremes of analyte concentrations from the porewater data were used to determine which analytes were most likely to influence estimated K_d values. Results indicated that calcium, SO_4, sodium, and chlorine were the analytes most likely to affect partitioning. Consequently, multivariate statistical analyses were performed to identify trends in concentrations of these analytes and pH across all coal source types (bituminous, subbituminous, etc.), combustion process types (FBC, non-FBC, FGD, etc.), and combustion product types (fly ash, bottom ash, etc.). Single-variable analyses for each of the dependent variables (pH, calcium, SO_4, sodium, chlorine concentrations) were also performed because few samples presented measurements for all five dependent variables. The goal of these analyses was to evaluate similarities among these diverse samples with regard to the dependent variables for the purpose of choosing leachate chemistries for use in MINTEQA2 modeling.

Results of the statistical analyses and geochemical judgment were used to select four representative leachate chemistries. The most statistically significant differences in the porewater data for the five dependent variables occurred across combustion process type, especially FBC versus non-FBC. Statistically significant differences across coal source type occurred, but these were not consistent across combustion process or product types. Examination of the five dependent variables and the concentrations of other analytes in the porewater data and consideration of the result from the statistical analysis led to the following four choices to represent leachate chemistries:

- Leachate 1 (L1): Ash and Coal Refuse
  Characterized by low to mid pH (1.7–8.2), high SO4, elevated iron and manganese.
- Leachate 2 (L2): FBC Waste
  Characterized by very high pH (12–13), high calcium, high SO4, some CO3, may have high sodium, potassium, and chlorine
- Leachate 3 (L3): FGD Waste
  Characterized by mid to high pH (8.7–11.3), high calcium, high SO_4, high sodium, high chlorine
- Leachate 4 (L4): Combined Ash
  As a reflection of various CCR codisposal practices, this group has more variability in pH (3.9–12.3), calcium, and SO_4

The landfill and surface impoundment porewater data were grouped according to these categories. Within each category, plots of sum of anions versus sum of cations (in equivalents per liter) were prepared to assess the degree of charge balance (see example in **Figure 3**).

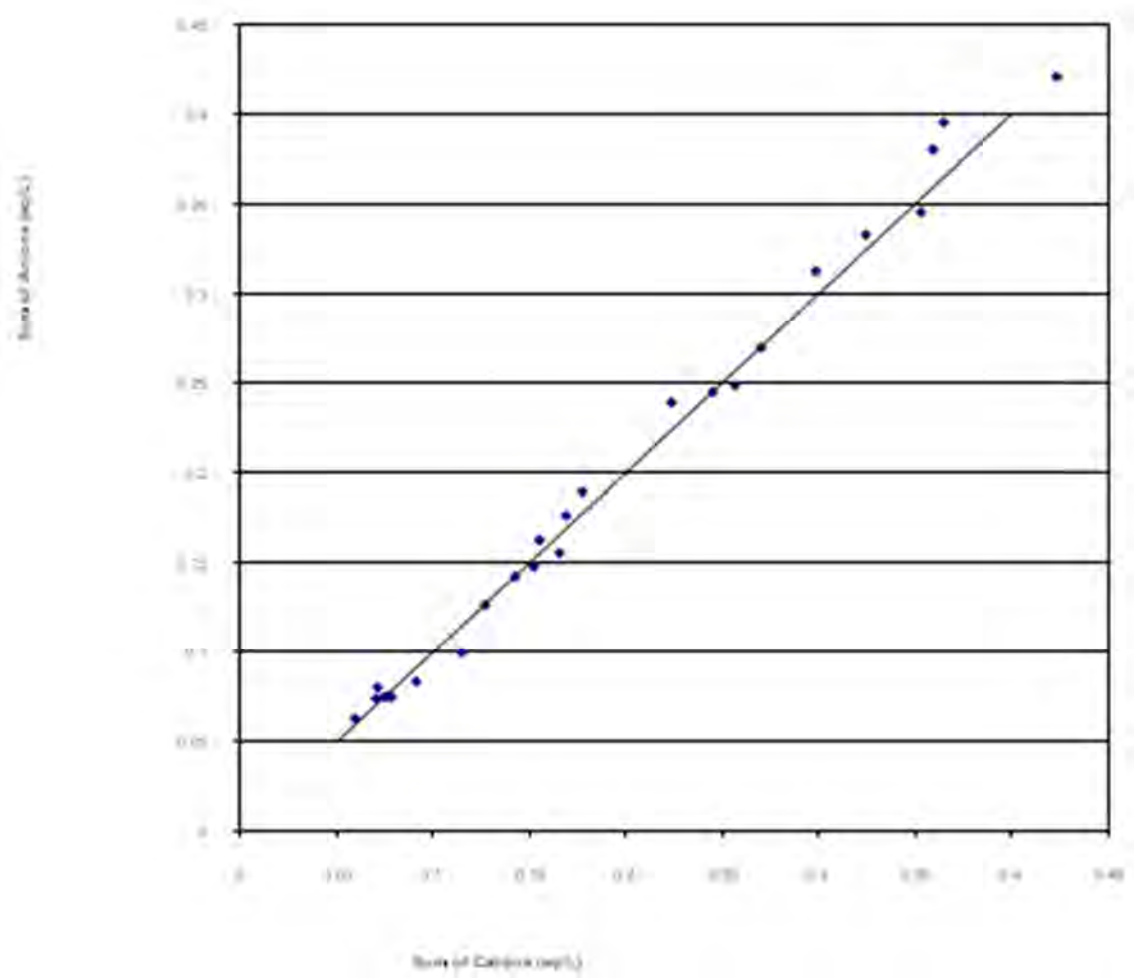

Figure 3. Sum of anions versus sum of cations plotted to assess charge balance of sample.

Although these four leachate categories served to segregate the data in accord with measurements likely to impact K_d values, considerable variability in important analyte concentrations occurred within each leachate type. Therefore, within each of the leachate categories, three representative samples were selected based on sum of anions. (Because the samples were reasonably well charge balanced, selection based on sum of cations would have resulted in the same selected samples.) Selection based on sum of anions (or cations) is analogous to selection based on ionic strength or overall leachate "richness." The samples within each of the four leachate categories were ranked according to sum of anions and the sample closest to the 17th, 50th, and 83rd percentiles were selected and labeled low, medium, and high. The composition (all major ions) of each of the low, medium, and high samples was made available to the MINTEQA2 model in the runs used to estimate K_d (see modeling procedure section below). **Table 10** gives the composition of each of the low, medium, and high porewater samples for each of the four leachate types.

Table 10. Composition of Four Leachates at Three Concentrations Levels

Analyte	Low (mg/L)	Medium (mg/L)	High (mg/L)
L1: Codisposed Ash and Coal Refuse Leachate			
Ca	12.3	572.1	602.9
Mg	7.0	179.4	333.1
Na	3.1	12.4	71.7
K	4.2	41.8	447.7
SO4	387.0	6,231.7	53,918.0
Cl	1.7	19.4	11.1
Al	53.7	58.0	58.0
Fe (II)	0.2	2,050.0	22,394.0
Mn	0.9	52.7	30.4
L2: FBC Waste Leachate

Cl	109.0	610.0	2,000.0
Al	0.3	0.1	0.1

3 MINTEQA2 Modeling Procedure

The MINTEQA2 modeling was conducted separately for each of the 22 contaminants selected for the full-scale groundwater risk assessment (see Table 1 in **Section 1.2**). For each contaminant, the modeling was performed separately for the unsaturated and saturated zones for each of the two groundwater chemistries (carbonate and noncarbonate). Thus, results were produced in four main categories: the carbonate unsaturated zone, the carbonate saturated zone, the noncarbonate unsaturated zone, and the noncarbonate saturated zone. Within each of these four categories, separate results were produced for each of the four leachate types discussed in **Section 2.2**. A similar modeling procedure was followed for all contaminants, groundwater chemistries, hydrologic zones, and leachate types. The modeling procedure consisted of two steps, each involving execution of the MINTEQA2 model. First, the sorbents were pre-equilibrated with the groundwater at the natural groundwater pH. This step was performed with original "pristine" groundwater at the ambient pH of the original groundwater for both carbonate and noncarbonate systems and before introduction of the contaminant and leachate. In the second step, leachate and the contaminant were added to the pre-equilibrated systems and the new equilibrium distribution of contaminant among dissolved, sorbed, and precipitated phases was computed.

3.1 Pre-equilibration with Sorbents

The goethite and POM sorbents were pre-equilibrated with the groundwater at all nine combinations of their concentration levels. Because the sorbents adsorb some of the noncontaminant ions present as groundwater constituents (calcium, magnesium, sulfate), it is to be supposed that the representative compositions used for both the carbonate and noncarbonate groundwaters reflect dissolved concentrations at equilibrium with an unknown sorbed concentration. The purpose of the pre-equilibration step is to estimate this unknown sorbed concentration so that it may be included with the total concentrations for these constituents in subsequent model runs. The method of discovering the sorbed concentrations for each of the groundwater constituents that undergoes sorption was trial and error. Specifically, MINTEQA2 was executed repeatedly with adjusted total concentrations of these sorbing constituents until the equilibrium dissolved concentration for each was equal to the measured dissolved concentrations reported for the groundwater. This trial and error pre-equilibration method was performed separately for each of nine possible combinations of the FeOx and POM sorbent concentrations (low FeOx, low POM; low FeOx, medium POM; etc.).

The pre-equilibration step was conducted at the natural pH of each groundwater with calcite imposed as an equilibrium mineral for the carbonate groundwater type and quartz imposed as an equilibrium mineral for the noncarbonate groundwater type. Small additions of inert ions (Na^+, K^+, NO_3^-, etc.) were added to maintain charge balance.

3.2 Equilibration with Leachate and Contaminants

The model representations of leachate and the contaminant were introduced to the pre-equilibrated groundwater model systems. In this step, the equilibrium pH was specified at a series of discrete values selected to span the range of expected pH values given the groundwater type and leachate type modeled. For each selected pH, a preliminary run was performed to estimate the ionic strength of the system being modeled, and subsequent model runs at ever increasing contaminant concentrations were constrained to this same ionic strength. Thus, each MINTEQA2 model execution to produce an isotherm for a particular contaminant was defined by the following selections of system variables:

- groundwater type (carbonate or noncarbonate)
- hydrologic zone (unsaturated or saturated)
- FeOx sorbent concentration level (low, medium, high)
- POM/DOM concentration level (low, medium, high)
- equilibrium pH (range depends on groundwater type and leachate type; see **Table 11**)
- leachate type (ash and coal refuse, FBC waste, FGD waste, or combined ash)
- leachate "richness" or ionic strength (low, medium, or high).

Table 11. Range of Equilibrium pH Values Used in Modeling

Waste Leachate Type	pH Range	
	Carbonate GW	Non-Carbonate GW
Ash and Coal Refuse	5.1–8.2	1.8–8.2
FBC Waste	5.1–12.6	4.5–12.6
FGD Waste	5.1–12.6	4.5–12.6
Combined Ash	5.1–12.6	4.5–12.6

For the purpose of establishing the concentration of calcium, magnesium, SO_4, sodium, and other leachate ions in the saturated zone, a constant dilution ratio of one part leachate to six parts groundwater was used for all modeling. For each system modeled (defined by the selections of system variables), the system was equilibrated at a series of 44 total concentrations of the contaminant spanning the range from 0.001 to 10,000 mg/L. The results were compiled as the equilibrium distribution of the contaminant among dissolved, sorbed, and precipitated fractions for each contaminant concentration. The compilation of the equilibrium contaminant distribution at a series of total contaminant concentrations was saved in a separate file indexed with the settings of all variables defining the system.

4 Results

The files containing the equilibrium dissolved, sorbed, and precipitated fractions, each indexed with the settings of all system variables, were compiled into a database for use in transport modeling using EPACMTP. The contaminant concentration in the dissolved and sorbed fractions, along with the corresponding total contaminant concentration, defines each nonlinear isotherm. All three concentrations (dissolved, sorbed, and precipitated) are made available for use in EPACMTP. The ratio of the equilibrium sorbed and dissolved concentrations recorded in the isotherm is the dimensionless K_d. For the sorbed fraction, the concentration recorded in the isotherm is the amount of contaminant sorbed *from* 1 liter of solution. Of course, this amount is also sorbed *onto* the mass of soil with which 1 liter was equilibrated. This mass is the phase ratio: 4.57 kg/L for the unsaturated zone and 3.56 kg/L for the saturated zone. The K_d in units of L/kg is thus computed by normalizing the dimensionless K_d by the appropriate phase ratio.

For each contaminant, the modeling resulted in 432 isotherms for the carbonate groundwater for the ash and coal refuse leachate type and 702 isotherms for all other leachate types. For the noncarbonate groundwater, 702 isotherms were produced for the ash and coal refuse leachate type and 756 for each of the other leachate types. Given the groundwater and leachate types, each isotherm corresponds to particular concentration levels of FeOx and POM sorbents, pH, and leachate richness. In Monte Carlo or site-specific mode, EPACMTP selects the appropriate isotherm based on the conditions being modeled. Isotherms were produced for all 22 contaminants listed in **Section 1.2**, Table 1.

Isotherms were computed for two environmentally relevant oxidation states of arsenic, selenium, and chromium. The different oxidation states of these contaminants exhibit differences in sorption behavior, but both arsenic and selenium tend always to behave as anions in groundwater. Separate human toxicity values have not been established for the two forms of these metals, and most of the available leachate data are based on total metal concentrations rather than concentrations of the individual species. Isotherms were generated for each to be used for separate model runs in EPACMTP to reflect the differences in fate and transport that could result depending on which form is predominant in a particular subsurface environment.

4.1 Example Isotherms

Example isotherms illustrating the influence of key variables on the estimated K_d values are shown in **Figures 4** through **8**. **Figure 4** shows K_d versus total As (V) concentration for the carbonate groundwater saturated zone for the combined ash leachate type at three levels of FeOx sorbent concentration. The isotherms plotted are for the medium level for leachate richness and the medium POM concentration level for pH 6.6. As expected, sorption is enhanced at the higher FeOx concentrations resulting in larger K_d values.

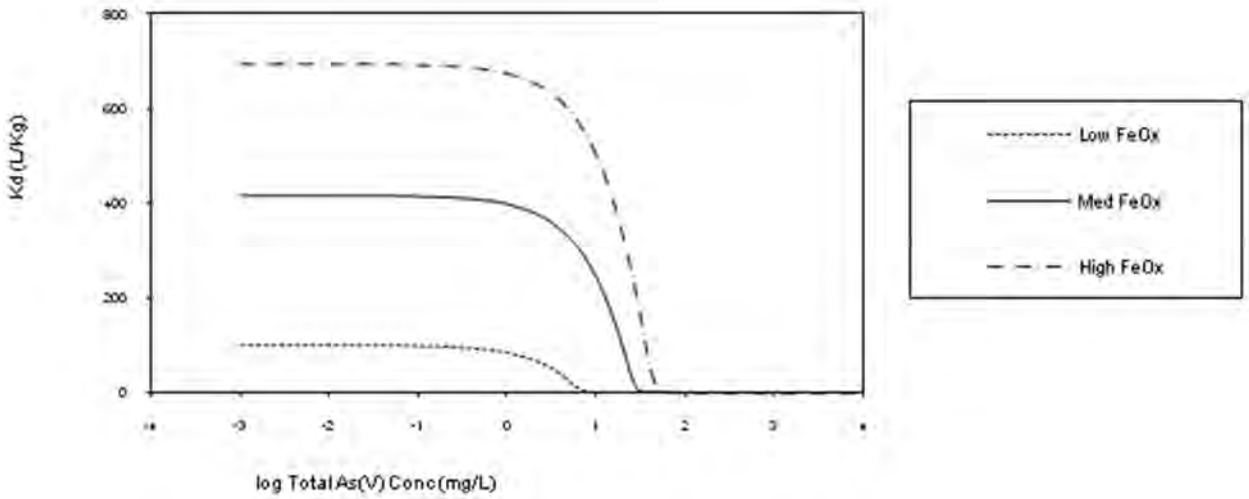

Figure 4. Estimated K_d versus total arsenic concentration for three FeOx sorbent concentration levels (combined ash).

The impact of varying the POM concentration level differs among the various metals. The effect of POM concentration level also depends on the pH. The variable impact of POM is due to two factors: the absence of organic matter reactions for anionic metals and the concurrent influence of DOM for those metals for which organic matter reactions are included. In the MINTEQA2 modeling procedure used here, increasing the POM sorbent concentration is always accompanied by a proportional increase in the DOM concentration. The overall impact on the amount of metal sorbed depends on the relative competition among all constituents in the systems for these two substances. The "winner" of this relative competition (POM or DOM) shifts with pH because both substances undergo acid-base reactions.

Figure 5 shows the impact of varying the POM/DOM concentration level on lead sorption for the noncarbonate groundwater unsaturated zone with medium FeOx concentration level and leachate richness level at pH 8.2. In this example, the highest POM level results in the highest K_d values. However, this is not true for all cases; the outcome due to increasing the POM is dependent on the aforementioned competition between the trace metal and major ions on all three sorbing surfaces (FeOx, POM, and DOM).

The influence of the leachate "richness" level is illustrated in **Figure 6** for cobalt sorption. Leachate richness refers to a general concentration level analogous to ionic strength. The low, medium, and high settings represent concentration levels for sum of anions. Figure 6 shows the K_d response for each of the three levels for the noncarbonate groundwater, unsaturated zone with ash and coal refuse leachate, and medium concentration levels of FeOx and POM sorbents. The pH for this example was 9.8.

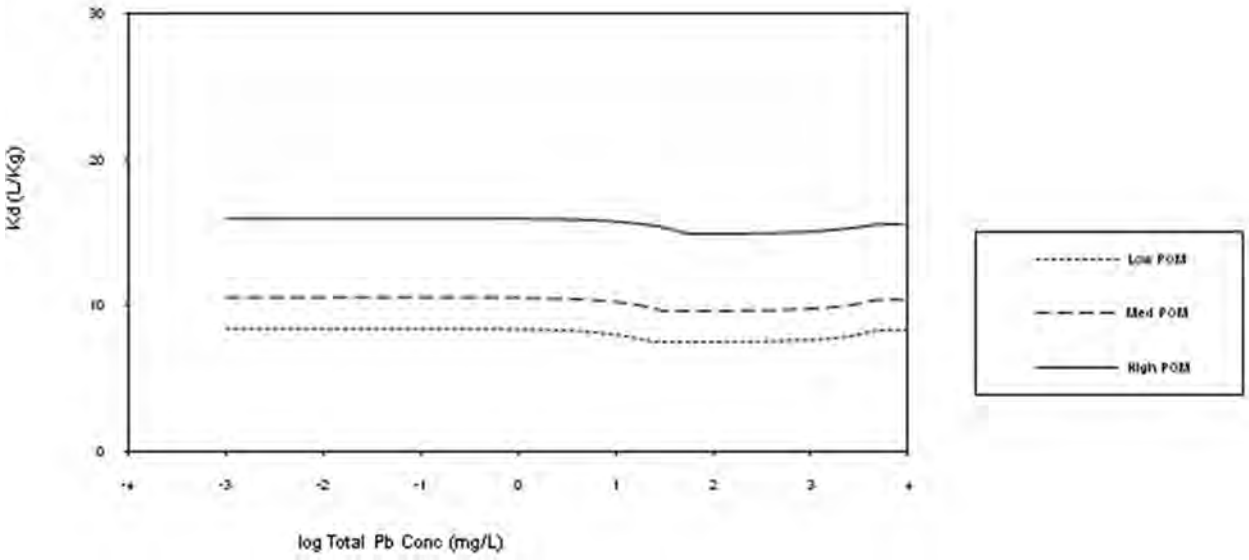

Figure 5. Estimated K_d versus total lead concentration for three POM/DOM concentration levels.

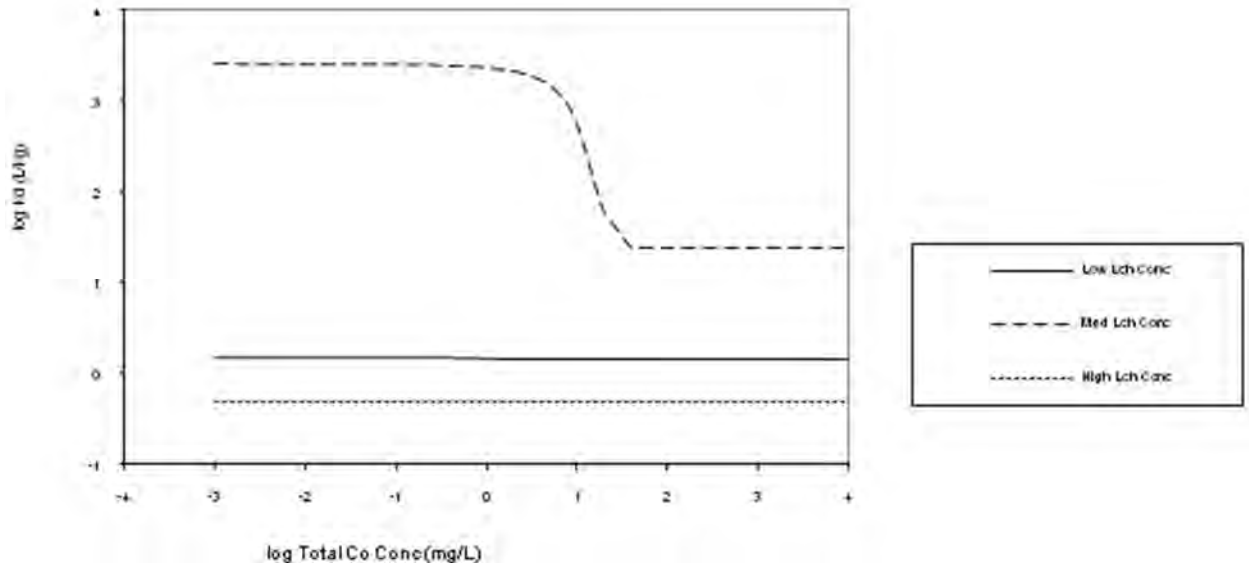

Figure 6. Estimated K_d versus total cobalt concentration for three different leachate richness levels (ash and coal refuse).

Figure 7 depicts the K_d versus pH for lead in a single system (noncarbonate groundwater, unsaturated zone, high FeOx and POM sorbent levels, medium leachate richness level for combined ash leachate type) at a single total lead concentration (0.001 mg). K_d values in this system increase steadily from pH 4 to 7, then increase more rapidly up to pH 9.8. After pH 9.8, K_d begins to decrease abruptly due to formation of lead-hydroxy solution species.

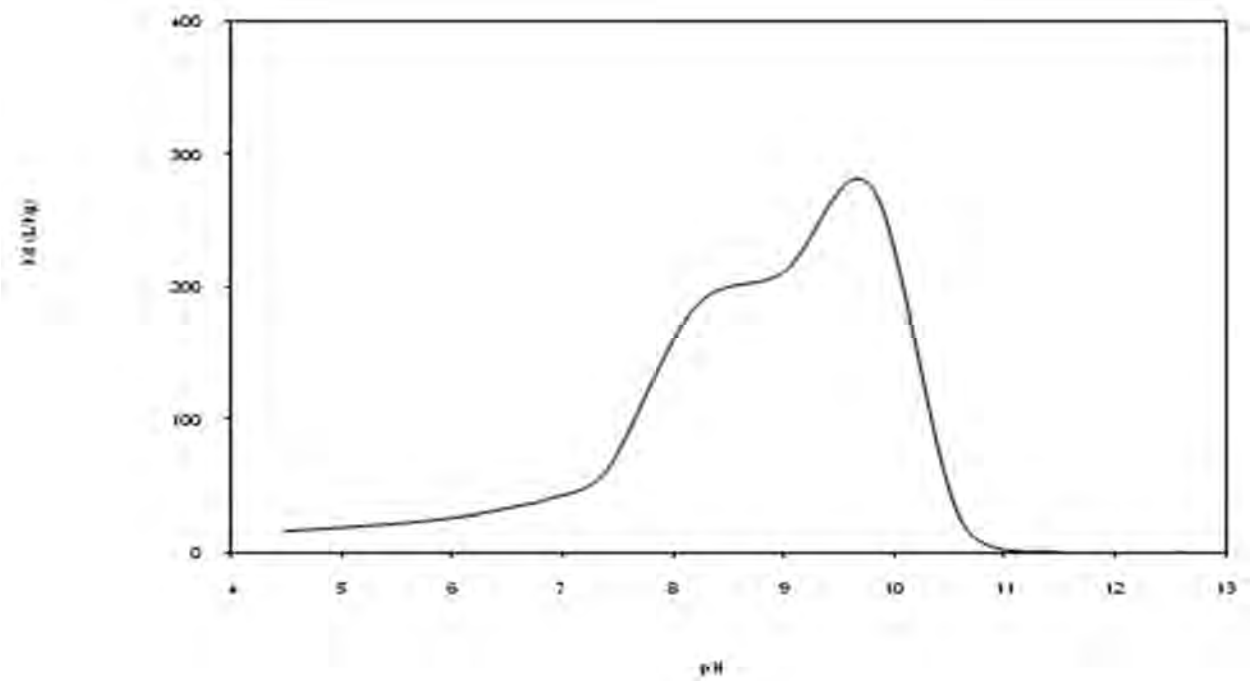

Figure 7. Estimated K_d versus pH for lead in a single system at a single total lead concentration (0.001 mg/L) (combined ash).

Figure 8 shows the K_d response for lead in a single system (noncarbonate groundwater, unsaturated zone, high FeOx and POM sorbent levels, and pH 8.2) for each of the four different waste leachate types at the high leachate richness level.

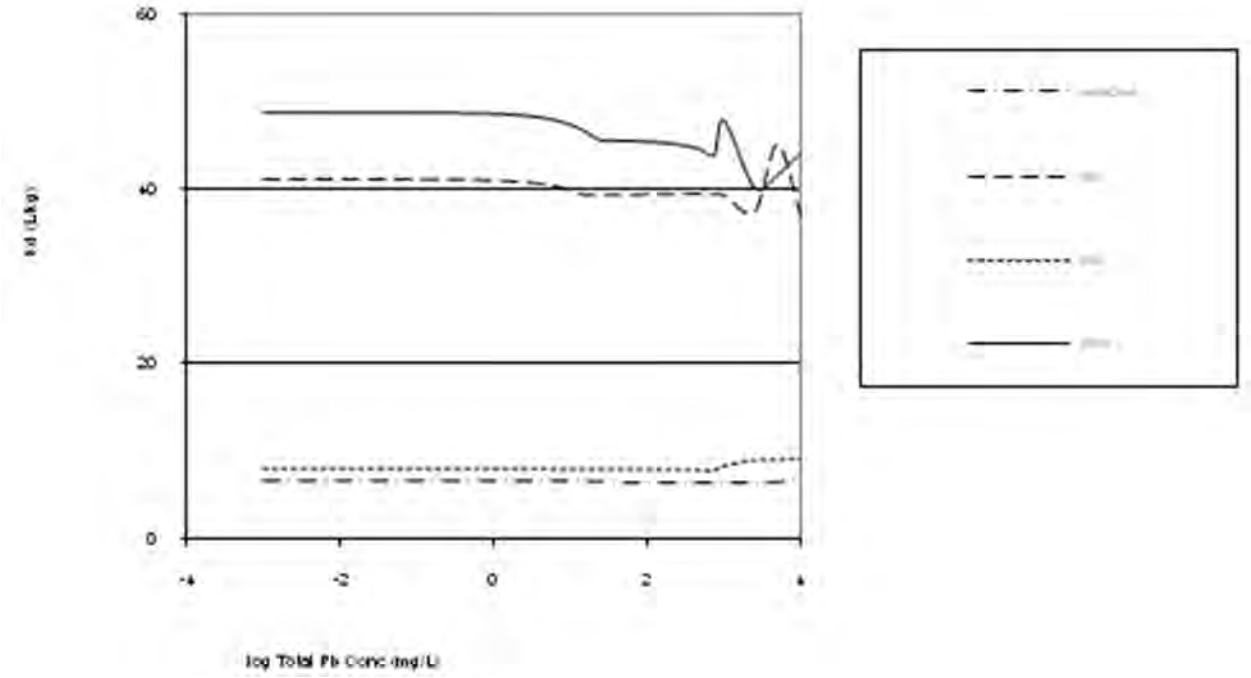

Figure 8. Estimated K_d versus pH for a single setting of system variables shown for each of four waste leachate types.

5 Assumptions and Limitations

Many assumptions are inherent in using a speciation model to estimate partition coefficients. Some of these must be acknowledged to result in limitations on the utility of the model results. Undoubtedly, the results are better for some contaminants than for others. Various modeling assumptions and limitations are presented below. These are organized as those resulting from the manner in which the groundwater composition, the sorbents, and the leachate were characterized and certain broader, more general issues. The discussion is limited to pointing out each assumption or limitation. Although the direction of possible error in the estimated K_d values is apparent from some of these limitations, it would be difficult to quantify the uncertainty in the estimated K_d values.

5.1 Groundwater Characterization Issues

- The categorization of all groundwater chemistries into two types, carbonate and noncarbonate, is quite broad. The noncarbonate category is especially broad, and sorption behavior among different groundwater compositions that might fall into this category could be quite variable. This variability is not accounted for in the current approach.
- Although the pre-equilibration step is helpful in more realistically establishing appropriate major ion concentrations, it is somewhat artificial in the sense that the concentrations of the sorbents are not correlated with groundwater major ion concentrations. Both the FeOx and POM sorbents were represented as general concentration distributions obtained from sources separate from the groundwater data. Therefore, the sorbent concentration levels used do not correlate specifically to the groundwater compositions used.
- Both groundwater chemistries were artificially adjusted to different pHs by simply specifying a desired equilibrium pH. Potassium, sodium, and nitrate were used to balance charge in this procedure, so the result should be analogous to titrating with strong acid or base. The degree to which this procedure can result in model groundwater chemistries that adequately represent true variability in factors that impact Kd is unknown.

5.2 Sorbent Characterization Issues

- Only two sorbents are represented in the model systems. Other sorbents are important in some circumstances, including clays, hydrous aluminum and manganese oxides, calcite, and silica. Failure to include all potential sorbents could result in underestimation of sorption.
- The FeOx was accounted in the modeling as goethite. Other FeOx may be important in groundwater, including HFO. HFO has a higher specific surface area and greater reactivity for some metals than does goethite. The degree of sorption may be underestimated for some contaminants in systems where HFO is the dominant form of FeOx. Also, equilibrium constants for adsorption onto goethite were unavailable for some contaminants; estimates were used.

- The data used to quantify the FeOx and POM sorbents (and the DOM) are sparse. The degree to which the true variability in concentration levels of these sorbents has been captured in the modeling is unknown.
- There is no provision in the modeling to account for occlusion of sorbents. Both FeOx and organic matter may form coatings over other surfaces. Failure to account for occlusion could result in overestimating the available sorption sites.
- The FeOx (goethite) sorbent is included in all model runs. This implies that it is ubiquitous. However, there are natural groundwater conditions that preclude the formation of FeOx precipitates. As illustrated in **Figure 9**, FeOx is not the stable iron solid phase at conditions of low pH and low Eh (oxidation/reduction potential), so these conditions are inconsistent with the use of FeOx as a sorbing phase. Including the goethite sorbent where it cannot exist could obviously lead to overestimating sorption, unless other sorbents that are not modeled (e.g., clays) are important. The omission of the stable iron phases siderite and pyrite as model sorbents serves to compensate for this flaw, although the extent of this compensation is unknown.

- The Gaussian model for estimating metal interactions with organic matter was developed for DOM. It has not been tested for estimating the degree of metal sorption onto POM. Also, mean log K values for some metals have not been measured, so estimates were used.

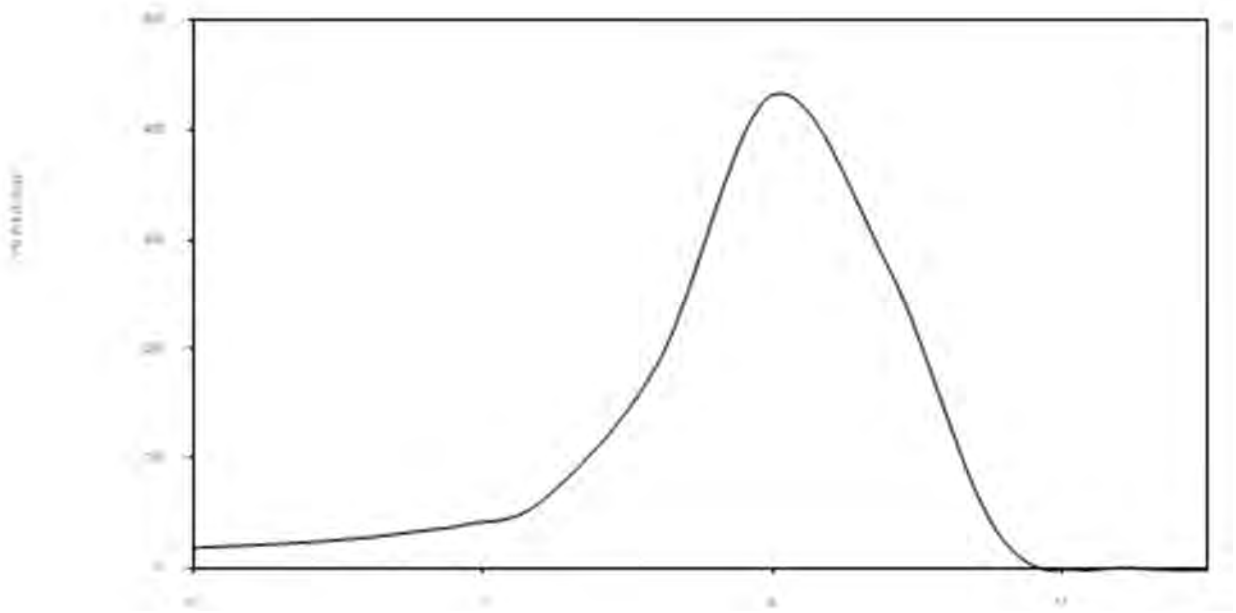

Figure 9. Stability fields for iron minerals (after Hem, 1977).

5.3 Leachate Characterization Issues

The concentration levels for important leachate constituents (e.g., calcium, magnesium, SO_4, chlorine) is based on a limited CCR constituent data set. This is especially true for the FBC wastes; leachate and porewater data were available for only one site. (Note: Other FBC waste characterization data are available but were measured on extraction procedures such as TCLP or SPLP.)

- The presence of CCR leachate constituents at elevated concentrations is accounted for in the MINTEQA2 modeling, but the dilution of the leachate in the mixing zone is oversimplified. A single dilution ratio of one part leachate to six parts groundwater was assumed for all saturated zone modeling. Some of these constituents are themselves adsorbed onto aquifer and soil matrix materials; it is their propensity to sorb that requires they be included in the modeling. Sorbing constituents (including H^+) will be transported away from the facility at different rates in accordance with their implied retardation factors. Use of a single recipe for leachate composition for all points in the unsaturated or saturated zones cannot represent this effect. The degree to which this oversimplification will result in errors in K_d estimates of contaminants is unknown.
- Methylated forms were not accounted for in this modeling. Mercury and arsenic are known to undergo methylation in the environment.

5.4 Other Issues

- The system redox potential was not explicitly defined in the modeling. All species that might undergo oxidation–reduction reactions were constrained to remain in the form in which they were entered in the model. This restriction applied to major ions such as sulfate and to all trace metals. The impact on K_d is unknown but is expected to be contaminant specific.
- All contaminants were introduced separately and individually in the modeling. The possible simultaneous presence of multiple contaminants is unaccounted for. The impact on K_d is not expected to be great except at high contaminant concentrations where competition for sorption sites may result in less sorption for some contaminants than suggested by this modeling.

Attachment H-2.
Nonlinear Sorption Isotherm Plots

This attachment presents graphs plotting the nonlinear sorption isotherms discussed in **Appendix H**. For each model iteration of the probabilistic analysis presented in **Section 4**, EPACMTP selected values from these isotherms based on constituent concentration (x-axis), whether the groundwater composition type is carbonate or noncarbonate, the groundwater or soil pH, the natural organic matter level (NOM), the iron oxide content (FeOx), and the leachate ionic strength (Xtra 1). Each constituent's isotherms are presented separately for carbonate and noncarbonate environments as the upper and lower panels within each figure. Furthermore, separate figures are presented for the saturated zone (red plots) and the unsaturated zone (blue plots). The groundwater or soil pH, NOM, FeOx, and Xtra 1 (ionic strength) levels used to select the isotherms presented in each plot are listed in the boxes to the left in each panel; the values in these boxes are explained in **Section 2** of **Attachment H-1**. Sorption isotherms for landfills (LFs) with combined ash are presented in **Figures H-2-1** through **H-2-20**. Sorption isotherms for surface impoundments (SIs) with combined ash, ash and coal refuse, and FGD wastes are presented in **Figures H-2-21** through **H-2-50**. **Table H-2-1** summarizes which isotherms are in which figures. Isotherms are shown only for contaminant-WMU combinations that were modeled in the probabilistic analysis.

Attachment H-3. Percentiles of K_d as Modeled

This attachment presents K_d percentiles selected from the inputs of the probabilistic modeling conducted in **Section 4**. For each constituent that was modeled, K_d values are presented for both the saturated and unsaturated zones[2] in the following tables:

- **Table H-3-1.** Select Percentiles of K_d (cm^3/g) for Landfills Containing Combined Ash Sampled from MINTEQA2 Isotherms by Updated EPACMTP via Constituent Species and Subsurface Domain
- **Table H-3-2.** Select Percentiles of K_d (cm^3/g) for Surface Impoundments Containing Combined Ash Sampled from MINTEQA2 Isotherms by Updated EPACMTP via Constituent Species and Subsurface Domain
- **Table H-3-3.** Select Percentiles of K_d (cm^3/g) for Surface Impoundments Containing Ash and Coal Refuse Sampled from MINTEQA2 Isotherms by Updated EPACMTP via Constituent Species and Subsurface Domain
- **Table H-3-4.** Select Percentiles of K_d (cm^3/g) for Surface Impoundments Containing FGD Wastes Sampled from MINTEQA2 Isotherms by Updated EPACMTP via Constituent Species and Subsurface Domain.

[2] As discussed in **Section 4**, chloride and iron are ions for which EPACMTP assigns concentrations. Thus, these ions were not modeled using isotherms. Instead, the chloride and lithium K_d values were fixed at 0 and the iron K_d value was fixed at 25.

Table H-3-1. Select Percentiles of K_d (cm^3/g) for Landfills Containing Combined Ash Sampled from MINTEQA2 Isotherms by Updated EPACMTP via Constituent Species and Subsurface Domain

Constituent	CASID	Zone	Percentiles of K_d (cm^3/g)

Appendix I.

Landfill Source Term Development

[This Page Intentionally Left Blank]

I.1 Introduction

The U.S. Environmental Protection Agency (EPA or the Agency) used SW-846 Leaching Evaluation Assessment Framework (LEAF) Methods 1313, 1314 and 1316 to characterize the leaching behavior of coal combustion residual (CCR) waste over a range of environmental conditions. These methods were developed through a collaborative research effort between EPA, Vanderbilt University, ARCADIS, Inc., the Energy Centre of the Netherlands, and Dutch and Danish partners (Kosson et al, 2002; Sanchez et al, 2002; Thorneloe et al, 2010; U.S. EPA, 2010b). EPA originally proposed the use of LEAF data in a 2011 Notice of Data Availability (NODA)[1] and further described how it might use the data in the subsequent 2013 NODA.[2] Further discussion of these LEAF methods is provided in **Appendix C**. The remainder of this appendix summarizes how data from these methods were used in the revised risk assessment to model leaching from landfills.

I.2 Source Term Development

The information provided by the three LEAF methods were used together to identify trends in leaching behavior and to characterize both the total mass available to be leached (i.e., leachable mass) and the leachate concentrations of individual COPCs in each sample. Method 1313 provided data on the equilibrium leachate concentration as a function of waste pH. Method 1314 provided data on the leachate concentration as a function of cumulative liquid to solid (L/S) ratio. Method 1316 provided data on the equilibrium leachate concentration as a function of L/S ratio.

Leachable mass was characterized using Method 1313 data. For all samples, the leachable mass was taken as the maximum concentration measured over the pH range of 2.8 to 12.8 multiplied by the L/S ratio used in Method 1313 (10 L/kg), as described in U.S. EPA (2009a). The calculated value was used by EPA's Composite Model for Leachate Migration with Transformation Products (EPACMTP) to determine the duration of leaching. Once all leachable mass was depleted, leaching of that particular constituent ceased.

Leachate concentrations were characterized using Method 1313 data. The representativeness of these equilibrium concentrations was confirmed with data obtained from Methods 1314 and 1316. The application of Method 1313 data depended on the leaching behavior exhibited by a constituent at a given pH. Leaching behavior fell into one of two categories: washout-controlled and solubility-controlled. A single constituent may alternate between these two behaviors over the relevant pH range (e.g. washout-controlled at a low pH and solubility-controlled at a high pH). In addition, this behavior profile as a function of pH is not constant across all wastes. Ashes generated by different coal and pollution controls may exhibit a completely different leaching profile for the same constituent. These handling of data for these two leaching behaviors is discussed in greater detail in the following subsections.

[1] Available online at: www.regulations.gov/#!documentDetail;D=EPA-HQ-RCRA-2011-0392

[2] Available online at: www.regulations.gov/#!documentDetail;D=EPA-HQ-RCRA-2012-0028

I.2.1 Solubility-Controlled Leaching Behavior

Solubility-controlled leaching is characterized by the releases where the leachate concentration is limited by solubility of the species. This behavior occurs when the total constituent mass available to be released from the waste is greater than the maximum amount that can be dissolved in the mass of water present. In Method 1313 data, this is characterized by highly variable leachate concentrations over the pH range because the maximum amount that can be dissolved varies with pH (U.S. EPA, 2014). **Figure I-1** shows an example of an ash (Sample ID: AaFA) for which chromium falls within the solubility-controlled zone over the entire pH range.

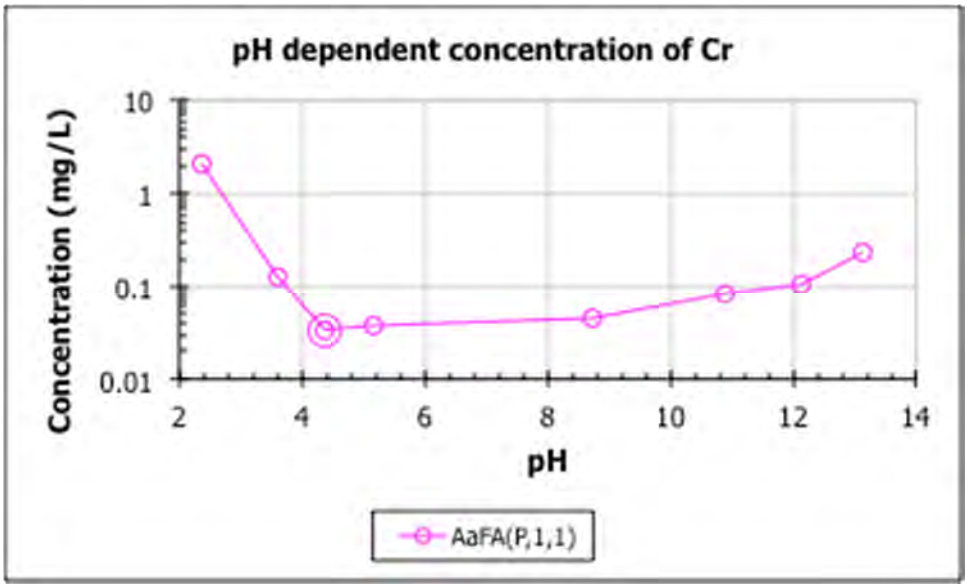

Figure I-1. Example of a solubility-controlled species over the full experimental pH domain (Adapted from data in U.S. EPA, 2009a).

If a constituent was determined to fall within the solubility-controlled zone at a particular pH, then the initial leachate concentration for that sample, C_0 (mg/L), was modeled as the concentration obtained from Method 1313. This leachate concentration was held constant over time until the leachable mass, M_0 (mg/kg), was depleted. This occurs when the cumulative L/S ratio is equal to M_0/C_0, also referred to as LS_{max}. The empirical relationship identified with Methods 1314 and 1316 agree well with this approach. **Figure I-2** illustrates this empirical relationship for solubility-controlled leaching as a function of cumulative L/S ratio.

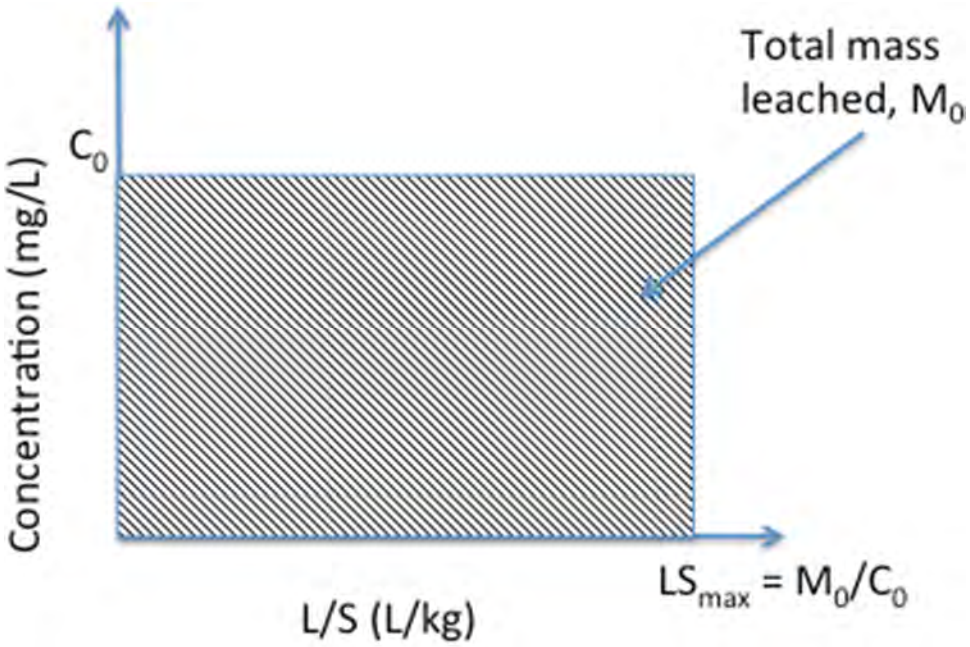

Figure I-2. L/S partitioning curve for solubility-controlled constituents at simulation pH.

I.2.2 Washout-Controlled Leaching Behavior

Washout-controlled leaching is characterized by the quick dissolution and release of the more soluble species from the CCR waste into the pore water. In Method 1313 data, this behavior is characterized by a generally constant leachate concentration over a pH range (U.S. EPA, 2014). **Figure I-3** shows an example of an ash (Sample ID: AaFA) for which boron falls in the washout-controlled zone over the entire pH range evaluated and leachate concentrations are almost constant.

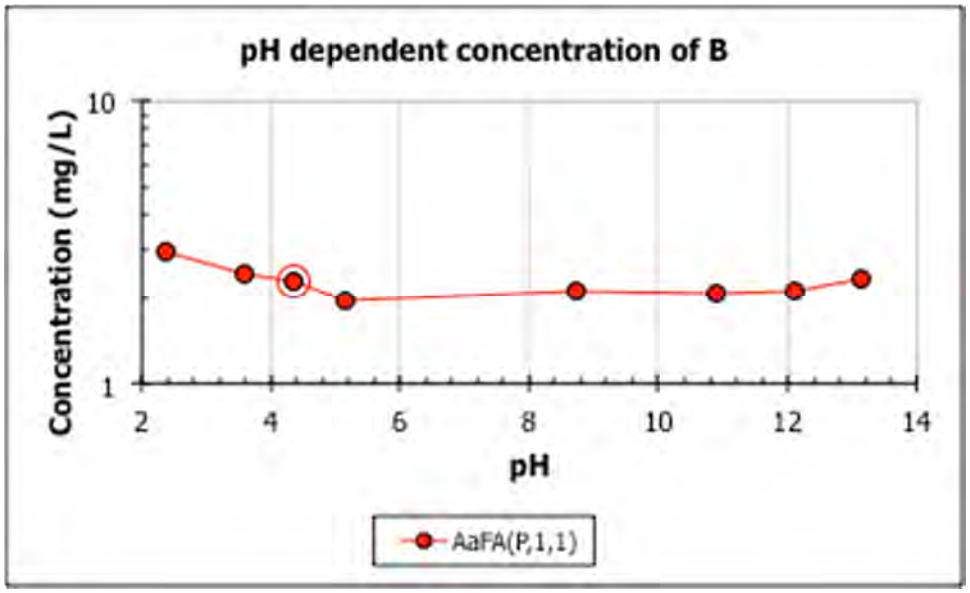

Figure I-3. Example of a washout-controlled constituent over the full experimental pH domain (Adapted from data in U.S. EPA, 2009a).

Method 1313 is carried out at a single L/S ratio of 10 mL/g (U.S. EPA, 2012). However, the L/S ratio present in the field is closer to 0.5 mL/g, based on a typical porosity of around 0.2 to 0.5 (unitless). Thus, if a constituent was determined to fall within the washout-controlled zone at a particular pH value, then C_0 was modeled as the concentration obtained from Method 1313 at that pH multiplied by a factor of 20. This factor adjusts for the difference between the L/S ratio specified in the Method 1313 test and those that occur in the field (U.S. EPA, 2014). The results of Methods 1314 and 1316 agree well with an initial leachate concentration defined by 20 times the Method 1313 leachate concentration, but show a variable leaching profile as the cumulative L/S ratio increases. The following empirical relationship was developed based on the observed changes in leachate concentration:

(I-1) $$M_0 = C_0 \cdot LS_{0.2} + \int_{0.2}^{1} 1.78C_0\left(e^{-2.9LS}\right)dLS + 0.1C_0\left(LS_{max} - LS_1\right)$$

Where:

M_0 = Total available mass (mg/kg);
C_0 = Initial leaching concentration (mg/L);
LS_X = Liquid-to-solid ratio of X (L/kg); and
LS_{max} = Liquid-to-solid ratio at which total available mass is depleted (L/kg).

At a cumulative L/S ratio of 0.2, the measured leachate concentration began to decrease exponentially until a cumulative L/S ratio of 1. At this point, the concentration stabilized at a tenth of the original value and remained at this concentration until all of the remaining leachable mass was depleted. **Figure I-4** illustrates this empirical relationship for washout-controlled leaching as a function of cumulative L/S ratio.

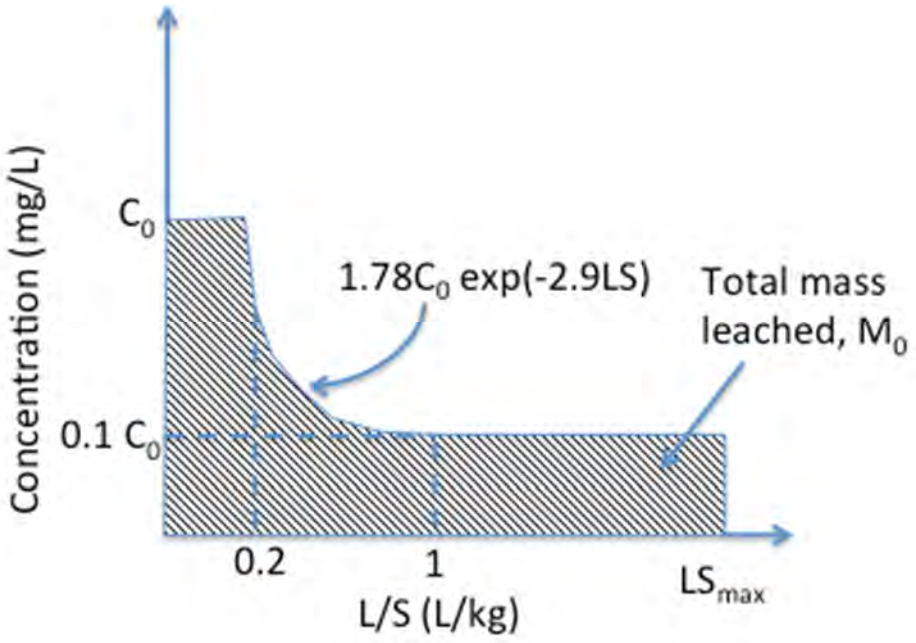

Figure I-4. L/S partitioning curve for washout-controlled species at simulated pH.

As seen in the figure above, leaching is not constant for constituents in the washout-controlled zone. As shown in the 2009 Sensitivity Analysis, higher leachate concentrations consistently led to higher well concentrations in the 2010 Risk Assessment (U.S. EPA, 2009b). Thus, the initial pulses of higher concentration in the washout-controlled releases are anticipated to capture peak ground water concentrations in down-gradient wells. Furthermore, the use of the EPACMTP non-linear sorption isotherms requires the use of a square pulse source as described in U.S. EPA (2003a,b). As a result, EPA chose not to represent the entire washout leaching profile laid forth in the figure above. Instead, all washout-controlled releases were modeled as square pulses selected to represent leachate concentrations that would not underestimate risks. These pulses are similar to the solubility-controlled pulse portrayed in **Figure I-2**, except that C_0 was set to 20 times the Method 1313 leachate concentration.

I.3 Arsenic Source Term Development

Arsenic exhibits washout- and solubility-controlled leaching behaviors like other constituents. However, the data collected with LEAF methods have demonstrated that the leaching behavior of arsenic is also strongly influenced by the presence of calcium, which inhibits arsenic release through oxidation and complexation (Wang et al, 2007). To more accurately characterize the leaching behavior of arsenic, EPA used Method 1314 data to link arsenic leachate concentrations with the mass of calcium present as a function of the cumulative L/S ratios. **Sections I.3.1** and **I.3.2** discuss the leaching behaviors of calcium and arsenic, respectively. **Section I.3.3** discusses the integration of these data to calculate arsenic-specific leachate profiles for EPACMTP.

I.3.1 Summary of Calcium Leaching Behavior

Through a comparison of Method 1313 and 1314 data, EPA observed that the initial calcium leachate concentration is strongly dependent on the mass available to be leached. If the availability of calcium is high (> 5,000 mg/kg), then the initial leachate concentration is around 1,000 mg/L. If the calcium availability is low (≤ 5,000 mg/kg) then the initial leachate concentration of calcium is around 700 mg/L. Regardless of the initial amount of calcium available, once 90 percent of leachable mass has been depleted, the leachate concentration decreased to approximately 10 mg/L.

I.3.2 Summary of Arsenic Leaching Behavior

Arsenic leaching from landfills was modeled as having one of two relationships with dissolved calcium concentrations based on empirical data. This behavior as a function of the cumulative L/S ratio is described, as well as illustrated in **Figure I-5**, below:

- **Case (a) High Calcium Arsenic Leaching:** In high-calcium waste, arsenic complexation with the calcium restricts the amount of arsenic initially available for leaching. Empirical data shows that little to no arsenic will leach from the material after an L/S ratio of 1 is reached, as long as significant levels of calcium remain. Initially, arsenic leaches at C_0 calculated from Method 1313 data from a cumulative L/S ratio of 0 to 1. After this point, arsenic concentrations become non-detect and are assumed to be negligible. Once 90 percent of the calcium has been depleted ($LS_{90,Ca}$), the complexation that had bound the

arsenic originally can no longer be sustained at levels high enough to keep the arsenic in the material. A second pulse of arsenic leaching begins at $LS_{90,Ca}$ at the same concentration and continues until the leachable mass of arsenic has been depleted ($LS_{max,As}$).

- **Case (b) Low-Calcium Arsenic Leaching:** In low-calcium waste, little complexation occurs between arsenic and calcium. Empirical data shows that, in these cases, arsenic leaching is not inhibited. Arsenic leaching begins at C_0 calculated from Method 1313 data and is held constant until the leachable mass is depleted.

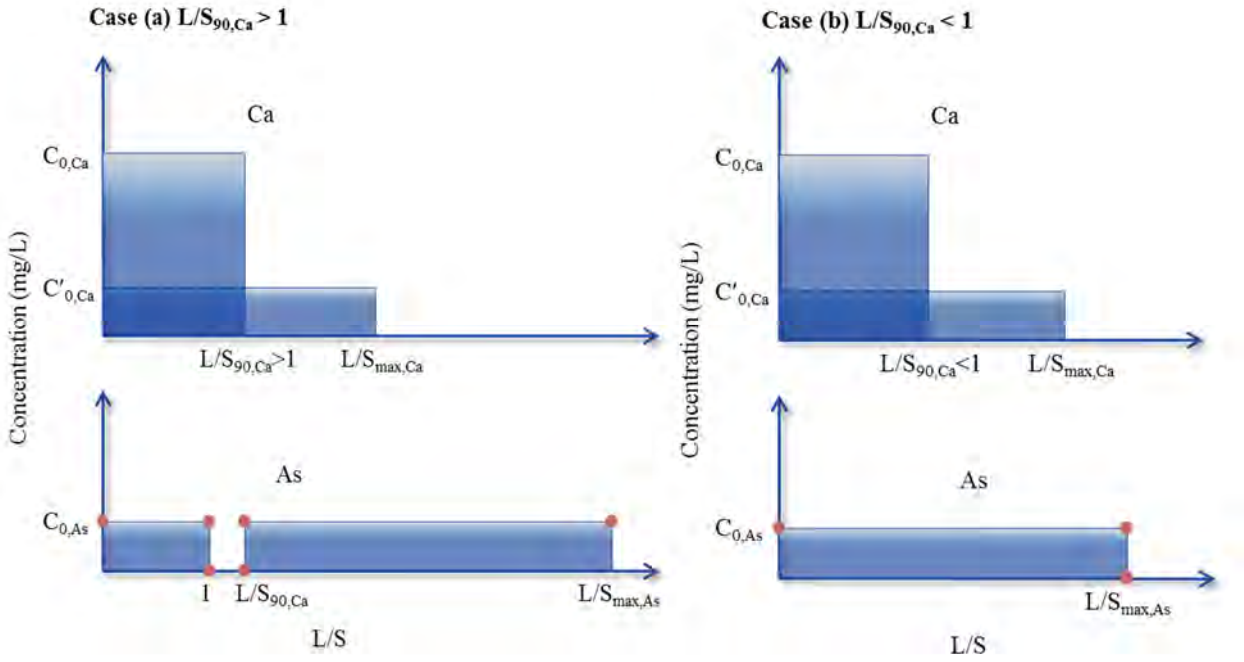

Figure I-5. Generic high- and low calcium leaching and generic calcium-dependent arsenic leaching as a function of cumulative L/S ratio.

I.3.3 Calculation of Specific High-Calcium Arsenic Leachate Curves

A total of five samples analyzed with the LEAF methods contained high-calcium levels (Sample ID: AaFA, CaFA, DaFA, EaFA, and UFA). For each of these samples, EPA evaluated $LS_{90,Ca}$ and $LS_{max,As}$ to determine the duration of the first and second leachate pulses for purposes of modeling in EPACMTP. **Figures I-6** through **I-10** show the interaction between arsenic and calcium leachate over the range of cumulative L/S ratios for these five samples. These idealizations mirror the empirical Method 1314 test results.

Fly Ash Sample	Own pH	Calcium		Arsenic

I.4 Estimating Flux and Leaching Duration

The leaching profiles discussed above are presented in terms of C_0 and cumulative L/S ratio. Additional steps are required to translate these data into inputs for EPACMTP. While C_0 represents a concentration released into infiltrating water (mg/L), EPACMTP requires leachate to be expressed as a mass flux per unit area of the WMU (g/m^2-yr). Similarly, while the cumulative L/S ratio is measured in units of L/kg, EPACMTP requires that leaching duration be expressed as time (yr). This subsection presents a general description of the methods used to convert C_0 into mass flux and the cumulative L/S ratio into time.

I.4.1 Converting Concentration into Flux

Mass flux, the total amount of constituent mass that is released from a landfill over specific period of time, was calculated with **Equation I-2**. EPA used C_0 calculated from Method 1313 data, together with infiltration rates calculated with precipitation data from the most representative climate center, to calculate site-based values for each landfill:

(I-2) $$\dot{m} = C_0 \cdot I \left(\frac{g}{1{,}000\ mg}\right)\left(\frac{1{,}000\ L}{m^3}\right)$$

Where:

$\dot{m}$ = Annual constituent mass flux (g/m2-yr);
C_0 = Initial Leachate Concentration (mg/L);
I = Infiltration rate (m/yr).

I.4.2 Converting Cumulative Liquid-to-Solid Ratio into Time

The amount of time required to reach a specific cumulative L/S ratio was calculated with **Equation I-3**, adapted from U.S. EPA (2006). EPA used landfill depths drawn from survey data and infiltration rates calculated with precipitation data from the most representative climate center, together with a fixed landfill density, to calculate site-based values for each landfill.

(I-3) $$t = LS_{cum}\left(\frac{\rho_{LF} \cdot d_{LF}}{I}\right)\left(\frac{m^3}{1{,}000\ L}\right)$$

Where:

t = Time (yr);
LS = Liquid-to-solid ratio (L/kg);
ρ_{LF} = Landfill density of 1,600 kg/m3 based on Kosson et al (2006);
d_{LF} = Landfill depth (m);
I = Infiltration rate (m/yr).

Using this equation, the times to reach different cumulative L/S ratios were calculated for landfills using the regional recharge rates assigned based on the most representative climate station. For reference, percentiles of the calculated times necessary to reach cumulative L/S ratios of 1 and 10 are presented in **Table I-1**.

Table I-1. Time to Reach Cumulative L/S Ratio of 1 and 10

Percentiles	L/S Ratio of 1 (years)	L/S Ratio of 10 (years)
5th	24.4	244
10th	41.6	416
25th	85.4	854
50th	143	1,425
75th	291	2,910
90th	1,171	11,710
95th	5,087	50,870

Appendix J.

Surface Water Modeling

[This Page Intentionally Left Blank]

J.1 Introduction

The probabilistic analysis considered risks resulting from Constituents of Potential Concern (COPCs) in surface water that result from ground water discharges. Modeling this pathway required estimating the mass flux of ground water (and COPC mass in that ground water) into surface water, as well as modeling the fate of COPCs once in the surface water. EPA's Composite Model for Leachate Migration with Transformation Products (EPACMTP), which was used to model ground water transport, does not include transfer from ground water to surface water bodies. This appendix presents the equations used to model surface water concentrations due to ground water intercepting surface water. It also describes the surface water models used to determine constituent partitioning between water and sediments.

- **Attachment J-1** provides the equations comprising the surface water equilibrium partitioning model, including equations that estimate steady-state concentrations in the water column (dissolved and total) and sediments.

J.2 Ground Water to Surface Water Modeling

At some sites, waste management units (WMUs) are located upgradient from one or more surface water bodies (e.g., stream, lake). At these sites, it is possible that the water body intercepts the flow of ground water before it reaches a receptor well. To determine the mass flux of constituents into these surface water bodies, as well as the effect of surface water interception on receptor well concentrations further downgradient, two separate procedures were developed. These two procedures were developed only for the case of gaining streams, which are streams that receive baseflow from ground water. Losing streams, which discharge to ground water, receive no water or constituent loading from ground water. Instead, the stream may discharge to the surficial aquifer, potentially diluting the constituent concentrations that are present.

Although it is known that some water bodies alternate between gaining and losing on a seasonal basis, this analysis assumed that each modeled water body was gaining year-round. While this approach may underestimate some fraction of potential exposures from ingestion of ground water by always intercepting and capturing some ground water flow, it does not include the dilution effect from losing streams that could balance this effect. Also, this assumption will not significantly affect the high-end ground water receptor risks that are dominated by sites where no intercepting water bodies are present.

The mathematical descriptions of ground water flow into a gaining stream and chemical transport downgradient from the stream must be modified to account for the mass of both water and constituents lost to the stream. To handle these special cases, two independent procedures were developed. The first procedure was developed to estimate the mass flux of constituents into the intercepting stream. The second procedure was developed to estimate the constituent concentrations at a receptor well located downgradient from an intercepting stream.

J.2.1 Mass Flux from Aquifer into a Stream

To predict the mass flux of a constituent from an aquifer into a stream, the distribution of constituent concentrations and volumetric ground water fluxes along the upgradient edge of the stream must be known. The volumetric ground water flux depends on the difference between the stream stage and the hydraulic head in the aquifer. If the hydraulic head in the aquifer is higher than the stream stage, the ground water from the aquifer will enter the stream as baseflow. When this occurs, the stream is said to be a gaining stream. The procedure below was developed for gaining streams only. **Figure J-1** provides a graphical conceptualization of the modeled scenario.

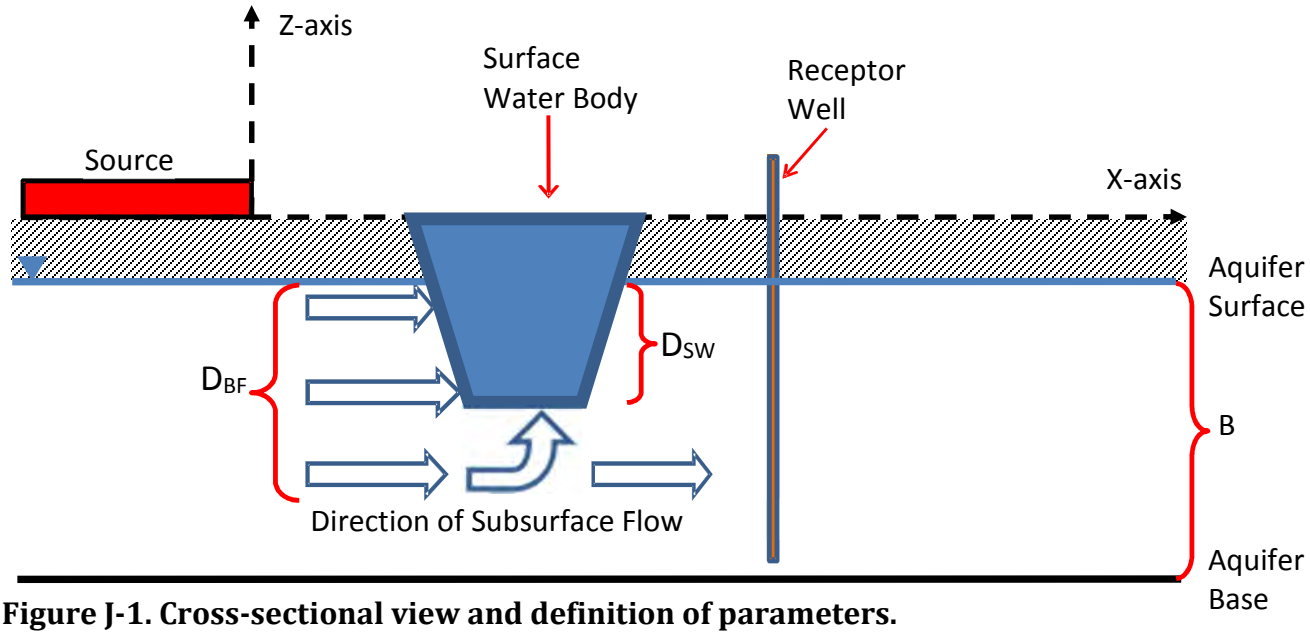

Figure J-1. Cross-sectional view and definition of parameters.

The ground water volumetric flux per unit area of stream bed is governed by the difference in ground water hydraulic head, hydraulic conductivity of streambed, and streambed thickness. In many watersheds, baseflow in terms of volumetric inflow rate per unit length of stream is available. Assuming that the base flow information is available, mass flux may be estimated by integrating the product of baseflow flux per unit area and constituent concentration over the total baseflow area. The total baseflow area is determined by the baseflow depth, D_{BF}, and the domain half width, Y_B. The total mass flux is determined using the baseflow rate and the output constituent concentration from EPACMTP according to the equation below.

(J-1)
$$M = 2\,\frac{q_{Baseflow}}{D_{BF}} \int_{y=0}^{y=Y_B} \int_{z=0}^{z=D_{BF}} C(X = X_{SW}, y, z, t)\,dy\,dz$$

Where:

D_{BF} = Baseflow depth (L);
C = Chemical concentration at $X = X_{SW}$ (M/L^3);
x = Horizontal distance of stream from the downgradient edge of the WMU (L);
X_{SW} = Distance of stream from the downgradient edge of the WMU (L);

y = Horizontal distance (L) from the plume center line along a vertical plane at the upgradient side of the surface water body; and

z = Vertical distance (L) from the top of a vertical plane at the upgradient side of the surface water body, positive downward.

The concentration term, C, is obtained from Equation (4.92) in the EPACMTP Technical Background Document (U.S. EPA, 2003a) and baseflow depth which is defined by:

(J-2) $$D_{BF} = \left(\frac{q_{Baseflow}}{q_{Aquifer}}\right) B$$

Where:

B = saturated thickness of the aquifer.

The baseflow depth, D_{BF}, which is based on the Dupuit approximation (Bear, 1972), is considered more accurate than the surface water depth, D_{SW} for the following reasons: 1) baseflow is a measured quantity in gauged streams; 2) reference elevations for stream depth are not always known; 3) a reported stream depth for a given stream may not reflect its average depth; and 4) stream depth may not account for the contraction of ground water flow tube due to localized steepening of hydraulic gradient before entering the stream. **Figure J-2** provides a graphical conceptualization of the modeled scenario.

J.2.2 Concentration at Wells Located Downgradient from a Stream

In this scenario, a stream flows perpendicular to the direction of regional ground water flow. The distance between the downgradient edge of the WMU and the upgradient edge of the surface water body is X_{SW}. A receptor well is located at a distance of X_{RW} from the downgradient edge of the WMU. If $X_{RW} > X_{SW}$, the well is located downgradient from the surface water body, a situation the original EPACMTP transport module does not allow. This procedure was developed to overcome the deficiency.

The procedure described here estimates the surface water baseflow (the water transferred from the aquifer to the surface water body) and the ground water flow rate between the surface water body and the receptor well location. It corrects the EPACMTP transport module to reflect the presence of the surface water body, by relocating the well to a distance X'_{RW} from the downgradient edge of the WMU where the concentration is equivalent to the concentration from the actual receptor well. **Figure J-2** provides a graphical conceptualization of the modeled scenario. By relocating the receptor well location to X'_{RW} from the downgradient edge of the WMU, the concentration equivalent to the concentration from the actual receptor well (located at the distance of X_{RW}) is calculated using the solution of the ground water flow and constituent transport equations at the new well location, X'_{RW}.

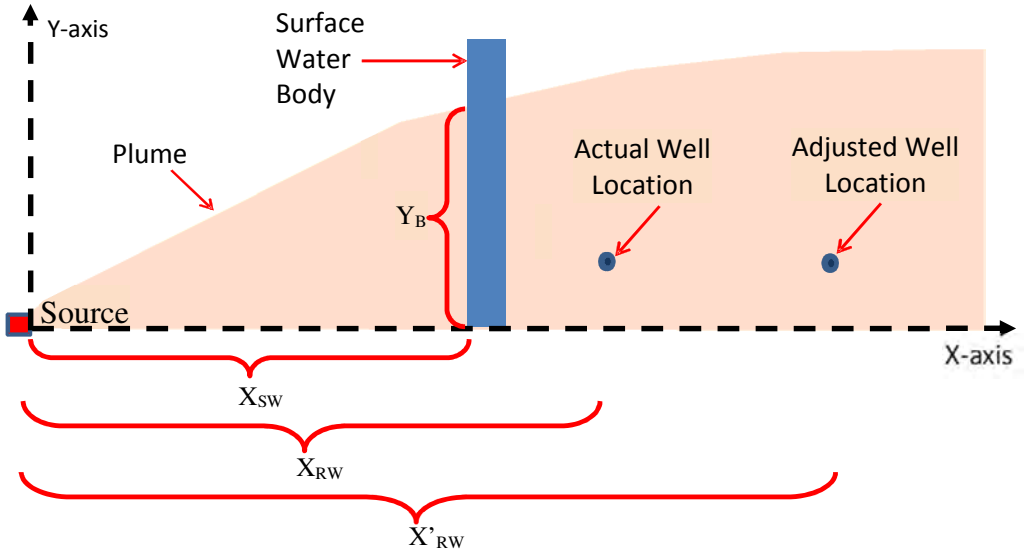

Figure J-2. Aerial view and definition of parameters.

The aquifer modeled by EPACMTP is assumed to receive clean and uniform recharge from the infiltration of precipitation across the entire area around the WMU, which includes the entire footprint of the constituent plume (U.S. EPA, 2003a). As a result, the aquifer flow rate per unit width, $q_{Aquifer}$, along the x-axis may gradually increase due to the cumulative effects of recharge along the flow direction. In the EPACMTP transport module, the aquifer flow rate is assumed to be uniform. To account for variations in the flow rate, spatial averaging of $q_{Aquifer}$ between two points of interest is performed. Between the surface water body and the receptor well, spatially averaged flow rate per unit width is given by:

(J-3) $$q_{Averageflow} = \frac{1}{X_{RW} - X_{SW}} \int_{x=X_{SW}}^{x=X_{RW}} q_{Aquifer}\, dx$$

Where:

$q_{Averageflow}$ = Averaged aquifer flow rate per unit width of the flow domain with baseflow included (L2/T);
$q_{Aquifer}$ = Aquifer flow rate per unit width of the flow domain with baseflow included (L2/T);
X_{SW} = Distance to the stream from the downgradient edge of the WMU (L); and
X_{RW} = Distance to the receptor well from the downgradient edge of the WMU (L).

However, EPACMTP is not designed to account for loss to water bodies. Therefore, $q_{Averageflow}$ is calculated as though the water body does not exist and includes the baseflow that would be intercepted. Baseflow, or the total volumetric flux of water intercepted by a gaining stream, is:

(J-4) $$Q_{Baseflow} = 2\, Y_B\, q_{Baseflow}$$

Where:

$Q_{Baseflow}$ = Total baseflow water flux intercepted by the stream (L3/T);
$q_{Baseflow}$ = Baseflow water flux intercepted per unit length of the stream (L2/T); and
Y_B = Half-width of the intercepted constituent plume (L).

Note that because of the assumed symmetry of the plume, only half the plume is explicitly modeled; the other half is assumed to be a mirror image of that modeled. After excluding baseflow to the stream, the resulting net aquifer flow rate per unit width between the stream and the well is given by:

(J-5) $$q_{Netflow} = q_{Averageflow} - q_{Baseflow}$$

Where:

$q_{Netflow}$ = Net aquifer flow rate per unit width of with the constituent plume with baseflow removed (L^2/T).

As shown above, the interception of baseflow changes the ground water flow rate per unit width downgradient from the surface water body from $q_{Averageflow}$ to $q_{Netflow}$. Knowing $q_{Netflow}$, it is possible to use the original solution to the ground water fate and transport equations by relocating the receptor well from X_{RW} to X_{RW}', where X_{RW}' represents a new distance that will result in the same concentration based on $q_{Netflow}$ as a receptor well at X_{RW} based on $q_{Averageflow}$. This relocation procedure is based on an assumption that the dispersion is much smaller than the advection. This assumption is valid when the Peclet number is greater than 10 (Garges and Baehr, 1998).[1] An estimate of the Peclet numbers for the sites modeled in this analysis was conducted based on the dispersivity of the aquifers and the receptor well distribution data in the EPACMTP Background document (US EPA, 2003b) as the characteristic length. This estimate showed that the majority of sites modeled have Peclet numbers varying from 10 to 5,000. Therefore, a transformation procedure was developed to modify the receptor well locations using the equations below:

(J-6) $$(X'_{RW} - X_{SW}) = \frac{q_{Averageflow}}{q_{Netflow}}(X_{RW} - X_{SW})$$

Since $q_{Netflow}$ is not known *a priori*, it is necessary to locate X'_{RW} iteratively, as follows:

Step 1: As an initial estimate, assume that the new location of the receptor well is at the original position, so that the current approximate receptor well location $\bar{X}_{RW}$ is equal to X_{RW}.

Step 2: Estimate $q_{Netflow}$ using the current value of $\bar{X}_{RW}$, as follows:

(J-7) $$q_{Netflow} = \left(\frac{1}{\bar{X}_{RW} - X_{SW}} \int_{X=X_{SW}}^{X=\bar{X}_{RW}} q_{Aquifer}\, dx\right) - q_{Baseflow}$$

Step 3: Use $q_{Netflow}$ obtained in Step 2 to estimate a new value of X'_{RW}:

[1] The Peclet number (Pe) is a dimensionless number used to describe the flow of fluids. It is defined as the ratio of the rate of advection and the rate of diffusion of a fluid through a given medium. In general, where Pe >> 1, advection dominates transport and, where Pe << 1, diffusion dominates transport.

(J-8) $$X'^{i}_{RW} = \frac{q_{Averageflow}}{q_{Netflow}}(X^{o}_{RW} - X_{SW}) + X_{SW}$$

Where:

X'^{i}_{RW} = ith iteratation of X'RW.

Step 4: Update the approximate location of the receptor well (Note that $X'^{0}_{RW} = X_{RW}$).

(J-9) $$\overline{X}_{RW} = \frac{1}{2}\left(X'^{i}_{RW} + X'^{i-1}_{RW}\right)$$

Step 5: Check convergence until the difference between the most current X'_{RW} is sufficiently close to the value calculated in the previous iteration. In other words,

(J-10) $$\left|X'^{i}_{RW} - X'^{i-1}_{RW}\right| < \epsilon$$

Where:

ϵ = acceptable tolerance (a typical value is 0.1 m or 0.3 ft).

J.2.3 Post-Processor Verification

The stream interception routine was verified by comparing results obtained from a number of scenarios using EPACMTP (U.S. EPA, 2003a) and MODFLOW-based Hydrologic Modeling System (MODHMS) (HydroGeoLogic, 2011). MODHMS is an enhanced version of the U.S. Geological Survey MODFLOW modular three-dimensional ground water flow code (McDonald and Harbaugh, 1988). The MODHMS code has been selected for this verification because it can handle variable saturation, has been extensively verified and documented, and has been implemented by a number of government agencies in different settings. MODHMS can solve the equations without any approximate transformation for the case of baseflow intercepted by a surface water body. The transport equation solutions provided by the MODHMS code were considered accurate and treated as a standard against which the EPACMTP solutions were compared. The mass flux into the intercepting water body (**Section J.2.1**) and the concentration in a receptor well downgradient from an intercepting water body (**Section J.2.2**) were verified separately.

Verification Scenario Description

The verification scenario is shown in **Figure J-3**. The size of the model domain is (1,000 ft × 1,000 ft). The regional ground water gradient in the MODHMS-based model was imposed by constant heads along the upgradient (western) and downgradient (eastern) boundaries. Regional gradient across the flow domain from is 0.005 ft/ft. The model domain is homogeneous with an effective porosity of 0.3 and a hydraulic conductivity of 10 ft/day. A 60 ft × 60 ft square source is located 40 ft from the upstream boundary and 470 ft from the lateral boundary. An infiltration rate of 4.49 × 10^{-4} ft/day is imposed at the source only. A 10-ft wide stream, perpendicular to the regional flow direction, traverses the x-axis 400 ft downgradient from the source. The longitudinal, transverse and vertical dispersivities are 100 ft, 10 ft and 1 ft, respectively. The saturated thickness is 100 ft and uniform. The domain is mainly discretized into horizontally uniform grid cells with the 10 ft × 10 ft dimensions with a 1 ft thickness for the top 10 layers, a 5-ft thickness for the bottom 16 layers and increasing thickness for the middle 4 layers from 1 ft to 4 ft. To allow comparison of

receptor well concentrations at various locations downgradient from the water body, two discrete receptor well locations were chosen. Both wells are located at 250 ft from the water body. One well is located 0 ft from the centerline of the plume and the other is offset by 30 ft. Each well is screened at depths of 0.5 ft, 1.5 ft, and 2.5 ft below the ground water table. Leachate concentration from the surface impoundment is 1 mg/L.

Constituent transport was simulated using the EPACMTP postprocessing module and MODHMS under a baseflow flux of approximately 10% and 1% of the regional aquifer flux. This range was chosen to test the accuracy of the procedures when the baseflow depth is relatively small (thus making the mass flux estimation relatively difficult) and when a large fraction of mass is allowed to travel to the receptor well (thus making the constituent concentration relatively significant). In both cases, it was assumed that the vadose zone did not exist so that the infiltration with constituent entered the water table immediately after leaving the bottom of the WMU. This configuration makes the leachate influx at the top of the water table (a model input) the same for both models, thereby allowing the mass fluxes and concentrations at the receptor well location predicted by the MODHMS and the EPACMTP models to be compared directly. It was assumed that neither adsorption nor degradation occurred in the ground water.

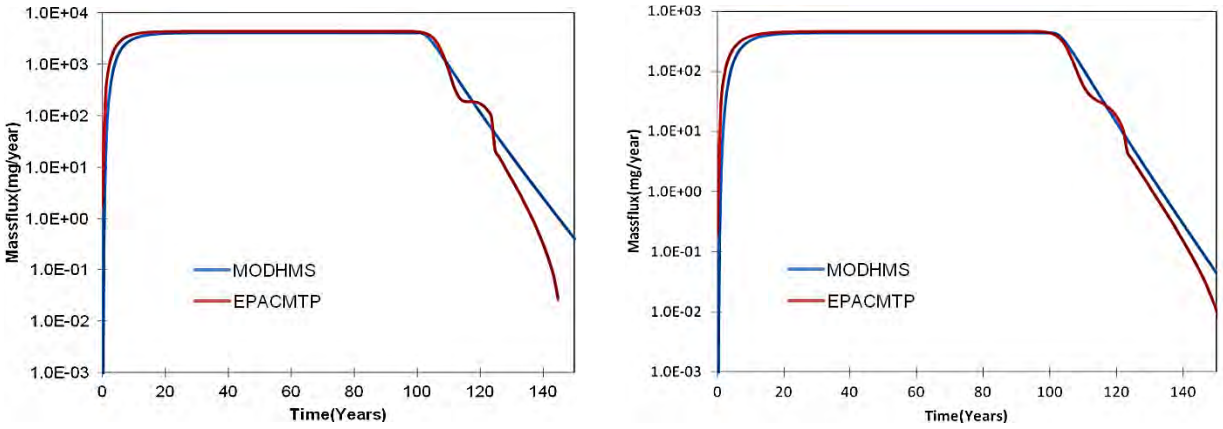
Verification Results

Figure J-4 compares the EPACMTP-generated and MODHMS-generated mass fluxes to the stream from Scenarios 1 and 2. As shown in these figures, the EPACMTP-based mass fluxes agree reasonably well with those based on the more accurate numerical MODHMS-based model. However, the EPACMTP model tends to be more conservative than the MODHMS-based model. **Figure J-5** compares the EPACMTP-generated breakthrough curves at adjusted well locations and the corresponding MODHMS-generated breakthrough curves at actual observation locations from Scenario 1, Layers 1, 2 and 3. In all of these figures, breakthrough curves are almost identical. EPACMTP tends to return slightly more conservative results than MODHMS. Minor oscillations in the EPACMTP curve as it decreases are artifacts of the limitation of computer precision in the numerical computations and should be ignored.



Scenario 1: 10% baseflow Scenario 2: 1% baseflow

J.3 Surface Water Model Overview

The surface water model used in this analysis is a simple steady-state model used previously in the EPA *Methodology for Assessing Health Risks Associated with Multiple Pathways of Exposure to Combustor Emissions* (U.S. EPA, 1998). The specific equations used are presented in **Attachment J-1**. The following are the key assumptions of this model and the specifics on how it was applied for the revised risk assessment:

- The model assumes steady-state flow and transport conditions. Long-term average annual stream flow and climatic data and assumptions were used.
- The model is able to account for constituent loadings into the water body through ground water discharge, waste outfalls, and direct air deposition. The only source relevant to the revised risk assessment is discharges from ground water.
- The model estimates the rate of incorporation, or burial, of constituents into bed sediments as a function of the rate at which sediments deposit from the water column onto the surficial sediment layer. For the coal combustion residual (CCR) risk assessment, the burial rate was set to zero (a protective assumption) because of the lack of national data available to estimate this process.
- The model can incorporate separate decay rate constants for the water column and the benthic sediments to allow for consideration of decay mechanisms that remove constituents from the water body. However, because all of the inorganics considered are persistent in the environment, degradation was not relevant to this risk assessment.

The model describes the partitioning of constituents between aquatic sediments, suspended solids, and surface water using linear equilibrium partition coefficients (i.e., equilibrium is maintained between dissolved constituents within the water column and constituents in suspended solids and bed sediments). **Table J-1** provides distributions for the partitioning coefficients used by the surface water model. These distributions were derived primarily from published empirical data presented in U.S. EPA (2005) and were sampled during the preparation of the input files in the Monte Carlo process.

Table J-1. Sediment/Water and Suspended Solids/Water Partition Coefficients: Empirical Distributions*

Constituent	Sediment/Water				Suspended Solids/Water			
	Min	Mean	Max	SD	Min	Mean	Max	SD
Aluminum	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A
Antimony	0.6	3.6	4.8	1.8	3.9	4.8	4.9	0.5
Arsenic	1.6	2.4	4.3	0.7	2	3.9	6	0.5
